Agents for Diagnostic Imaging

TIM B. HUNTER, T. KENT WALSH, AND JACK N. HALL

Diagnostic imaging encompasses a group of techniques used in the diagnosis and treatment of disease. These techniques often use chemical agents to improve the information provided in the imaging. This chapter is a discussion of the pharmacology, chemistry, and physics of those agents used in medical imaging.

Medical imaging techniques often present less risk to patients than direct surgical visualization. Also, they often provide information or treatment methods that are simply not available by any other means. What these techniques have in common is that the information is often (but not always) displayed as an image for interpretation by a physician trained to evaluate the meaning of the image in the context of pathophysiology. Also, all of the techniques use physical phenomena (electromagnetic radiation, ultrasonic waves) that can pass through tissue to convey the internal information necessary to create an image. From that point, the techniques of medial imaging diverge in their physical means, methods, and the information that they can provide.

Medical imaging began with Roentgen's discovery of x-rays in 1895, and it has been the domain of diagnostic radiology since then. In its earliest days, the specialty of radiology used x-rays to produce images of the chest and skeleton. At the present time, diagnostic radiology uses ionizing radiation (x-rays), magnetic resonance imaging (MRI) techniques, radionuclides (nuclear medicine), and high-frequency sound waves (ultrasound) to produce diagnostic images of the body. Today, radiologists and other physicians also use diagnostic imaging techniques to guide themselves in interventional procedures, such as organ biopsy or abscess drainage.

INTRODUCTION TO RADIATION

Radiation is the propagation of energy through space or matter. In chemical reactions, only the valence electrons of an atom are affected, and the nucleus remains unchanged. Nuclear reactions may result from bombardment of a stable nucleus with high-energy particles or decomposition of an unstable nucleus. The nuclei of atoms are of two kinds: stable and radioactive. Radioactive nuclei have more internal energy than nuclei with a stable arrangement of protons and neutrons. They obtain stability by emitting energy in the form of particulate and electromagnetic radiation.

Ionizing radiation is radiation that when interacting with matter can cause changes in the atomic or nuclear structure of matter. The first type of ionizing radiation is particulate, which includes alpha (α), beta (β^-), positron (β^+), proton (p), and neutron (n) particles. Radiation is energy in the form of kinetic energy and on the atomic scale is usually measured in electron volts (eV). By definition, an *electron volt* is the

energy needed to accelerate an electron across a potential difference of 1 volt. The second type of ionizing radiation is called *electromagnetic radiation*. Electromagnetic radiation is an electric and magnetic disturbance that is propagated through space at the speed of light. This type of radiation has no mass and is unaffected by either an electrical or magnetic field because it has no charge. These properties are shared by radio waves (10^{10} to 10^{-6} eV), microwaves (10^{-6} to 10^{-2} eV), infrared (10^{-2} to 1 eV), visible light (1 to 2 eV), ultraviolet (2 to 100 eV), or x-rays and gamma (γ) rays (100 to 10^{+7} eV). The various forms of electromagnetic radiation differ in their frequency and, therefore, their energy. The energy of electromagnetic radiation can be calculated in electron volts from the following equation:

$$E = h\nu = \frac{hc}{\lambda}$$

where h is Planck's constant (4.13×10^{-15} eV-sec), ν is the frequency (hertz), c is the speed of light (cm/sec), and λ is the wavelength (cm). The difference between x-rays and γ -rays is based on where they originate: x-rays come from outside the nucleus, while γ -rays originate in the nucleus of an atom. X-rays and γ -rays can exhibit some particulate properties, so they are sometimes called *photons*.

Applying a very high voltage (20,000 to 150,000 volts) to a glass vacuum tube that contains a cathode and a rotating anode produces x-rays used in diagnostic radiology (Fig. 13-1). The cathode is a filament that is heated to a very high temperature, which provides a copious source of electrons. The electrons are accelerated toward the positively charged anode (tungsten). When the accelerated electrons strike the anode (called the *target*), x-rays are produced. The distribution of x-rays is a continuous spectrum, and the low-energy x-rays, which will not travel through the body to the x-ray film, are absorbed by a filter (aluminum). An invaluable modification of the x-ray system is fluoroscopy. This modality allows one to visualize organs in motion, position the patient for spot film exposures, instill contrast media into hollow cavities, and, most importantly, insert catheters into arteries. Figure 13-2 shows a schematic of a fluoroscopic system.

With conventional radiography and with computed tomography (CT) (sometimes called computed axial tomography [CAT]) scanning, organs and tissues are made visible according to how well they attenuate x-rays. The attenuation of x-rays by tissues is a complex process that depends on many factors, including the energy of the x-ray beam and the density of the tissue. Bone has an average density of about 1.16 g/cm³, which accounts for its ability to absorb most of the radiation it encounters. CT scanning (Fig. 13-3) uses ordinary x-ray energies for imaging but uses complex

Figure 13-1 ■ Schematic diagram of an x-ray tube producing x-rays that pass through the patient and expose the photographic film. The photographic film will not stop the x-rays, so a plastic screen coated with fluorescent particles that are activated by the x-rays emits light to expose the film within a light-tight film cassette. As x-rays pass through the body, some of them are scattered, so a moving grid device composed of alternating strips of lead and plastic decreases the scattered x-rays that degrade the image.

mathematical reconstructions to produce images of the body in the axial and other planes. In the process, it can increase the visibility of small differences in the radiographic densities between tissues to a far greater extent than ordinary radiographic film can.

Radionuclides undergoing transformation processes, called *radioactive decay*, in most cases involve transmutation of one element into another. A nucleus may undergo several decays before reaching a stable configuration. A nuclear particle, either a proton or a neutron, is called a *nucleon*. A species of atom with a specified number of neutrons and protons in its nucleus is called a *nuclide*. Nuclides with the same number of protons and a different number of neutrons are called *isotopes*. Nuclides with same atomic mass are called *isobars*. Nuclides with the same number of protons and atomic mass but at two energy levels are called *isomers*.

The nucleus has energy levels analogous to the orbital electron shells but at a higher energy. The lower energy level is called the *ground (g) state*, and the highest energy level is called the *metastable (m) state*. Nuclides are all species of elements, of which there are about 265 stable nuclides, 130 naturally occurring radionuclides, and more than 2,500 artificially produced radionuclides. In accordance with a rec-

ommendation of the International Union of Pure and Applied Chemistry, the following notation should be used for the identification of a nuclide:

where X is the symbol of the chemical element to which the nuclide belongs. A represents the atomic mass (number of neutrons plus the number of protons), and Z represents the atomic number (number of protons). The right side of the element is reserved for the oxidation state, and N represents the number of neutrons. For most medical applications, it suffices to indicate the element chemical symbol and the mass number (i.e., ${}^{131}\text{I}$, I-131, or iodine-131).

The radionuclide at the beginning of the decay sequence is referred to as the *parent*, and the radionuclide produced by the decay is referred to as the *daughter*, which may be stable or radioactive. There are five types of radioactive decay, distinguished according to the nature of the primary radiation event. A radioactive nucleus may decay by more than one method. The dominant method at any given time depends on such factors as the size of the nucleus and the balance of protons and neutrons. The types of decay described below are in order of how commonly they are used in current diagnostic nuclear medicine practice:

1. **Isomeric transition (IT).** Isomeric transition is a decay process involving neither the emission nor the capture of a particle. The nucleus simply changes from a higher to a lower energy level by emitting γ -rays. Therefore, both mass number and atomic

Figure 13-2 ■ Schematic diagram of a fluoroscopic unit with the x-ray tube located behind the patient and a fluorescent screen-image intensifier system positioned on the opposite side. Amplification of the faint fluorescing image by the image intensifier increases brightness level and contrast. The real-time fluoroscopic images can be shown on a television camera for convenient viewing during the examination and stored on videotape, video disk, or computer for later viewing without distortion or destruction of the images.

Figure 13-3 ■ Schematic diagram of a computerized axial tomography (CAT) system that produces thin cross-sectional images of the body. An x-ray tube rotates around the patient, and the transmitted x-rays are detected by a circle of moving radiation detectors. The absorptions of x-rays by tissues of different densities are assigned numerical values (CT numbers). The computer uses complex algorithms to reconstruct an anatomical cross-sectional image on a television monitor.

number remain unchanged. The daughter nucleus is the same chemical element as the original nucleus. The original nucleus before the transition is said to be in a metastable (m) state.

2. **Electron capture decay (EC).** The nucleus captures an electron from the electron cloud of the atom (mainly the K shell), and a proton becomes a neutron.

3. **Positron emission (β^+).** The nucleus emits a positive electron when a proton changes to a neutron. A γ -ray may or may not accompany the emission of the positron. A positron (particle of antimatter) emitted from the nucleus loses its kinetic energy, however, by interacting with surrounding atoms. It finally combines with a free electron from one of the surrounding atoms in an interaction in which the rest masses of both particles are given up as 2 γ -rays of 0.511 MeV emitted at 180° to each other. Einstein's theory of relativity states that mass and energy are equivalent and is represented by the following equation:

$$E = mc^2$$

where in the case of an electron, E represents energy equivalent to mass ($m = 9.109 \times 10^{-31}$ kg) at rest, and c is the speed of light (3×10^8 m/sec). By using the proper units it can be shown that the mass of an electron is equivalent to 0.511 MeV. This is called *annihilation radiation*. It is used in a specialized imaging technique called *positron emission tomography* (PET).

4. **Beta-particle emission (β^-).** The nucleus emits a negative electron when a neutron changes to a proton. A γ -ray may or may not accompany the emission of a β particle.

5. **Alpha-particle emission (α).** The nucleus emits an α particle which consists of a helium nucleus without the electrons. If the emission of the α particle leaves the nucleus in an excited energy state, the excess energy is liberated in the form of a γ -ray.

CHARACTERISTICS OF DECAY

It is impossible to predict when an individual atom of a radionuclide will decay. In quantitative terms, however, this transformation occurs at a rate that is characteristic of each specific radionuclide and is expressed as its physical half-life. This is the time in which one-half of the original number of atoms decay. The activity of radionuclides can be expressed in three ways: (a) in curies (Ci), millicuries (mCi), or microcuries (μCi); (b) in disintegrations per second (dps) and (c) in becquerels (Bq; 1 Bq = 1 dps). A curie is the quantity of any radionuclide that decays at a rate of 3.7×10^{10} dps. This number was chosen for a historical reason—this is the number of disintegrations per second in 1 g of radium. The international system of units has adopted the becquerel as the official unit of radioactivity, but the curie is still widely used, and we will use this unit in addition to the official unit. A relevant conversion factor to remember is the following:

$$1 \text{ millicurie (mCi)} = 37 \text{ megabecquerels (MBq)}$$

The basic equation for radioactive decay is expressed as follows in terms of atoms:

$$N_t = N_0 e^{-\lambda t}$$

N_t (number of atoms at time t) and N_0 (number of atoms at time 0) can be replaced, however, with activities:

$$A_t = A_0 e^{-\lambda t}$$

where A_0 is the original activity in Ci, mCi, or μCi , A_t is the activity at time t , λ is the decay constant ($= 0.693/t_{1/2}$, the physical half-life); and $e^{-\lambda t}$ is the decay factor. An example of a radioactive decay calculation follows:

A sample of ^{123}I -sodium iodide had an activity of 200 μCi on May 14 at 12 noon C.S.T. What is the activity on May 15 at 1 PM E.S.T.? (Note: Calculations of elapsed time must also

indicate variations in time zones—elapsed time in this case is 26 hours.)

$$\begin{aligned}
 (t_{1/2} &= 13.2 \text{ hours}) \\
 A &= (200 \mu\text{Ci}) e^{-\left[\frac{0.693 \times 26 \text{ hours}}{13.2 \text{ hours}}\right]} \\
 A &= (200 \mu\text{Ci}) (e^{-1.36}) \\
 A &= (200 \mu\text{Ci}) (0.255) \\
 A &= 51.0 \mu\text{Ci}
 \end{aligned}$$

BIOLOGICAL EFFECTS OF RADIATION

The absorption of ionizing radiation by living cells always produces effects potentially harmful to the irradiated organism. An undesirable aspect to the medical use of these types of radiation is that a small number of the atoms in the body tissues will have electrons removed as a result of the energies of these photons. Radiation that does this is often called *ionizing radiation* and is damaging to body tissues. Therefore, in using ionizing radiation, as in using other pharmaceutical agents, the risks must be balanced with the medical benefits provided for the patient.

The amount of radiation energy absorbed by tissue is called *radiation absorbed dose* and is specified in rads or millirads. A dose of 1 rad implies 100 ergs of energy absorbed per gram of any tissue. The unit of exposure for x-rays and γ radiation *in air*, the roentgen, is used to specify radiation levels in the environment. (One roentgen is the amount of radiation that produces 1 electrostatic unit of charge of either sign per 0.001293 g of air at STP.) The international system of units (SI) has adopted the gray (Gy) to replace the rad (1 Gy = 100 rads), but again we will use the more traditional units. In the case of x-rays or γ radiation for medical diagnosis, the roentgen and rad turn out to be numerically equivalent. The major difference between electromagnetic radiation (x-rays or γ -rays) and particulate type radiation (β and α particles) lies in the ability of electromagnetic rays to penetrate matter. Whereas β particles travel only a few millimeters before expending all their energy, x- and γ -rays distribute their energy more diffusely and travel through several centimeters of tissue. Therefore, particles deliver highly localized radiation doses, whereas x- and γ -rays deliver more uniform doses in a less concentrated way throughout the irradiated volume of tissue. The radiation dose of particles is more useful for a therapeutic dose of a radionuclide but not for a diagnostic dose. When cells are irradiated, damage is produced primarily by ionization and free radicals. Particles produce damage by ionization, whereas x-rays and γ -rays produce damage by free radicals. Free radicals are atoms or molecules with an unpaired electron.

The effects of large doses of radiation were derived from epidemiological studies of the atomic bomb survivors at Hiroshima and Nagasaki. Radiobiological damage from large doses of ionizing radiation can be caused by two different mechanisms. One mechanism is the *direct effect* of radiation, in which damage results from absorption of radiation energy directly in a critical biological site or target. The other, called

the *indirect effect*, involves aqueous free radicals as intermediaries in the transfer of radiation energy to the biological molecules. All biological systems contain water as the most abundant molecule (70 to 90%), and radiolysis of water is the most likely event in the initiation of biological damage. The absorption of energy by a water molecule results in the ejection of an electron with the formation of a free radical ion ($\text{H}_2\text{O}^{\cdot -}$). The free radical ion dissociates to yield a hydrogen ion (H^+) and a hydroxyl free radical (HO^{\cdot}). The hydroxyl free radicals combine to form hydrogen peroxide (H_2O_2), which is an oxidizing agent. In addition, hydrogen free radicals (H^{\cdot}) can form, which can combine with oxygen (O_2) and form a hydroperoxy-free radical (HO_2^{\cdot}). These two reaction intermediates are very reactive chemically and can attack and alter chemical bonds. The only significant "target" molecule for biological damage is DNA. Types of DNA damage include single- and double-chain breakage, and intermolecular or intramolecular cross-linking in the double-stranded DNA molecule. With the direct effect of radiation, the damage makes cell replication impossible, and cell death occurs. In the indirect effect of radiation, if the damage is not lethal but changes the genetic sequence or structure, mutations occur that may lead to cancer or birth of genetically damaged offspring. Some effects of radiation may develop within a few hours; others may take years to become apparent. Consequently, the effects of ionizing radiation on human beings may be classified as somatic (affecting the irradiated person) or genetic (affecting progeny).

Radiation dose can only be estimated and its "measurement" is called *radiation dosimetry*. In the case of x-ray exposure, most radiation "doses" in the literature are described as the entrance exposure (in roentgens per minute) to the patient. In diagnostic nuclear medicine procedures, patients are irradiated by radiopharmaceuticals localized in certain organs or distributed throughout their bodies. Since the radionuclides are taken internally, there are many variables, and the radiation absorbed dose (r.a.d. or rad) to individual patients cannot be measured but only estimated by calculation. The methods of calculating the absorbed dose to patients from radiopharmaceuticals were changed in 1964 and then revised by the Medical Internal Radiation Dose (MIRD) Committee under the auspices of the Society of Nuclear Medicine in 1991.

Although the effects of radiation are not totally understood, the benefits associated with low doses of radiation almost always outweigh any potential risks to individual patients. A large number of scientific and advisory groups have published risk estimates for ionizing radiation, but the most widely quoted is report number 5 of the National Academy of Sciences Committee on the Biological Effects of Ionizing Radiation (BEIR-V).¹

Under normal circumstances, no radiation worker or patient undergoing diagnostic investigation by radiopharmaceutical or radiographic procedures should ever suffer from any acute or long-term injury. Typical radiation doses to patients from radiopharmaceuticals are similar to, or less than, those from radiographic procedures.

The first artificial radionuclide (phosphorus-30) was produced by the French radiochemists Frederic Joliet and Irene Curie. Nuclear medicine became a specialty in 1946 when radionuclides became available from cyclotrons and nuclear reactors. In many medical centers, nuclear medicine is con-

sidered part of diagnostic radiology, although in some locales it may be a freestanding discipline or reside in a pathology or internal medicine department.

RADIONUCLIDES AND RADIOPHARMACEUTICALS FOR ORGAN IMAGING

Medical science provides a framework or paradigm in which to understand disease and to maintain health. Nuclear medicine is the branch of medical science that contributes to medicine by the use of the radiotracer method for diagnosis and use of in vivo unsealed radioactivity for therapy.

Nuclear medicine involves the administration of radioactively labeled compounds to trace a biological process. This process may be mechanical (gastric emptying, blood flow, cardiac wall motion) or a variety of other physiological functions. Within the concept of a "radiotracer" is the implication that the agent administered will not disturb the functioning of the process you wish to examine. In nuclear medicine, this concept is used to trace physiological processes in vivo and then compare them to known normal images or levels. These are then evaluated with a knowledge of pathophysiology to allow diagnosis of disease. The data can also be used to follow the patient for improvement after treatment. In clinical practice, nuclear medicine also makes use of in vitro diagnostic methods (radioimmunoassay) and in vivo radiopharmaceutical therapy. These last two are not further addressed in this chapter, and there is minimal discussion of investigational diagnostic radiotracers.

The specialty of nuclear medicine did not become available to the private hospital until the 1960s, after the introduction of the molybdenum-99/technetium-99m generator and the gamma (scintillation) camera developed by Hal Anger (Fig. 13-4). The most common use of nuclear medicine is to image the distribution of radiopharmaceuticals in specific tissues or organ systems with a scintillation (Anger) camera for diagnostic purposes. Fundamentally, these instruments or cameras allow in vivo detection and localization of radiotracers. The purpose of the gamma camera is to record the location and intensity of the radiation within the imaging field.

Radiation in the form of gamma photons (occasionally x-rays) initially enters the camera through the collimator, which usually is a sheet of lead with multiple small, precisely made holes. It covers the detector crystal. The purpose of the collimator is to decrease scattered radiation and increase the overall resolution of the system. Photons that are not blocked by the collimator then enter a large sodium iodide (with a small amount of thallium) crystal that absorbs γ -rays. The absorbed energy in the crystal is emitted as a flash of light (called a *scintillation*), which is proportional to the energy of the γ -ray. Coupled to the back of the NaI(Tl) crystal are photomultiplier (PM) tubes that convert the light flashes to electrical pulses proportional to the amount of light. To localize the original source of the photon (and create an image), a computer assigns x-y spatial coordinates to the various γ -rays coming from the patient and stores this information in a matrix. After collection, the digital image is converted into an analogue video signal for display on a

Figure 13-4 ■ Schematic diagram of scintillation camera (Anger) system with a multihole lead collimator attached (to eliminate scattered γ -rays), which is used to visualize tissues and organs after a diagnostic dose of a radiopharmaceutical is administered.

video monitor. The images obtained with the scintillation camera are called *scintigrams*, *scintigraphs*, or *scans*. Nuclear medicine imaging studies involve the generation of images that represent the functional status of various organs in the body. Especially when interfaced with computer systems, information regarding dynamic physiological parameters such as organ perfusion, metabolism, excretion, and the presence or absence of obstruction can be obtained. Figure 13-5 demonstrates a normal dynamic function study of the liver, made by using Tc-99m mebrofenin and the scintillation camera. Images can be acquired of one organ or of the whole body by moving from head to toe.

Cross-sectional images of organs can be obtained by rotating a position-sensitive scintillation camera detector about the patient. This type of procedure is called *single photon emission computed tomography* (SPECT), which is the counterpart of CT or CAT scans in diagnostic radiology. Figure 13-6 is a schematic of a SPECT system. The majority of SPECT systems use one to three scintillation camera detectors that rotate about the patient. SPECT is routinely used when imaging the brain or heart to demonstrate three-dimensional distribution of radioactivity in these organs. Figure 13-7 depicts a SPECT myocardial perfusion scan of the heart.

A newer modality for imaging uses multiple detectors to image positron-emitting radiopharmaceuticals by PET (Fig. 13-8). Many biologically important molecules that are physiologically identical with the nonradioactive compound can be radiolabeled with positron-emitting radio-

Figure 13-5 ■ Dynamic study of the liver and biliary system with a gamma camera. This is a normal study after injection of Tc-99m mebrofenin, with each image a 3-minute time exposure. The study was done on a patient with suspected acute cholecystitis (a blockage of the duct to the gallbladder). If the patient had acute cholecystitis, the radiotracer would not have entered the gallbladder. The arrow in frame 16 shows the normal location of the gallbladder.

Figure 13-6 ■ Schematic diagram of a rotating triple-detector scintillation camera system for single photon emission computed tomography (SPECT) demonstrating a "cold" spot lesion in the brain on the sagittal view (open arrow).

Figure 13-7 ■ SPECT myocardial perfusion study using thallium-201 as the radiotracer. SPECT images are three-dimensional and are often viewed in tomographic slices. The *long* arrows indicate the abnormally diminished myocardial perfusion in the anterior wall of the left ventricle during stress (exercise or pharmacological), compared with that of the same patient during rest. The stress and rest images are matched in spatial location for easier comparison. The *single short* arrow indicates an additional abnormal area in the inferior portion of the left ventricle. The abnormalities indicate that the patient has a high likelihood of significant coronary artery narrowing, which can be confirmed by coronary angiography.

Figure 13-8 ■ Schematic diagram of a PET imaging system with multiple scintillation detectors that localize the positron decay along a line. By using multiple position-sensitive detectors around the patient, the annihilation photons are acquired along many parallel lines and many angles simultaneously with four rings of detectors (only one ring shown). After use of reconstruction algorithms, the internal distribution of the radioactivity can be determined and displayed on a cathode ray tube.

TABLE 13-1 PET Radiotracers

Positron Emitter	Radiotracer
Fluorine-18 (F-18)	F-18-haloperidol
	F-18 fluorodeoxyglucose (FDG)
	F-18 fluorodopa
	F-18 fluoroethylpiperone
	F-18 fluorouracil
Nitrogen-13 (N-13) Carbon-11	N-13 ammonia
	C-11 Acetate
	C-11 carfentanil
	C-11 cocaine
	C-11 Deprenyl
	C-11 leucine
	C-11 methionine
	C-11 methylpiperone
Oxygen-15	O-15 water
	O-15 oxygen
	O-15 carbon dioxide
Rubidium-82	Rubidium-82

Figure 13-9 ■ PET whole-body images performed to detect metastases after injection of 4 mCi (148 MBq) of fluorine-18 [^{18}F]-2-fluoro-2-deoxy-D-glucose (F-18 FDG). **A.** Normal whole-body PET image (coronal view) obtained on a patient with lymphoma after treatment with chemotherapy and radiotherapy. The patient fasted for 12 hours to maintain the blood glucose level between 80 and 140 mg/100 mL. If the blood glucose level is not in that range, F-18 FDG uptake is decreased in the tumors because the mechanism of uptake is an increased rate of glycolysis. (Note increased brain and cardiac uptake because of high glycolytic rates in these organs.) **B.** PET whole-body image obtained with the same technique on a patient with pancreatic carcinoma. Abnormal sites of F-18 FDG uptake are seen in the upper abdomen, posterior mediastinum, and left lower neck (arrows) consistent with neoplastic involvement. (Note increased brain, but not cardiac, uptake of F-18 FDG in this patient who had a desirable blood glucose level for tumor imaging.)

slides such as carbon-11 ($t_{1/2} = 20$ minutes), oxygen-15 ($t_{1/2} = 2$ minutes), nitrogen-13 ($t_{1/2} = 10$ minutes), and fluorine-18 ($t_{1/2} = 110$ minutes). Table 13-1 shows examples of several positron radiotracers that have been investigated in the scientific literature.

Figure 13-9 shows PET whole-body images from patients as a cancer management modality.

RADIONUCLIDE PRODUCTION

The radionuclides used in nuclear medicine are artificially produced. This is accomplished when neutrons, protons, α particles, or other particles impinge on atomic nuclei and initiate a process of nuclear change. The artificial production of a radionuclide requires preparation of a target system, irradiation of the target, and chemical separation of the radionuclide produced from the target material. The radiochemical is converted to the desired radiopharmaceutical and quality assurance of the physical, chemical, and pharmaceutical qualities (i.e., sterility and apyrogenicity) of the final product is obtained. The systems used for practical production of radionuclides are a nuclear reactor, cyclotron, or radioisotope generator.

The shorthand nuclear physics notation of a cyclotron production reaction is as follows:

where Cd-112 is the stable target material, a proton (p) is the bombarding particle, two neutrons (2n) are emitted from the nucleus, and In-111 is the radionuclide produced.

The introduction of radionuclide generators into nuclear medicine arose from the need to administer large doses of a short half-life radionuclide to obtain better statistics in imaging. In consideration of radioactive (parent and daughter) pairs, we can distinguish two general cases, depending on which of two radionuclides has the longer half-life. If the parent has a longer half-life than the daughter, a state of so-called radioactive equilibrium is reached. That is, after a certain time, the ratio of the disintegration rates of parent and daughter become constant. In the second case, if the parent half-life is shorter than that of the daughter, no equilibrium is reached at any time. Therefore, the general principle of the radionuclide generator is that the longer-lived parent is bound to some adsorbent material in a chromatographic ion exchange column and the daughter is eluted from the column with some solvent or gas. There are more than 100 possible generator systems for clinical use, but there is only one in routine use in nuclear medicine (the molybdenum-99/technetium-99m system). All of the molybdenum-99 at the present time is obtained as a fission product of uranium-235 in a nuclear reactor.

By use of elegant inorganic radiochemistry, the molybdenum-99 is separated from the other radionuclides. Molybde-

Figure 13-10 ■ Cross section of a radionuclide generator for the production of technetium-99m (Tc-99m) by sterile 0.9% sodium chloride elution of a sterile alumina (Al_2O_3) column that has molybdenum-99 (Mo-99) adsorbed on it. (Courtesy of Dupont-Pharma, Billerica, MA.)

num-99 ($t_{1/2} = 66$ hours) decays by β -particle emission to technetium-99m ($t_{1/2} = 6$ hours), which decays by isomeric transition (IT) to technetium-99 by emission of a γ -ray (140 keV). The anionic molybdate ($^{99}\text{MoO}_4^{2-}$) is then loaded on a column of alumina (Fig. 13-10). The molybdate ions adsorb firmly to the alumina, and the generator column is autoclaved to sterilize the system. Then the rest of the generator is assembled under aseptic conditions into its final form in a lead-shielded container. Each generator is eluted with sterile normal saline (0.9% sodium chloride). The column is an inorganic ion exchange column, and the eluate contains sodium pertechnetate, so the chloride ions (Cl^-) are exchanging for the pertechnetate ions ($^{99\text{m}}\text{TcO}_4^-$) but not molybdate ions (MoO_4^{2-}). The method for calculating how much daughter is present on the column at any given time is more complex, because it must consider the decay rates of the parent and daughter (Fig. 13-11). The simplified equation for any case in which both the parent and the daughter are radioactive and in equilibrium is as follows:

$$A_d = (A_p)\lambda_d [(e^{-\lambda_p t} - e^{-\lambda_d t})/(\lambda_d - \lambda_p)]$$

where A_p is the activity (mCi) of the parent, A_d is the activity of the daughter, λ_p and λ_d are their respective decay constants, and t is the time since the last elution of the generator. In the case of Mo-99 ($t_{1/2} = 66$ hours), only 87.2% of the atoms decay to Tc-99m ($t_{1/2} = 6$ hours), and 12.8% of the atoms decay directly to Tc-99. The generator system can be eluted several times per day to obtain more activity (mCi) per day because the increase in Tc-99m is a logarithmic function.

Figure 13-11 ■ Elution graph of radioactivity (exponential versus time (linear)) of the Mo-99m/Tc-99m radionuclide generator with sterile 0.9% sodium chloride for 2 days (actual generator is useful for 12 days postcalibration). The upper straight line represents the radioactive decay of the parent (Mo-99) to the daughter (Tc-99m), which reaches equilibrium at four half-lives of the daughter (6 hours \times 4 = 24 hours).

TECHNETIUM RADIOCHEMISTRY

Element 43 in the periodic table, technetium, is a transition state metal and is the only "artificial" element with a lower atomic number than uranium. All 22 known isotopes of technetium are radioactive, and there are eight nuclear isomers. Because no stable isotopes of technetium exist, the chemistry has been poorly developed; however, milligram quantities of Tc-99 (a weak β -particle emitter; $t_{1/2} = 2.1 \times 10^5$ years) are now available for determination of the structures of the technetium complexes, and more than 150 structures have been characterized. The chemistry of technetium is similar to that of rhenium and is dominated by forming compounds by bonding between the electron-deficient metal and electronegative groups, which are capable of donating electron pairs. Some examples of these electronegative groups are sulfhydryl, carboxylic acid, amine, phosphate, oxime, hydroxyl, phosphine, and isonitrile.

Basically, all technetium radiopharmaceuticals are metal-electron donor complexes. Compounds that contain two or more electron donor groups and bind to a metal are called *chelating agents*. Technetium as a transition state element can have oxidation states from 1 to +7. As a pertechnetate (TcO_4^-) ion, technetium will not form many metal-donor complexes, although it can be reduced to species that will complex with a variety of monodentate, bidentate, or polydentate ligands. The oxidation state of technetium in various complexes and the actual structure are unknown for several of the compounds. Deutsch et al.² claim that the oxidation states that are most common in the chemistry of technetium are +1, +3, and +5. Technetium (TcO_4^-) can be reduced by a stannous salt, ascorbic acid, sodium borohydride, and electrolysis. The most common reducing agent is the stannous ion because of water solubility, stability, low toxicity, and effectiveness at room temperature.³ Reviews of the chemistry of technetium are presented by Hjeltnen⁴ and Schwochau,⁵ but the stereochemistry of the technetium coordination complexes is not shown. An excellent review by Jurisssen et al.⁶ covers all coordination compounds used in nuclear medicine, with a special emphasis on Tc-99m complexes.

Tc-99m radiopharmaceuticals are by far the most commonly used radiotracers in day-to-day diagnostic nuclear medicine practice. In fact, most gamma cameras are designed to work most efficiently (crystal thickness and the electronics) with Tc-99m-based radiotracers. Tc-99m radiopharmaceuticals are prepared at the hospital or local nuclear pharmacy by combining $^{99m}\text{TcO}_2$ nonradioactive components in a sterile serum reaction vial. The primary chemical substances in the vial are the complexing agent (ligand) and reducing agent, usually some stannous salt (stannous chloride, stannous fluoride, or stannous tartrate). After preparation of the radiopharmaceutical, tests for radiochemical purity should be carried out to ensure that the radiotracer is in the right chemical form. The analytical methods used include paper and thin-layer chromatography, column chromatography, and solvent extraction. Likely radiochemical impurities include sodium pertechnetate ($\text{Na}^{99m}\text{TcO}_4$), some insoluble compound (i.e., reduced hydrolyzed technetium [TcO_2] or technetium-tin colloid), and a complex different from the one expected (i.e., ^{99m}Tc -monodentate rather than ^{99m}Tc -

bidentate ligand). The sterile serum vials containing the stannous salt and the ligand are lyophilized under a sterile inert gas atmosphere (i.e., nitrogen or argon). The ligand in the reaction vial determines the final chemical structure of the ^{99m}Tc -complex and the biological fate after intravenous injection of the radiopharmaceutical.

Technetium Radiopharmaceuticals

Technetium (^{99m}Tc) Albumin Injection. ^{99m}Tc albumin for injection is a sterile, colorless to pale yellow solution containing human albumin (MW ~60,000) radiolabeled with Tc-99m pertechnetate. The reducing agent is stannous tartrate, which reduces the $^{99m}\text{TcO}_4^-$ to an unknown oxidation state and is weakly chelated by the tartrate and possibly forms a complex with sulfhydryl groups on the albumin by ligand exchange. The precise structure of the stannous technetium-albumin complex is currently unknown. The patient receives an intravenous injection of 25 mCi (925 MBq) of Tc-99m albumin.

Multiple images of the blood in the heart are taken by electrocardiogram gating (R-R interval). The rising portion of the R wave coincides with end-diastole. These images are stored in a computer to reconstruct a movie of the beating heart. This procedure is sometimes called a *multigated acquisition* (MUGA) or a *radionuclide ventriculogram*. Information obtained by this technique includes cardiac chamber wall motion and calculation of ejection fraction. Indications for the procedure include evaluation of effects of coronary artery disease, follow-up of coronary artery bypass graft patients, heart failure, heart transplant evaluation (preoperative and postoperative), cardiomyopathies, and effects of cardiotoxic drugs (i.e., doxorubicin).

Technetium (^{99m}Tc) Albumin Aggregated. ^{99m}Tc -albumin aggregated is a sterile white suspension of human albumin aggregates formed by denaturing human albumin by heating at 80°C at pH 4.8 (isoelectric point of albumin). The precise structure of the stannous technetium-albumin aggregated complex is unknown at this time. The particle size and number can be estimated with a hemocytometer grid. The particle size of the suspension should be between 10 and 100 μm , with no particles greater than 150 μm . This agent is used clinically to image the pulmonary microcirculation for pulmonary embolus and to assess regional pulmonary function for surgery (i.e., lung transplants or resection). The patient receives an intravenous injection of 2 to 4 mCi (74 to 148 MBq) of the Tc-99m-albumin aggregates, which lodge in some of the small pulmonary arterioles and capillaries, and the distribution can be imaged. The number of aggregates recommended for good image quality and safety is 100,000 to 500,000 particles; thus, only a small fraction of the 280 billion capillaries are occluded. Multiple images of the lung are obtained to assess lung perfusion. The distribution of the particles in the lung is a function of regional blood flow; consequently, in the normal lung, the particles are distributed uniformly throughout the lung. When blood flow is occluded because of emboli, multiple segmental "cold" (decreased radioactivity) defects are seen. This procedure is almost always combined with a xenon-133 gas lung ventilation scan (should be normal in pulmonary embolism) and same-day chest radiograph x-ray (should be normal).

Technetium (^{99m}Tc) Albumin Colloid Injection.

^{99m}Tc -albumin colloid injection is a sterile, opalescent, colorless dispersion of colloidal human albumin labeled with Tc-99m pertechnetate after it is reduced with a stannous salt. The precise structure of the stannous technetium-albumin colloid complex is unknown at this time. The particle size may be examined with a hemocytometer grid. The particle size range of the colloid is 0.1 to 5.0 μm . After the patient receives an intravenous injection of 5 mCi (185 MBq) of Tc-99m -albumin colloid, the agent is cleared from the blood by the reticuloendothelial (RE) cells. These RE cells are located principally in the liver (85%) and spleen (10%), and the remainder are in the bone marrow, kidney, and lung. An initial dynamic flow study may be obtained to determine liver and spleen perfusion in cases of abdominal trauma. Liver and spleen imaging is useful to determine organ size, the presence of hepatic metastases, and the degree of hepatocellular dysfunction in diffuse liver disease (i.e., cirrhosis).

Technetium (^{99m}Tc) Apcitide. This new radiotracer is a synthetic peptide that binds to the GPIIb/IIIa adhesion-molecule receptors found on activated platelets. This allows the detection of acute venous thrombosis and is Food and Drug Administration (FDA)-approved for detection of acute lower extremity deep venous thrombosis. A lyophilized preparation of 100 μg of bapcitide in the presence of heat will split and then complex to 20 mCi Tc-99m pertechnetate. Images of area of concern are acquired at 10 and 60 minutes.

Technetium (^{99m}Tc) Bicisate Injection. A sterile colorless solution of bicisate is complexed with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure of the technetium complex is $[\text{N,N'-ethylene-di-L-cysteinato(3-)}]_2\text{oxo } [^{99m}\text{Tc}] \text{technetium(V) diethyl ester}$. This radiopharmaceutical is a neutral and lipophilic complex that crosses the blood-brain barrier and is selectively retained in the brain. Therefore, this radiotracer is used as a brain-perfusion imaging agent. After intravenous injection of 20 mCi (740 MBq) of Tc-99m bicisate, about 5% of the injected dose is localized within the brain cells 5 minutes after injection and demonstrates rapid renal excretion (74% in 24 hours). This radiotracer is used clinically to evaluate dementia, stroke, lack of brain perfusion ("brain death"), cerebral vascular reserve, or risk of stroke (acetazolamide challenge study) and to localize a seizure focus for surgical removal.

Technetium Bicisate

Technetium (Tc-99m) Depreotide Injection. Technetium depreotide injection is a new radiolabeled synthetic

peptide with high-affinity binding to somatostatin receptors (subtypes 2, 3, and 5) present in many types of cancer, including lung cancer. It is approved for use in patients who are known to have, or are highly suspect for, malignancy and exhibit pulmonary lesions on CT and/or chest x-ray. Over 170,000 new cases of lung cancer are diagnosed each year in the United States alone, and the alternative methods for determining malignancy are needle biopsy, which has an estimated 15% complication rate, and surgery.

The precise structure is cyclo-(L-homocysteiny-L-methyl-L-phenylalanyl-L-tyrosyl-D-tryptophyl-L-lysyl-L-valyl)-(1,1'-sulfide with 3-[(mercaptoacetyl)amino]-L-alanyl-L-lysyl-L-cysteinyl-L-lysineamide. A technetium Tc-99m complex of depreotide is formed when sterile, nonpyrogenic sodium pertechnetate Tc-99m (15 to 20 mCi) injection, in 0.9% sodium chloride is added to a nonpyrogenic lyophilized mixture of 50 μg of depreotide, sodium glucoheptonate dihydrate, stannous chloride dihydrate, 100 μg of edetate disodium dihydrate, and enough sodium hydroxide or hydrochloric acid to adjust the pH to 7.4 prior to lyophilization.

Technetium Disofenin

Technetium (^{99m}Tc) Disofenin Injection. A sterile colorless solution of disofenin is complexed with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure of the technetium complex is unknown at this time. Costello et al.⁷ specify, however, that an analogue of this Tc-99m -disofenin complex provides a single technetium (III) distorted octahedral (1:2) complex with a coordination number of 6. A newer biliary imaging agent is Tc-99m mebrofenin, which is more lipophilic because it has bromine on the benzene ring. In the presence of high serum bilirubin levels, there is less renal excretion because of its higher lipid solubility. In addition, the product is more stable, which makes it more cost-effective for a centralized nuclear pharmacy.

The patient receives an intravenous injection of 5 mCi (185 MBq) of Tc-99m disofenin, which is taken up by the hepatocytes in the liver by active anionic transport. Then the radiopharmaceutical is excreted in bile, via the biliary canaliculus, into the bile ducts, with accumulation in the gallbladder and finally excretion via the common bile duct into the small bowel. The normal patient exhibits early accumulation of the radiopharmaceutical in the liver and the gallbladder and small bowel can be visualized within 1 to 2 hours after injection. An example is seen in Figure 13-5.

The primary clinical indication for this study is possible acute cholecystitis. In acute cholecystitis, there is obstruction of the cystic duct leading to the gallbladder. The gallbladder is not visualized because the radiotracer cannot enter it. Some other clinical conditions that can be diagnosed by the

ay images are common bile duct obstruction, biliary leak from surgery, biliary atresia, and a choledochal cyst.

Technetium (^{99m}Tc) Exametazime Injection. A sterile colorless solution of exametazime is complexed with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure of the technetium complex is unknown at this time. Jurisson et al.⁸ specify, however, that analogues of this complex Tc-99m propylene amine oxime provide a technetium (V) square pyramidal complex with a coordination number of 5. This radiopharmaceutical is lipid-soluble and, therefore, crosses the blood-brain barrier and is trapped within the brain. The possible mechanisms proposed for localization include binding to glutathione, change in ionic state, and chemical degradation. The patient receives an intravenous injection of 20 mCi (740 MBq) of Tc-99m exametazime in a controlled environmental state. The patient is supine, with covered eyes (20 minutes), in a quiet room and with indirect lighting prior to injection. The radiopharmaceutical is irreversibly bound to the brain after 10 minutes. Some of the indications for this study are localization of seizure foci, evaluation of dementia, identification of drug abuse-induced brain defects (i.e., cocaine), and evaluation of stroke. The normal study is represented by a homogeneous and symmetric distribution of radioactivity throughout the brain. Cerebellar activity is usually greater than activity in the rest of the brain. This is the agent of choice to determine brain death in patients on life support systems. The major use of this radiopharmaceutical at this time is for the radiolabeling of autologous leukocytes as an adjunct in the localization of intra-abdominal infection and inflammatory bowel disease.

Technetium (^{99m}Tc) Medronate Injection. A sterile, colorless solution containing sodium medronate (methylene diphosphonate) and a stannous salt is complexed with Tc-99m pertechnetate. A structure proposed by Libson et al.⁹ for the technetium medronate complex is shown below. De Ligny et al.¹⁰ specify, however, that Tc-99m bone imaging agents are mixtures of many components (polymers and oligomers) that can be separated by high-performance anion exchange chromatography.

The clinical use of this agent is for investigation of skeletal problems such as metastatic disease to the bones, osteomyelitis, Paget's disease, fractures, primary bone tumors, avascular necrosis, metabolic bone disease, and loose or infected hip prostheses. Stress fractures can be diagnosed by bone imaging when x-rays are completely normal. Bone radiography is one of the most commonly performed nuclear medicine diagnostic procedures because the whole-body survey allows evaluation of the entire skeleton, which cannot be done as cost-effectively by any other imaging modality.

The patient receives an intravenous injection of 15 to 20 mCi (555 to 740 MBq) of Tc-99m medronate, which localizes in bone according to the degree of metabolic activity. Tc-99m medronate is absorbed onto hydroxyapatite crystals at sites of new bone formation with about 50 to 60% of the injected dose distributed throughout the skeleton within 3 hours; the rest is excreted by the kidneys.

A newer bone-imaging agent, Tc-99m oxidronate (a hydroxyl group on the carbon of medronate) has a higher binding affinity for hydroxyapatite crystals in bone; however, objective criteria indicate no advantage to use of this agent.

Technetium (^{99m}Tc) Mertiatide Injection. The technetium mertiatide complex is a sterile, colorless solution of mertiatide complexed with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure is shown below.

This radiopharmaceutical is the agent of choice to provide information about relative function of the kidneys and urine outflow because it has a higher extraction efficiency than Tc-99m pentetate. Indications include renal artery stenosis in nonperfused kidneys, renal transplant assessment, and outflow obstruction. The patient receives a bolus intravenous injection of 10 mCi (370 MBq) of Tc-99m mertiatide, and dynamic images are obtained every 3 to 5 seconds to study blood flow to the kidneys. Sequential static images are then obtained for 20 to 30 minutes to evaluate renal cortical uptake, excretion, and tubular clearance. Delayed images may be required to evaluate patients with obstruction or renal failure. Normally, there is prompt symmetric bilateral perfusion, good cortical accumulation bilaterally with visualization of the collecting systems by 3 to 5 minutes postinjection, and rapid excretion into the bladder, with no delay to indicate partial or complete obstruction. An older renal imaging agent, Tc-99m gluceptate (a Tc-99m hydroxy acid complex; see below for the ligand), is now used as a transchelation agent for radiolabeling monoclonal antibodies.

Technetium (^{99m}Tc) Pentetate Injection. A sterile, colorless or slightly yellow solution of sodium pentetate or calcium trisodium pentetate is complexed with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure of Tc-99m pentetate is unknown; however, Jurisson et al.⁶ suggested the possible structure below. The primary clinical use of this agent is for renal studies and glomerular filtration rate (GFR), but it is occasionally used for brain death and brain tumor localization. The patient receives an intravenous injection of 3 to 20 mCi (111 to 740 MBq), and the kidneys are imaged for 20 to 30 minutes. The GFR is calculated by a quantitative method using a combination of imaging and counting the radioactivity in serum and urine samples. Normal extraction efficiency is 20% (80 to 140 mL/min).

Technetium (^{99m}Tc) Red Blood Cells (Autologous). A sterile reaction vial containing stannous citrate (Ultratag RBC kit) is used to radiolabel a patient's red blood cells (RBCs) with Tc-99m pertechnetate. Briefly, the patient's blood (1 to 3 mL) is drawn with acid citrate dextrose (ACD) or heparin (100 units) used as an anticoagulant. The blood is labeled with the patient's name and hospital number and added to the sterile reaction vial. After mixing and incubation for 5 minutes, sodium hypochlorite (6 mg) is added to the vial to oxidize excess stannous ions (Sn^{+2}) to stannic ions (Sn^{+4}). A citrate buffer is added to adjust the pH to about 7.4. Then, 30 mCi (1,110 MBq) of Tc-99m pertechnetate is added to the blood in the vial and mixed and incubated for 20 minutes. Without further preparation, the patient receives an intravenous injection of 25 mCi (925 MBq) of his or her own radiolabeled red blood cells.

Three different studies can be performed after injection of the Tc-RBC. First, the radionuclide ventriculogram study for evaluation of cardiac function can be done as with Tc-99m albumin (discussed above). Use of Tc-RBCs is considered the superior technique because the Tc-99m red blood cells remain in the circulating blood volume, whereas the Tc-99m albumin leaks into the extracellular spaces. This leakage increases the background radioactivity around the heart and contributes to degradation of the blood pool image. Second, the Tc-RBCs are used for noninvasive localization of the preoperative site of active gastrointestinal (GI) bleeding. Patients are injected with their own Tc-RBCs, which remain within the circulating blood long enough to extravasate and accumulate within the bowel lumen at the site of bleeding. The final use of Tc-RBCs is to evaluate the spleen after trauma or to confirm an accessory spleen or to study

successful surgical splenic transplants by using heat-damaged RBCs.

Technetium (^{99m}Tc) Sestamibi Injection. A sterile, colorless solution of sestamibi is synthesized by reaction with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure of the technetium complex is $\text{Tc-99m}(\text{MIBI})_6^{+}$, where MIBI is 2-methoxyisobutyl isonitrile. This was the first Tc-99m-labeled agent introduced to replace thallous (^{201}Tl) chloride for myocardial perfusion imaging. The shorter half-life of Tc-99m (6 hours) than of Tl-201 (73 hours) allows administration of a larger dose, which provides better image quality. Another major difference from Tl-201 is that Tc-99m sestamibi exhibits little "redistribution," or movement out of the myocardium back into the bloodstream. This cytosol binding of sestamibi allows more flexibility in the imaging time, although it also necessitates separate sestamibi injections at stress and at rest, which increases the expense of this method.

The other radiotracers currently used to evaluate myocardial perfusion include Tl-201 and Tc-99m tetrofosmin. Myocardial perfusion studies usually compare "stress" or increased blood flow images with resting images. The stress can be brought about by physical means (treadmill, bicycle) or by pharmacological vasodilation (with dipyridamole, adenosine, or dobutamine). Myocardium with significantly narrowed arterial supply may appear to have normal blood flow at rest but, during increased blood flow during exercise, demonstrate abnormal blood flow relative to areas with normal arteries. There are a variety of protocols for the stress/rest imaging sessions, even one that combines Tl-201 (rest) and Tc-99m-sestamibi (stress). Additional indications for the use of the Tc-99m-sestamibi complex now include the preoperative localization of parathyroid adenoma and the early diagnosis of breast cancer.

Technetium (^{99m}Tc) Sodium Pertechnetate. Technetium sodium pertechnetate is a sterile, colorless solution containing sodium pertechnetate ($\text{Na}^{99m}\text{TcO}_4$) in normal saline (0.9% NaCl), obtained by elution of the sterile Mo-99/Tc-99m generator. The pertechnetate ion ($^{99m}\text{TcO}_4^-$), which has an ionic radius and charge similar to those of the iodide ion (I^-), is concentrated in the thyroid, salivary glands, kidney, stomach, and choroid plexus in the brain. It can be used directly from the Mo-99/Tc-99m generator to image the thyroid, Meckel's diverticulum (stomach tissue in the intestine), and salivary glands for tumors and to detect processes

that disrupt the blood-brain barrier (i.e., tumors, abscesses, strokes). Unlike the iodide ion, the pertechnetate ion is not converted to thyroid hormone but only trapped. Thyroid nodules can appear nonfunctional, with little or no radiotracer present. These nonfunctional nodules have about a 20% probability of being cancerous and generally require biopsy. The patient receives an intravenous injection of 5 to 10 mCi (185 to 370 MBq) of Tc-99m pertechnetate, and images are obtained of the thyroid 0 to 20 minutes after injection. The usual dose for the other imaging procedures is the same for Meckel's diverticulum and salivary glands, and 20 mCi (740 MBq) is used for brain tumor imaging.

Technetium (^{99m}Tc) Succimer Injection. A sterile, colorless solution of succimer (2,3-dimercaptosuccinic acid) is complexed with Tc-99m pertechnetate after reduction with a stannous salt at acid pH. The precise structure of Tc-99m (III) succimer is unknown; however, Moretti et al.¹¹ suggested the possible structure below. Tc-99m succimer is very useful for demonstrating the functioning renal parenchyma, because about 40% of the dose is bound to the renal cortex 1 hour after injection. The patient is injected with 5 mCi (185 MBq) of Tc-99m succimer, and multiple images are taken 2 to 4 hours later. This study can be useful for evaluating renal trauma, renal masses (e.g., tumors, cysts), and renal scarring. Tc-99m succimer is the diagnostic agent of choice in children who have chronic urinary tract infections causing renal scarring. If the pH is adjusted to 8.0 to 8.5, a technetium (V)-succimer complex is formed, which is useful for imaging tumors.¹² Blower et al.¹³ have proposed the following structure for Tc-99m (V) succimer.

Technetium (III) Succimer

Technetium (V) Succimer

Technetium (^{99m}Tc) Sulfur Colloid Injection. Technetium-sulfur colloid injection is a sterile, opalescent colloidal dispersion of sulfur, a unit of structure built up from polymeric molecules and ions (micelles) radiolabeled with Tc-99m pertechnetate formed by heating in dilute hydrochloric acid. The radiocolloid should be stabilized with gelatin A to inhibit clumping of the negatively charged colloidal parti-

cles. The particle size of the colloid is 0.1 to 3 μm . After intravenous injection of 5 to 10 mCi (185 to 370 MBq) of Tc-99m sulfur colloid, the radiopharmaceutical is rapidly cleared from the blood by the RE cells of the liver, spleen, and bone marrow. Uptake of the Tc-99m-sulfur colloid depends on the relative blood perfusion rate and the functional capacity of RE cells. In the normal patient, 85% of the radiocolloid is phagocytized by Kupffer cells in the liver, 7.5% by the spleen, and the remainder by the bone marrow, lungs, and kidneys. Bone marrow imaging studies are performed 1 hour after injection of 10 mCi (370 MBq) of Tc-99m-sulfur colloid. Normal bone marrow will take up the radiocolloid, but diseased bone marrow appears as "cold" defects in patients with tumor deposits in the marrow. Tc-99m-sulfur colloid is used as a secondary agent in liver and spleen imaging if Tc-99m-albumin colloid is not available. It is used as the primary agent, however, for GI studies such as gastroesophageal reflux (GER) and gastric emptying of solid food. Gastroesophageal reflux imaging is performed after having the patient swallow acidified orange juice mixed with Tc-99m-sulfur colloid. Normal patients have no GER. This study reportedly has 90% sensitivity in detecting GER. Gastric emptying imaging is performed after the patient swallows solid food (i.e., scrambled eggs or pancakes) radiolabeled with Tc-99m sulfur colloid. In general, the normal gastric emptying half-time is less than 90 minutes for solid food.

Technetium (^{99m}Tc) Tetrafosmin Injection. A sterile, colorless solution of tetrafosmin is complexed with Tc-99m pertechnetate after reduction with a stannous salt. The precise structure of the technetium complex is shown below.¹⁴ The formulation contains gluconate to form a weak technetium (V) chelate to keep the technetium in the (V) oxidation state for transchelation to form the technetium (V)-tetrafosmin complex. Technetium (V)-tetrafosmin is another cationic Tc-99m complex that thallous (^{201}Tl) chloride accumulates in viable myocardium. Myocardial uptake of this agent in humans is about 1.2% 5 minutes after intravenous injection and decreases to 1.0% at 2 hours. This agent was less specific for detecting ischemia (66%) than Tl-201 chloride (77%) in a small study (252 patients). It appears, however, to have rapid clearance through nontarget organs (liver) and thus fewer high-background imaging problems.

Technetium Tetrafosmin

FLUORINE RADIOCHEMISTRY

The useful radioisotope of fluorine for organ imaging is fluorine-18. Fluorine-18 is produced in a cyclotron by the $^{18}\text{O}(p,n)^{18}\text{F}$ nuclear reaction. Fluorine-18 ($t_{1/2} = 109$ minutes) decays by electron capture and positron emission to oxygen-18 with γ -ray emissions of 511 keV (194%). Fluorine-18 can be attached to a number of physiologically active molecules and, with the great strength of the C-F bond, appears to be a very useful label for radiopharmaceuticals.¹⁵ Radiotracer production involves relatively complicated synthetic pathways, however, and the preparation of high-specific-activity compounds presents many problems. The short half-life of fluorine-18 makes it necessary to complete the synthetic and purification procedure within 3 hours. Consequently, a separate chemistry system (black box type) is needed for each compound. The chemistry of fluorine is complicated, but some compounds can be fluorinated by $^{18}\text{F}^-$ exchange reactions and direct fluorination with elemental fluorine ($^{18}\text{F}_2$); also, compounds with an aromatic ring may be fluorinated by several synthetic reactions. For example, partially fluorinated heteroaromatics are readily obtained by the conversion of an amino group on the aromatic ring to fluoride, with use of the Balz-Schiemann and several related reactions.

Fluorine (^{18}F)-2-Fluoro-2-Deoxy-D-Glucose. The only F-18 radiopharmaceutical presently available is fluorine (^{18}F)-2-fluoro-2-deoxy-D-glucose (F-18 FDG). The precise structure of F-18 FDG is shown below. It is the only PET agent approved by the FDA. Hamacher et al.¹⁶ introduced the current method of synthesis of F-18 FDG by nucleophilic fluorination. Use of this radiotracer for diagnostic imaging in oncology has increased dramatically in the last several years. It is used also as a myocardial viability agent and in evaluation of seizure disorders.¹⁷ The high glycolytic rate of many neoplasms compared with that of the surrounding tissues facilitates tumor imaging with this glucose analogue. Because of the widespread anatomical distribution of metastases, a whole-body imaging technique using a tumor-specific radiopharmaceutical is very useful for tumor detection and mapping to evaluate the extent and relative metabolic activity of the disease.

GALLIUM RADIOCHEMISTRY

The only radioisotope of gallium that is presently used is gallium-67, which is produced in a cyclotron by proton bombardment of a zinc metal target by a $^{68}\text{Zn}(p,2n)^{67}\text{Ga}$ nuclear reaction. Gallium-67 ($t_{1/2} = 78.2$ hours) decays by electron

capture to stable zinc-67 with principal γ -ray emissions of 93 keV (38%), 185 keV (24%), and 300 keV (16%). The radiotracer is isolated by dissolution of the target in hydrochloric acid followed by isopropyl ether extraction of the gallium-67 from the zinc and other impurities. The gallium-67 is back-extracted from the isopropyl ether into 0.2 M hydrochloric acid, evaporated to dryness, and dissolved in sterile, pyrogen-free 0.05 M hydrochloric acid. Gallium is an amphoteric element that acts as a metal at low pH but forms insoluble hydroxides when the pH is raised above 2.0 in the absence of chelating agents. At high pH, gallium hydroxide acts as a nonmetal and dissolves in ammonia to form gallates. Gallium forms compounds of oxidation states +1, +2, and +3; however, only the Ga^{+3} state is stable in aqueous solutions.

Gallium (^{67}Ga) Citrate. The gallium (III)-citrate complex is formed by adding the required amount of sodium citrate (0.15 M) to gallium (III) chloride and adjusting the pH to 4.5 to 8.0 with sodium hydroxide. The proposed structure of gallium (^{67}Ga) citrate is shown below.⁶ The patient receives an intravenous injection of 5 to 10 mCi (185 to 370 MBq) of gallium (^{67}Ga) citrate, and whole-body images are then obtained 24, 48, and 72 hours after injection. Gallium localizes at sites of inflammation or infection as well as a variety of tumors. It is used in clinical practice in the staging and evaluation of recurrence of lymphomas. Gallium localizes normally in the liver and spleen, bone, nasopharynx, lacrimal glands, and breast tissue. There is also some secretion in the bowel; consequently, the patient may require a laxative and/or enemas to evacuate this radioactivity prior to the 48-hour image. As more specific radiotracers have been developed, the nonspecific normal localization of gallium radioactivity has limited its clinical use.

IODINE RADIOCHEMISTRY

The useful radioisotopes of iodine for organ imaging are iodine-131 and iodine-123 because of their desirable physical characteristics. Iodine-131 is obtained from a reactor by production of tellurium-131. It is formed by the nuclear reaction $^{235}\text{U}(n,\text{fission})^{131}\text{Te}$ or $^{130}\text{Te}(n,\gamma)^{131}\text{Te}$. The tellurium-131 ($t_{1/2} = 25$ minutes) decays by β -particle emission to iodine-131. Iodine-131 ($t_{1/2} = 8.04$ days) transforms by β decay to stable xenon-131, with five significant γ -ray emissions of 80 to 723 keV. The major γ -ray of 364 keV (82%) provides good tissue penetration for organ imaging.

Undesirable properties of iodine-131 are the high radiation dose from the β particles, the long half-life, and the poor image produced by the high-energy γ -rays. Iodine-123 ($t_{1/2} = 13.3$ hours) decays by electron capture to tellurium-123, with a principal γ -ray emission of 159 keV (83%), which makes it the ideal radioisotope of iodine for organ imaging because of increased detection efficiency and reduced radiation to the patient. Iodine-123 is produced in a cyclotron bombarding an antimony metal target with α particles according to the $^{121}_{51}\text{Sb}(\alpha, 2n)^{123}_{53}\text{I}$ reaction or an iodine target with high-energy protons by the $^{123}_{53}\text{I}(p, 5n)^{123}_{53}\text{I}$ nuclear reaction. The xenon-123 decays by electron capture to iodine-123. It is, however, relatively expensive to produce and currently has limited availability for radiolabeling compounds. Iodine is in group VIIB with the other halogens (fluorine, chlorine, bromine, and astatine). In aqueous solution, compounds of iodine are known with at least five different oxidation states; however, in nuclear medicine, the -1 and $+1$ oxidation states are the most significant. The -1 oxidation state represented as sodium iodide (NaI) is important for thyroid studies and, when obtained in a reductant-free solution (no sodium thiosulfate), is the starting compound for the radiolabeling of most iodinated radiopharmaceuticals. The common methods for introducing radioiodine into organic compounds are isotope exchange reactions, electrophilic substitution of hydrogen in activated aromatic systems, nucleophilic substitution, and addition to double bonds.¹⁸ The replacement of aromatic hydrogen in activated aromatic systems is used for protein labeling, and electrophilic iodine (I^+) can be generated by a variety of oxidizing agents, including (a) chloramine-T (*N*-chloro-*p*-toluene sulfonamide) sodium, (b) enzyme oxidation of I^- (lactoperoxidase), and (c) iodogen 1,3,4,6-tetrachloro-3a-6a-diphenylglycoluril). The actual iodinating molecule depends on the oxidizing agent but is probably HOI or H_2OI^+ .

Iodine Radiopharmaceuticals

Iobenguane Sulfate (^{131}I) Injection (I-131-Metaiodobenzylguanidine Sulfate). Iobenguane sulfate is radiolabeled by a Cu^+ -catalyzed isotopic nucleophilic exchange reaction. It is a radioiodinated arylalkylguanidine and is similar to the antihypertensive drug guanethidine and to the neurotransmitter norepinephrine. The proposed structure of iobenguane (^{131}I) sulfate is shown below. Iodine-123 is also used to radiolabel this tracer and may have more favorable imaging properties. Functional tumors of the adrenal medulla (pheochromocytomas) and tumors of neuroendocrine origin (neuroblastoma) can be localized on I-131 meta-iodobenzylguanidine (^{131}I -MIBG) images, as abnormal tissue that takes up the radiopharmaceutical and exhibits increased activity on the image.¹⁹ Drug intervention studies in animals, using reserpine, have demonstrated that the ^{131}I -MIBG enters adrenergic neurons and chromaffin cells by an active transport mechanism of catecholamine uptake into adrenergic storage granules.

Neuroblastoma is a malignant tumor of the sympathetic nervous system, which occurs most often in children. The tumor is of neural crest origin and consists of cells that form the sympathetic nervous system, called *sympathogonia*, that migrate to the adrenal medulla and many other parts of the body. Metastases may be found in the liver (stage IV) and

in the regional lymph nodes, bone, bone marrow, and soft tissues. After an initial report by Kimmig et al.²⁰ of ^{131}I -MIBG uptake in neuroblastoma, successful use of this tracer was described by others. The increased uptake of ^{131}I -MIBG is so tissue specific that it can establish the diagnosis of neuroblastoma in a child with a tumor of unknown origin. The patient is treated with Lugol's solution (up to 40 mg/day) 24 hours before and 4 to 7 days after administration of the radiopharmaceutical, to block thyroid uptake of free $^{131}\text{I}^-$. The ^{131}I -MIBG is administered by slow intravenous injection 0.3 to 0.5 mCi (11 to 18.5 MBq), and patients are imaged 24, 48, and 72 hours later. Occasionally, the patient receives a renal imaging agent for better localization of the adrenal tumor.

Sodium Iodine (^{123}I) Capsules. The major indications for thyroid imaging with sodium iodide (^{123}I) are for evaluation of thyroid morphology, for ectopic thyroid tissue (e.g., lingual or mediastinal), and for substernal thyroid tissue. When thyroid nodules are being evaluated for possible thyroid cancer, ^{123}I has an advantage over Tc-99m pertechnetate scans, although I-123 is more expensive. This is because thyroid cancer cells sometimes retain the ability to trap, but not further process, iodine to thyroid hormone. Unlike iodine, Tc-99m pertechnetate is only trapped by the thyroid and in a nodule may give the false impression that a nodule is not cancerous. The patient fasts before receiving the oral dose of 0.4 mCi (15 MBq) of sodium iodine (^{123}I). Images are obtained of the thyroid and surrounding area 4 to 6 hours after ingestion.

Sodium Iodine (^{131}I) Oral (Solution or Capsule). The thyroid cancer patient receives an oral dose of 5 to 10 mCi (185 to 370 MBq) of sodium iodide (^{131}I), which localizes in residual thyroid tissue after "total" thyroidectomy and functioning thyroid metastasis from thyroid carcinoma. Images of the whole body are obtained 48 to 72 hours later. These metastatic radioiodide surveys are used to detect regional or distant metastases for large-dose 150 mCi (5,550 MBq) inpatient therapy for thyroid carcinoma. Any thyroid hormone medication should be discontinued for 2 weeks (T_3) or 4 weeks (T_4). In addition, the patient should have blood drawn for a thyroid-stimulating hormone (TSH) test to ensure that TSH is elevated before administration of the therapy dose, to permit maximum stimulation of thyroid tissue. The patient should fast before receiving the oral dose of radiotracer.

INDIUM RADIOCHEMISTRY

The most useful radioisotope of indium is indium-111, which is produced in a cyclotron by proton bombardment of a cadmium metal target by a $^{112}\text{Cd}(p, 2n)^{111}\text{In}$ nuclear reaction.

Indium-111 ($t_{1/2} = 67.4$ hours) decays by electron capture to stable cadmium-111 with principal γ -ray emissions of 172 keV (91%) and 247 keV (94%). The radiotracer is isolated by dissolution in hydrochloric acid to form ^{111}In -chloride and separated from cadmium and other impurities by several dissolution and extraction steps. The last extraction is done with isopropyl ether, evaporating to dryness, and dissolving in sterile, pyrogen-free 0.05 M hydrochloric acid. In aqueous solution, lower valence states of indium have been described, but they are unstable and are rapidly oxidized to the trivalent state. In acid solution, indium salts are stable at low pH but are hydrolyzed (above pH 3.5) to form a precipitate of indium hydroxide or trioxide. Indium will remain in solution above pH 3.5, however, if it is complexed with a weak chelating agent such as sodium citrate and stronger chelating agents such as 8-hydroxy quinoline (oxine) or diethylenetriaminepentaacetic acid (DTPA). Monoclonal antibodies or peptides are radiolabeled by indium by using compounds called *bifunctional chelating agents*. Bifunctional chelating agents are molecules that can both bind metal ions and be attached to other molecules; one example is the cyclic anhydride of DTPA.

Indium Radiopharmaceuticals

Indium (^{111}In) Chloride Injection. Indium (III) chloride is a sterile, colorless solution that is radiolabeled with indium-111 in a hydrochloric acid solution (0.05 M) and has a pH of 1.5. It is primarily used to radiolabel other compounds for use in cisternography and white blood cell labeling studies and is particularly recommended for radiolabeling monoclonal antibodies for metastatic cancer imaging. If this agent is injected intravenously for clinical use, the patient's blood must be drawn into the syringe containing the radiopharmaceutical to buffer the agent to a higher pH to eliminate the burning sensation on injection. When the acidic compound is mixed with blood, the indium-111 chloride binds quickly to transferrin, the iron-binding protein in the plasma. The localization of the indium (III) chloride in bone marrow is probably explained by its ability to behave metabolically like iron and yet not be incorporated into hemoglobin in the RBCs in the bone marrow. The localization of the radiotracer in tumors and abscesses is probably due to increased blood flow and capillary permeability in the area of tissue damage. Transferrin receptors have been suggested as a means of localization but not proved at this time.

Indium (^{111}In) Capromab Pendetide. Indium capromab pendetide is a new radiotracer for staging patients with newly diagnosed prostate cancer and for those with suspected recurrence but a negative localization with a standard evaluation.

Indium (^{111}In) Oncoscint CR/OV (Satumomabpendetide). The simplified structure of indium (^{111}In) satumomabpendetide is shown below. Antibodies are a heterogeneous group of proteins isolated from human and animal serum and are called *immunoglobulins*. They are divided into classes on the basis of differences in structure and biological properties and are assigned to major classes called IgG (80%), IgM (10%), and IgA, IgD, IgE (<10%). All antibodies have a general structure consisting of two heavy chains

(MW ~55,000) and two light chains (MW ~20,000) of glycoproteins, held together by disulfide bonds. Many tumors express antigenic markers on their surfaces that permit detection with radiolabeled antibodies. Antibodies are produced by B lymphocytes and plasma cells sensitized to an antigen. Hybridoma technology permits the manufacture of large quantities of antibody directed against specific antigens. Diagnostic antibodies are of two types: polyclonal and monoclonal. Each chain has a variable region for antigenic binding and a constant region for complement fixation. Polyclonal antibodies include numerous antibody species of varying affinity for the antigen-binding surfaces. Monoclonal antibodies are generated from a clone of a single antibody-producing cell and have uniform affinity for their antigenic determinant.²¹ Monoclonal antibodies are produced by immunizing a mouse with purified material from the surface of the human tumor cell. (See Chapter 7 for additional information.) The antigen used in Oncoscint CR/OV is a tumor-associated glycoprotein-72 (TAG-72), a high-molecular-weight glycoprotein expressed by colorectal and ovarian carcinomas.²² The radiolabeling of Oncoscint CR/OV monoclonal antibody was developed by Rodwell²³ as a site-specific method using a bifunctional chelate. Briefly, carbohydrate moieties on the monoclonal antibody (F-constant region) are oxidized with periodate, and the aldehyde groups on the antibody are reacted with α -amino groups of glycyl-tyrosyl-lysine-*N*-diethylene triaminepentaacetic acid. The Schiff's base form (imine) is stabilized by reduction with sodium cyanoborohydride. In-111 is chelated to a DTPA-carbohydrate molecule attached to the constant region of the monoclonal antibody. The specificity of radiolabeled antibody imaging for tumors exceeds that of gallium (^{67}Ga) citrate studies. Sites of non-specific uptake have been reported, however, such as recent surgical wounds, an inflamed colon, bone fracture, and normal colostomy stoma. A new method of labeling with Tc-99m has recently been approved by the FDA.

Indium (^{111}In) Oxine (8-Hydroxyquinoline). The indium (III)-oxine complex can be formed by adding the required amount of 8-hydroxyquinoline sulfate to indium (III) chloride and adjusting the pH to 6.5 to 7.5 with HEPES buffer. The precise structure of indium (III) oxine as determined by Green²⁴ is shown below. The patient has 45 to 90 mL of blood drawn for a 1.5- to 2-hour *in vitro* process of separating and labeling cellular elements such as leukocytes or platelets. Images are acquired 2 to 48 hours after reinjection of the labeled cells. In the case of indium-111 leukocytes, the procedure is performed to confirm the presence or absence of infection. This technique has replaced gallium (^{67}Ga) citrate imaging for acute infection because of greater specificity and better image quality. Some chronic infections such as osteomyelitis may be imaged better with gallium (^{67}Ga) citrate after a $^{99\text{m}}\text{Tc}$ -phosphate bone scan. Another method of radiolabeling leukocytes that has become popular uses $\text{Tc-}^{99\text{m}}$ -HMPAO (hexamethylpropyleneamine oxime). Finally, indium (^{111}In)-labeled platelets are used to detect thromboses, measure platelet life span, and monitor the success of kidney transplants.

Indium (^{111}In) Pentetate (^{111}In -DTPA). The indium (III)-pentetate complex is formed by adding the required amount of calcium or sodium pentetate (DTPA) to the indium (III) chloride and adjusting the pH to 7.0 to 8.0 with sodium hydroxide and/or hydrochloric acid. A proposed structure of indium (III) pentetate is shown below.⁶ The patient undergoes a lumbar puncture under sterile conditions and receives an intrathecal injection of 0.5 to 1.0 mCi (18.5 to 37.0 MBq) of indium (^{111}In) pentetate, which distributes into the cerebrospinal fluid (CSF). Initial images are obtained to ensure a good intrathecal injection. Images of the spinal canal and CSF spaces of the brain are acquired at 0 to 72 hours to assess CSF flow or leakage from the normal CSF space. The normal CSF flow pattern shows that the radiopharmaceutical ascends to the basilar cisterns in 2 to 4 hours and flows over the cerebral convexities in 24 hours. From 24 to 72 hours, there should be a gradual clearance from the CSF via the choroid plexus. Cisternography is helpful in evaluating for communicating hydrocephalus because there is abnormal CSF flow into the lateral ventricles of the brain in this disease. There is also an MRI method for evaluating this type of hydrocephalus. This disease may be treated surgically by shunting CSF to other areas of the body, such as the peritoneal space, and this radiotracer can be used to assess the possibility of a blockage of such a shunt.

Another indication for this technique is evaluation for a CSF leak after surgery or trauma. One variation of evaluating for a leak is to put cotton pledgets in the nostrils for 24 hours and check for abnormal radioactivity on the pledgets.

Indium (^{111}In) Pentreotide Injection. A proposed structure of indium (^{111}In) pentreotide is shown below.²⁵ Pentreotide has a bifunctional chelating agent, DTPA, linked to octreotide, which is a long-acting analogue of the human hormone somatostatin. Somatostatin is a peptide hormone consisting of 14 amino acids. It is present in the GI tract, pancreas, cerebral cortex, brainstem, and hypothalamus. Somatostatin receptors have been found on many cells of neuroendocrine origin. Neuroendocrine tumors are small and slow growing, which makes them hard to detect by CT or MRI. Somatostatin receptors are expressed in nearly all tumors of neuroendocrine origin and can be imaged with the DTPA-octreotide analogue, which chelates indium (III) chloride.

Indium (^{111}In) pentreotide binds to somatostatin receptors on many cell surfaces throughout the body. The patient receives an intravenous injection of 5 mCi (185 MBq) of ^{111}In -pentreotide, and within an hour, the radiopharmaceutical diffuses into the extracellular fluid space and concentrates in tumors containing a large number of somatostatin receptors. Whole-body images are obtained 4 to 48 hours after injection to localize the primary tumor and sites of metastases. Normally, the pituitary gland, thyroid gland, liver, spleen, kidneys, urinary bladder, and, in most patients, the bowel are visualized on the image.

THALLIUM RADIOCHEMISTRY

The only useful radioisotope of thallium is thallium-201, which is produced in a cyclotron by proton bombardment of a thallium metal target by a $^{203}\text{Tl}(p,3n)^{201}\text{Pb}$ nuclear reaction. The lead-201 ($t_{1/2} = 9.4$ hours) is allowed to decay by electron capture to Tl-201. Thallium-201 ($t_{1/2} = 73.0$ hours) decays by electron capture to stable mercury-201, with principal γ -ray emissions of 135 keV (2%) and 167 keV (8%), and mercury-201 daughter x-rays of 68 to 80 keV (94.5%), all of which can be used for organ imaging. The thallium target is dissolved in hydrochloric acid, and the Pb-201 is isolated from the thallium-203 by ion exchange column chromatography. The lead-201 (^{201}Pb) is allowed to decay on the column to thallium-201. The thallium-201 (^{201}Tl) is removed from the column by ion exchange, and the chloride salt is formed by adding hydrochloric acid and evaporating to dryness. Then the pH is adjusted to 4.5 to 7.0 with sodium hydroxide and the salt is sterilized. The solution is made isotonic with sodium chloride containing benzyl alcohol as a preservative.

Thallium Radiopharmaceuticals

Thallium (^{201}Tl) Chloride. Thallium chloride is the only radiopharmaceutical of thallium-201 currently in use. The most common clinical uses of this radiotracer are for the evaluation of myocardial perfusion and myocardial viability. In recent years, thallium-201 has also been used to evaluate a variety of types of cancer as well as hyperparathyroidism.

Research using radiolabeled microspheres with human volunteers demonstrated that the myocardial distribution of thallous (I) chloride correlates with regional blood perfusion. Thallium (^{201}Tl) chloride accumulation in myocytes requires an intact sodium-potassium pump mechanism within the cell membrane. Accumulation in the myocardial tissue therefore reflects viable tissue as well as blood flow to the myocardial tissue. Conversely, in clinical imaging studies, the areas of myocardial infarction (not viable scar) are visualized as nonperfused ("cold") areas. Although the Tc-99m-based myocardial perfusion radiotracers (sestamibi and tetrofosmin) are mostly bound in the heart cell, Tl-201 is continually, passively moving back out of the cells. This phenomenon is called *thallium redistribution*.

Currently, the most commonly performed test in all of nuclear medicine is the evaluation for significant narrowing of the coronary arteries. To do this, the patient submits to either physiological "stress" (treadmill exercise) or pharmacological "stress" with an intravenous infusion of a vasodilator (dipyridamole or adenosine), depending on physical condition. At maximum stress, the patient is injected with 2.0 to 4.0 mCi (74 to 148 MBq) of thallous (I) chloride, which localizes in the heart muscle (myocardium) in proportion to regional blood flow and cell viability. The "stress test" accentuates the myocardial perfusion abnormality because areas of significant arterial narrowing cannot respond to the increased blood flow demands of the stress as well as the normal arteries can. Images of the heart are obtained immediately after stress, and the damaged myocardium shows less Tl-201 chloride uptake than surrounding normal heart muscle. Four hours after stress, the resting patient is

injected with 1.0 mCi (37 MBq) of Tl-201 chloride to provide information under normal conditions. An example is shown in Figure 13-7.

XENON RADIOCHEMISTRY

The useful radioisotope of xenon for organ imaging is xenon-133. Xenon-133 is produced in a nuclear reactor as a by-product of uranium fission by the nuclear reaction $^{235}\text{U}(n, \text{fission})^{133}\text{Xe}$. Xenon-133 ($t_{1/2} = 5.3$ days) decays by β -particle emission to cesium-133, with γ -ray emissions of 81 keV (36%). Gases used in lung ventilation studies must be chemically inert and, at the concentrations used, be physiologically inert. Xenon-133 is chemically inert and insoluble in water, which makes it insoluble in body fluids. Unfavorable physical characteristics of xenon-133 include poor image quality because of the low tissue penetration of the low-energy γ -ray, increased patient dose due to β -particle emission, and the low γ -ray emission (36 γ -rays/100 disintegrations). An alternative would be xenon-127, which is unavailable and not cost-effective.

Xenon Radiopharmaceuticals

Xenon (^{133}Xe) Gas. Radioactive xenon gas is supplied at standard pressure and room temperature in a septum-sealed glass vial (2 mL) in doses of 10 to 20 mCi (370 to 740 MBq). The glass vial can contain atmospheric air or a mixture of 5% xenon and 95% carbon dioxide and is suitable for inhalation by the patient for diagnostic evaluation of pulmonary function and imaging. The general procedure involves mixing the xenon-133 gas in air or oxygen in a closed-circuit spirometer system that delivers the radioactive gas and rebreathing the gas mixture. The inhalation study consists of equilibrium and washout phases, with the patient sitting or supine. In the washout study, the patient exhales the xenon-133 gas into an activated charcoal trap to prevent exposure of the technologist. Images are obtained continuously for approximately 10 minutes with the gamma (γ -ray) camera. In the normal equilibrium study, there is an initial homogeneous distribution of the radioactive gas throughout the lungs. In the washout phase, the xenon-133 gas clears readily from the lungs. In the abnormal study, the initial flow into the lungs of xenon-133 gas is delayed, and the outflow is also delayed. These abnormal lung ventilation findings add significant information in the evaluation of pulmonary embolism (blood clots in the lungs) when combined with the results of a lung blood perfusion study with Tc-99m aggregated albumin.

RADIOLOGICAL CONTRAST AGENTS

A photographic film containing a radiographic image is properly called a *radiograph*, although it is commonly referred to as an *x-ray* or a *film*. The relative difference between the light and dark areas on a radiographic image reflects what is called *radiographic contrast*. Traditional radiographic images of the body, such as skeletal, abdominal, and chest x-rays, have five radiographic densities: air

(gas) density, fat density, fluid (soft tissue) density, bone (calcium) density, and metallic density.

Whereas traditional radiological "film" studies have been used since 1895 and continue to be a mainstay of diagnostic medical imaging, they have their limitations. Many organs and tissues of the body do not show up well on traditional radiographic images. For example, the liver, spleen, kidneys, intestines, bladder, and abdominal musculature all have very similar radiographic densities and are difficult, if not impossible, to distinguish from each other.

From the earliest days of radiology, much effort has been devoted to developing compounds that if swallowed or injected would increase the radiographic contrast between various tissues and organs. Injection of air or other gases into a GI tube in the esophagus, stomach, or duodenum or into a rectal tube in the colon provides increased radiographic contrast for evaluating the gut; however, the information obtained by this technique is limited, and more opaque substances have been developed.

Any agent or compound administered to a patient to improve the visualization of an organ or tissue is called a *contrast agent*. Contrast agents can be classified as negative or positive. Air and other gases are negative contrast agents because they render a structure, such as the gut, more translucent. An agent that increases the radiographic opacity of an organ or tissue is a positive contrast agent. The majority of contrast agents used in diagnostic radiology are positive contrast agents.

An ideal contrast agent should have the following properties: (a) ready availability and low cost; (b) excellent x-ray absorption characteristics at the x-ray energies used in diagnostic radiology; (c) minimal toxicity and ready patient acceptance; (d) chemical stability; (e) high water solubility with low viscosity and no significant osmotic effects; and (f) the ability to be administered for selective tissue uptake and excretion.

No compound has all of these characteristics. Barium sulfate and a variety of iodine compounds, however, produce excellent radiological contrast with low patient toxicity and relatively low cost. The use of barium and iodine compounds as radiological contrast agents is based on their radiographic appearance and their distribution and elimination from the body. Contrast media are used in very large quantities and are usually administered over a short time.

Barium sulfate is a nearly ideal contrast agent for oral and rectal studies of the GI tract. It produces a metal-like density on radiological studies, is readily available at low cost, and, when used properly, has minimal patient morbidity and mortality. Many water-soluble barium compounds are quite toxic, but barium sulfate is an insoluble white powder that is formulated in water as a colloidal suspension.

The majority of contrast agents used to opacify blood vessels and increase contrast in solid organs such as the liver are water-soluble organic iodides. Iodine absorbs x-rays effectively at many energy levels and produces a type of "calcific" or "bone" density on radiographic studies. Its density, somewhat less than that of barium sulfate, is quite acceptable.

Until the 1980s, most water-soluble contrast agents consisted of triiodinated benzoic acid salts. In solution, they dissociate into two particles, a triiodinated anion and a cation, which consists of either a sodium or methylglucamine

(meglumine) ion. These compounds (Table 13-2), known as *high-osmolar contrast media* (HOCM), have in effect three iodine atoms for every two ions in solution, a 3:2 ratio. They are often called *ionic ratio 1.5 contrast agents* or *triiodinated monomers*.²⁶ They are mainly represented by diatrizoate and iohalamate compounds and find frequent use in urography and contrast-enhanced CT studies.

One must administer the water-soluble iodinated organic compounds in fairly high concentrations to achieve satisfactory radiological contrast. It is not unusual to administer 100 mL or more of a 60% solution of one of these compounds intravenously for urography. A typical concentration used for intravascular studies has an osmolality 5 to 7 times greater than that of normal plasma. Therefore, administration of these agents can be associated with osmotoxic effects, such as local pain, flushing, nausea, and vomiting. The common triiodinated contrast agents listed in Table 13-2 represent what are commonly called *ionic* or *high-osmolar* agents. They are relatively inexpensive and have been in use since the 1960s.

Much research has gone into developing water-soluble compounds with a higher ratio of iodine to osmotic particles. The first commercially available nonionic contrast agent was metrizamide, which dissolves in water in a nondissociated form, giving three iodine atoms for every molecule in solution and is referred to as a *ratio-3 contrast agent*. Metrizamide was mainly used for myelographic studies of the spinal canal and has been largely replaced by newer agents. This has led to the development of ionic hexaiodinated dimers, such as ioxaglate (Hexabrix), and nonionic water-soluble contrast agents (Table 13-2).

Iopamidol, iohexol, and ioversol are newer "low-osmolar, nonionic" contrast agents (Table 13-2) and are heavily used around the world for many types of radiological studies. These types of agents, known as *low osmolar contrast media* (LOCM), produce far fewer osmotoxic effects, such as local arm pain, flushing, and nausea and vomiting. They are generally considered safer than the common ionic triiodinated contrast agents and, in many locales, have replaced them in daily practice. They are very expensive, however, compared with the ionic agents. In the United States, they may cost up to 10 to 20 times as much as the ionic agents.^{27, 28}

TABLE 13-2 Diagnostic Imaging Agents and Procedures**Common Contrast Agents****High-osmolality (1,400 to 2,938 mOsm/kg) ("ionic") agents.**

- Conray 60 (60% meglumine iothalamate)
- Conray 400 (66.8% sodium iohalate)
- Hypaque 50 (50% sodium diatrizoate)
- Hypaque 60 (60% sodium diatrizoate)
- Hypaque 76 (76% sodium diatrizoate)
- Hypaque M 90 (60% meglumine diatrizoate, 30% sodium diatrizoate)
- Renografin 60 (52% meglumine diatrizoate, 8% sodium diatrizoate)
- Renografin 76 (66% meglumine diatrizoate, 10% sodium diatrizoate)
- Renov-M-60 (60% meglumine diatrizoate)

Low-osmolality ("nonionic") agents (290 to 862 mOsm/kg)

- Amlpague (metrizamide)
- Hexahrix (ioxaglate; this is an ionic hexaiodinated dimer)—Guerbet, S.A.
- Isovue (iopamidol)—Bracco Diagnostics
- Omnipaque (iohexol)—Nycomed
- Optimy (ioversol)—Mallinckrodt
- Oxilan (ioxilan)—Cook Imaging
- Ultravist (iopromide)—Berlex Laboratories
- Visipaque (iodixanol)—Nycomed
- Xenetix (iothitridol)

Miscellaneous infrequently used hiliary contrast agents

- Cistobil, Colepax, Telepaque, Telernast (iopanoic acid)
- Cholebrine, Cholimil (ioctamic acid)
- Bilopac, Bilopaque, Lumopaque, Tyropaque (tyropanoate sodium)
- Bilimiro, Bilimiron, Oravue, Videobil (iopronic acid)

Oily and fat-soluble contrast agents (water-insoluble agents)

- Ethiodol (ethyl diiodostearate/ethyl monoiodostearate)
- Dinonil (propyl iodide)
- Lipiodol (iodinated poppy-seed oil)

Gadolinium-based magnetic resonance imaging (MRI) agents

- Dotarem (gadoterate meglumine)
- Euvist (gadovetic acid)
- Gadovist (gadobutrol)
- Magnevist (gadopentetate dimeglumine)
- Multihance (gadobenate dimeglumine)
- Omniscan (gadodiamide)
- ProHance (gadoteridol)
- OptaMark (gadoversetamide)

Radiological Procedures**Plain film radiography—Routine chest, abdomen, and skeletal studies****Contrast studies**

Barium studies—Esophagram, UGI examination, SBFT, BE, and other specialized GI tract examinations

Water-insoluble contrast studies—Lymphangiography, and formerly, bronchography and myelography

Gallbladder studies—Abdominal ultrasound, oral cholecystography, intravenous cholangiography

Studies using water-soluble contrast agents—Excretory urography (IVP), venography, arteriography, contrast-enhanced CT and MRI, arthrography, hysternalpangiography, and myelography

Cross-sectional imaging studies

Ultrasound examinations

CT studies

MRI studies

Data are from Mitchell, D. G.: MRI Principles. Philadelphia, W. B. Saunders, 1999; Franken, E. A., Jr.: Proceedings of the Contrast Media Research Symposium, Kyoto, Japan, May 18-22, 1997. Acad. Radiol. 5:S1, 1998; Kutzberg, R. W.: Urography into the 21st century: New contrast media, renal handling, imaging.

In general, high or moderate osmolality and high viscosity are the hallmarks of all iodinated contrast media. Because of this, considerable hemodynamic and subjective effects are caused by administration of these agents. Initially, water shifts rapidly from the interstitial and cellular spaces into the plasma after injection of an iodinated contrast agent. This is typically accompanied by vasodilatation, local pain and warmth, a metallic taste in the mouth, and flushing. Later, there is an osmotic diuresis as these agents are excreted by the kidneys.

All of the water-soluble iodinated contrast media are clear, colorless liquids with no visible precipitates. They are viscous and, when spilled, produce a somewhat sticky mess. Even though they are clear liquids, they are often called "dyes" when their administration is being explained to patients. The sodium salts are slightly less viscous than the meglumine salts. Contrast media viscosity can also be reduced by heating them to body temperature prior to administration.

The water-soluble iodinated contrast media have relatively small molecular sizes and low chemical reactivity with body fluids and tissues. Agents of this class include diatrizoate meglumine, diatrizoate sodium, ioctetamic acid, iopamide meglumine, iopanoic acid, iopronic acid, iothalamate sodium, ipodate sodium, and tyropanoate sodium. Their pharmaceutical characteristics are similar to those of extracellular tracers. They have low lipid solubility and distribute throughout the extracellular space. They do not penetrate significantly into the intracellular space. The water-soluble iodinated contrast agents are cleared from the body by glomerular filtration. They are neither reabsorbed nor secreted by the renal tubules. When renal function is compromised, these contrast agents are eliminated in part or totally through the liver and gut. The vicarious excretion occurs at a much slower rate than

elimination by normal glomerular filtration in a healthy person. The half-time for the renal clearance portion of a water-soluble contrast agent is 1 to 2 hours in a patient with normal renal function. The water-soluble organic iodides are the largest group of radiological contrast agents, and the importance of their clinical use is only approached by barium sulfate.

Iodipamide Meglumine

Iopanoic Acid

Iothalamate Sodium

Tyropanoate Sodium

Iopronic Acid

Iodate Sodium

On the other hand, there is a heterogeneous group of water-insoluble compounds of iodine that only rarely find use as radiological contrast agents. These compounds consist of ester derivatives of iodinated vegetable (poppy-seed) oils and iodinated pyridones such as propylidone (Table 13-2). In the case of iodized oils, unsaturated vegetable fatty acid moieties are iodinated by addition across double bonds and are then converted into various esters. Some water-insoluble aromatic iodides have also been used occasionally as radiological contrast agents. These substances are more resistant to breakdown from exposure to light and air, but like the iodized oils, they cannot be used intravascularly.

Propylidone

PARAMAGNETIC COMPOUNDS

MRI is a unique method of medical imaging (Fig. 13-12). When a patient is placed in a large, strong, uniform magnetic field, one can use smaller, well-directed gradient fields to selectively excite hydrogen nuclei (protons) in a selected small volume of the patient's body. The excitation is done by use of radiofrequency fields, and once the excitation fields are removed, the excited protons lose the energy they gained. They emit a weak, but detectable, radio wave, whose strength and manner of decay can be used to generate diagnostic medical images. The tesla (T) has been adopted as the official unit of magnetic field strength for the international system of units. The conventional unit, the gauss (G), is 10,000 times smaller. MRI is normally performed at 0.5 to 1.5 T.

The images produced by MRI are superficially similar to the cross-sectional images of the body produced by CT. MRI, however, has the added advantage of not using ionizing radiation, such as x-rays or γ -rays, and easily produces exquisite soft tissue images of the body in any desired plane (coronal, axial, sagittal, oblique, etc.). With MRI, image con-

trast agents have been introduced or proposed to provide selective imaging of various organs and tissues, such as the liver, the RE system, the lymphatic system, and the blood pool. For example, gadobenate dimeglumine (MultiHance) and gadoxetic acid (Eovist) accumulate in the interstitial space and the urine. They are eliminated by both the renal and hepatobiliary routes, and therefore, they can be used as selective hepatocyte and biliary excretion contrast agents.

Manganese (Mn^{2+}) is strongly paramagnetic, but it is toxic if used as a free ion. To make it safe for use in humans, various manganese complexes have been developed as MRI contrast agents. At this time, the only parenteral manganese compound used in humans is mangafodipir trisodium. This compound is delivered to tissues with active metabolism, such as the pancreas, renal cortex, GI tract, heart, and adrenal glands.

Specially designed parenteral particulate agents can be used to examine the RE system. One way to do this is to incorporate a paramagnetic material into a hollow structure composed of surrounding lipid layers. The size of these lipid complexes (liposomes) is then manipulated so that they will be selectively filtered by the RE system, producing MRI contrast enhancement of the liver, spleen, and lymph nodes, depending on the liposome size and other characteristics. Polysaccharide-coated superparamagnetic iron oxide particles (SPIO) can be specifically designed with useful properties. These contain a crystalline core composed of iron oxide complexes with ferrous (Fe^{2+}) and ferric (Fe^{3+}) ions. The core is coated with dextran or another large polysaccharide. Their size is between 1 and 10 μm , and their biological characteristics can be manipulated by changing their polysaccharide coating. Large particles accumulate in the liver and spleen, while smaller particles remain in the circulation longer and tend to aggregate in lymph nodes. Ferumoxides (Fendex or AMI-25), ferrixan (Resovist), and ferumoxtran (Combidex or AMI 227) are three examples of such agents. Because main MRI effect of the iron oxide particles is on T₂ images, they darken the tissue in which they accumulate.

Oral MRI contrast agents are being developed for improved visualization of the GI tract. One method of improving bowel visibility is to displace the bowel contents with air or liquids. Air is not widely used, because it requires intubation of the stomach or the rectum, and it has unpleasant aftereffects. Perfluorocarbon compounds have the same magnetic susceptibility as water and will displace bowel contents for improved imaging. They are, however, expensive and not widely used.

Clays, such as the formulation used in Kaopectate, superparamagnetic iron oxide particles (SPIOs), some natural foods or nutritional supplements, also may be used as gastrointestinal MRI contrast agents because of their distinct effects on the T₁ or T₂ relaxation times of bowel contents. Bananas and blueberries, for example, contain high amounts of manganese. Although all of these agents are potentially useful, they are generally reserved for special imaging situations. There are no generally accepted MRI contrast agents used for imaging the bowel contents. All of them have some type of disadvantage that limits their use, such as terrible taste, excessive cost, unpleasant aftereffects, or the production of excessive imaging artifacts on some imaging sequences. The most universally accepted bowel contrast agent is tap water. It gives the bowel a low signal intensity on T1

images and a high signal intensity on T2 images. Tap water is inexpensive, readily available, and readily accepted by patients. Unfortunately, its ability to image bowel contents and to contrast the bowel with surrounding organs and with pathological processes is not always good.

ULTRASOUND CONTRAST AGENTS

Diagnostic ultrasound imaging uses high-frequency sound waves from 1 to 12 MHz to produce cross-sectional images of the body. A small handheld transducer connected to a larger electronic box is used to scan the body part of interest (e.g., the abdomen), and the resultant images are displayed on a computer screen. They may be later printed on film or stored digitally. Various body tissues reflect the sound waves in characteristic fashion, and diagnostic ultrasound is similar to the sonar imaging used by aquatic mammals and submarines. Differing tissues (e.g., the liver and the right kidney) have different acoustic properties. At the interface between tissues with different acoustic properties, the sound waves are reflected back to the transducer and are displayed on the screen, showing the interface and the tissues at the interface. Unfortunately, gas-containing structures (lungs, bowel) and bones either absorb or scatter most of the sound waves and are not usually imaged satisfactorily by ultrasound. Solid organs (liver, spleen, kidneys), organs containing fluid (heart, gallbladder, urinary bladder), blood vessels, fatty tissue, and muscles, however, are usually amenable to diagnostic sonographic imaging.

Ultrasound finds widespread application in diagnostic radiology, obstetrics, gynecology, and cardiology because it produces diagnostic results comparable or even superior in some cases to other imaging techniques that require the use of ionizing radiation. Ultrasound machines are often portable and may be taken to the patient's bedside. Moreover, diagnostic ultrasound has no known harmful effects.

Contrast agents are not used for most diagnostic ultrasound examinations. Much research is being conducted, however, to develop safe, inexpensive ultrasound contrast agents that may be ingested orally or injected intravenously. Ultrasound relies on the detection of acoustic energy (sound waves) reflected at tissue interfaces within the body. Gases create prominent acoustic interfaces with body tissues and can be adapted as contrast agents. Microbubbles containing air or other gases introduced into the bloodstream may act as a contrast agent by increasing the ultrasound signal reflected from the vessel contents or from the structures fed by the vessels. Agents relying on microbubbles may be classified as (a) stabilized or encapsulated microbubbles, (b) polymer microballoons and gaseous liposomes, or (c) colloidal suspensions and emulsions. These agents allow visualization of small vessels, identification of tumor vascularity, improved contrast visualization of solid organs, and improved visualization of the heart chambers and vascular grafts and conduits and are generally very safe. They are designed so no large bubbles form in the body, and they have relatively short life spans and then break down and dissipate. The problems generally encountered with them are their instability during passage through the heart and lungs and their limited time of action. Research into ultrasound contrast agents is in its infancy and will no doubt produce useful products in the near future.

RADIOLOGICAL PROCEDURES

Modern radiology has many imaging procedures that use contrast agents (Table 13-2). Some of the more common procedures are discussed below and illustrated with examples to show the usefulness of contrast agents. Although it is traditional to think of radiological studies as using film, except in the case of CT or MRI, one should realize that the digital revolution has come to diagnostic imaging. Many traditional radiographic studies, such as chest radiology, no longer use traditional radiographic film. Instead, x-rays are used to "expose" an imaging plate instead of a piece of film. This imaging plate can create a digital signal if properly processed. The electronic signals from digital imaging plates are then used to create radiological images that are read from computer monitors instead of film view boxes. Thus, imaging studies can be stored, manipulated, and transported worldwide digitally over local area networks or over wide area networks. Diagnostic radiologists, however, perform the same type of studies and use the same contrast agents whether the studies are film based or computer based.

Intravenous Pyelography, Intravenous Urography, Excretory Urography, and Computed Tomography

The intravenous pyelogram (IVP) is one of the oldest and most fundamental diagnostic radiological studies using contrast material. It is a mainstay of genitourinary (GU) radiology and delineates the kidneys and the urinary tract (renal calices, pelvis, and ureters) as well as the bladder (Fig. 13-13). A more modern name and one that better describes the relevant physiology involved in the study is *excretory urography*. Nevertheless, the term *IVP* has been in common use for so long that it still is the name used most frequently. Excretory urography is based on the rapid renal clearance of water-soluble iodinated benzoic acid compounds (whether they are low-osmolar or high-osmolar agents) after they are injected intravenously. In normal individuals, the ionic and nonionic water-soluble iodinated contrast agents are all excreted by glomerular filtration.

Many body and head CT studies (Figs. 13-14 and 13-15) use intravenous contrast material to improve the quality of the study. The type of contrast material and their doses are similar to those in excretory urography except that higher volumes of contrast and a more rapid injection system are often used. The contrast material increases the relative contrast between space-occupying lesions (tumors, cysts, and

abscesses) and normal body tissues. It also frequently shows blood vessels to better advantage.

Arteriography and Venography

Angiography refers to the radiographic visualization of blood vessels by contrast injection directly into an artery (arteriography) (Fig. 13-16) or a vein (venography). There are many types of arteriograms, including those from cerebral angiography (visualization of head and neck vessels).

Figure 13-13 ■ IVP in an elderly patient. Note the contrast visualization of the kidneys (K), ureters (U), and bladder (B). The patient also has fixation screws in her right hip from past surgery to stabilize a hip fracture.

Figure 13-14 ■ CT scan of the upper abdomen in a middle-aged adult. The image is an axial view of the patient's upper abdomen viewed as if looking up from the patient's feet. The patient's right side is on the left side of the image. The liver (L), kidneys (K), and spleen (S) are partially visualized. There is a large cyst (C) in the spleen, with a calcified rim

coronary angiography (visualization of the coronary arteries), aortography (visualization of the abdominal or thoracic aorta), and peripheral arteriography (visualization of the major arteries of the upper and lower extremities).

Arteriography is widely practiced for diagnosing vessel

Figure 13-15 ■ Axial CT scan of the brain of a patient with an arteriovenous malformation (AVM), after injection of an intravenous iodinated contrast agent (arrow)

Figure 13-16 ■ Same patient as shown in Figure 13-15. A cerebral arteriogram was performed to delineate the vascular anatomy of the patient's AVM. In this case, a digital subtraction technique was used in which digital images obtained prior to injection of the contrast agent were subtracted from the contrast agent images by computer

narrowing or blockage, aneurysm formation, and sites of bleeding. The type of contrast used depends on the vessel being injected and the preferences of the physician performing the study. Venography, the contrast opacification of venous structures, is performed less commonly than arteriography. The main indication for venography is to diagnose deep venous thrombosis in the lower extremities, based on changes in ultrasound by a moving reflector (blood).

High-quality modern diagnostic ultrasonography coupled with Doppler imaging techniques has largely replaced venography in the workup of suspected deep venous thromboses. Sonography is easy to perform, is much safer than venography, and causes much less patient discomfort. Venography is still used in selected cases, particularly when sonography is equivocal or there is a past history of documented venous thrombosis that requires detailed evaluation of the venous anatomy.

Cholecystography and Cholangiography

Cholecystography refers to contrast visualization of the gallbladder. Modern gallbladder visualization and diagnosis rely mainly on abdominal ultrasonography or nuclear medicine and rarely use traditional radiological techniques.

Oral cholecystographic agents consist of analogues of 2,4,6-triiodinated alkylbenzoic acids. They have various substituents in the 1 and 3 positions and are absorbed orally, followed by hepatic excretion. Oral cholecystographic agents include iopanoic acid, iocetamic acid, sodium tyropanoate, and sodium ipodate. In general, these agents are bound to serum albumin and converted by the liver into water-soluble glucuronide conjugates. These conjugates are excreted in the bile and stored in the gallbladder, thus facilitating gallbladder visualization.

Iodipamide meglumine (Cholografin) is the main agent used for intravenous cholangiography. Under ideal circumstances, iodipamide meglumine produces excellent visualization of the intrahepatic and extrahepatic bile ducts as well as the gallbladder. Oral cholecystography generally produces better visualization of the gallbladder itself but poorer visualization of the bile ducts than intravenous cholangiography.

Myelography

Myelography involves injection of contrast material into the subarachnoid space, usually in the lower lumbar region, for visualization of the spinal cord, nerve roots, and subarachnoid space. It has been somewhat superseded by modern MRI and CT imaging of the spinal canal, and it can be performed by itself or in conjunction with a subsequent CT study of the spinal canal. Until the advent of the low-osmolar contrast agents, iophendylate (Pantopaque) was the standard agent used for myelography. It was first replaced by metrizamide, which has now been largely supplanted by iohexol and similar agents, which give improved image detail and have lower toxicity.

Great care must be taken when performing contrast injection into the subarachnoid space. Improper technique could lead to a devastating infection or spinal injury, and the use of the wrong contrast agent can also have devastating results such as convulsions and subsequent, severe arachnoid inflammation.

Hysterosalpingography

Hysterosalpingography refers to visualization of the uterine cavity and fallopian tubes (Fig. 13-17). Contrast material is injected into the uterus through the cervical canal to assess uterine anatomy and the patency of the fallopian tubes. Most practitioners use some type of water-soluble contrast material for hysterosalpingography, though in the past the use of oily agents such as Ethiodol was popular. One popular agent

Figure 13-17 ■ Normal hysterosalpingogram performed in a young woman as part of an infertility workup. The contrast material outlines the uterus (*U*) and has traveled through patent fallopian tubes to spill into her peritoneum (*arrows*).

(Salpix) consists of a water-soluble gel that is a 2:1 mixture of diatrizoate meglumine and iodipamide meglumine. Iohexol and other low-osmolar agents are also used for hysterosalpingography, and they may produce slightly lower incidence of abdominal pain and discomfort after the procedure.

Gastrointestinal Studies

Traditional GI tract studies have used various preparations of barium sulfate to opacify the hypopharynx and esophagus (barium swallow); the lower esophagus, stomach, and duodenum (upper gastrointestinal tract; UGI); the small bowel (small bowel follow-through; SBFT); and the colon (barium enema; BE) (Fig. 13-18). In the BE, the barium is administered per rectum as an enema, usually with the intention of visualizing the entirety of the colon and the terminal-most portion of the ileum. Gastrointestinal tract studies are used to diagnose peptic acid disease (ulcers), benign and malignant tumors, and such conditions as GER and inflammatory bowel conditions.

If there is a possibility of a GI tract perforation, a water-soluble agent is used in place of a barium sulfate preparation. If there is leakage of contrast from the GI tract into the peritoneum, retroperitoneum, or mediastinum, water-soluble agents are generally rapidly absorbed by these tissues with no untoward patient effects. Barium preparations are particulate and will not be easily cleared from these spaces. Barium mixed with feces may produce severe peritonitis and be life-threatening.

Oral contrast material is often used as part of an abdominal

Figure 13-18 ■ Results of a barium enema performed on an elderly man. Barium absorbs x-rays very well and has a white appearance that shows the rectum and sigmoid portions of the colon. In the rectum, a large tumor (*arrows*) encircles the rectum and narrows the barium column.

CT study to opacify the bowel. A relatively dilute barium sulfate mixture or a dilute solution of ionic contrast material mixed with a flavoring agent are commonly used.

Arthrography

Arthrography is radiographic visualization of the internal structure of a joint. The shoulder, hip, knee, and wrist are joints commonly visualized by arthrography, although the procedure may be applied to other joints, such as the elbow or ankle. Some forms of arthrography, especially knee arthrography, have been completely replaced by MRI studies. An arthrogram is obtained by injecting a small amount (1 to 10 mL) of water-soluble, usually low-osmolar, contrast material into the joint space. The contrast agent may be mixed with a local anesthetic to reduce patient discomfort, and air or carbon dioxide may also be injected to produce a double-contrast effect. In the latter case, the water-soluble contrast material outlines the surface of the joint, including the joint capsule and cartilage surfaces, whereas the gas produces a negative-contrast effect as it distends the joint space.

Adverse Reactions

Radiological contrast agents can be taken orally in large amounts, and some of them are injected intravascularly in gram amounts with no ill effects. Nevertheless, any radiological contrast material may produce an untoward patient reaction, even sudden death.³⁰⁻³³ Untoward patient events occur when contrast material is aspirated or when it leaks from the GI tract. Hypertonic ionic water-soluble contrast agents are potentially dangerous if aspirated into the tracheobronchial tree. They are very irritating and reportedly have caused pulmonary edema. Any contrast material that leaks out of the bowel into the abdomen, pelvis, or chest is potentially quite dangerous, especially barium sulfate. Barium sulfate is insoluble, and its particulate nature means it is poorly cleared from the mediastinum, peritoneum, and retroperitoneum. Water-soluble agents, on the other hand, are rapidly absorbed from the mediastinum, peritoneum, and retroperitoneum, almost as quickly as if they had been injected intravenously. In general, water-soluble agents that leak from the GI tract cause no significant problems beyond a transient inflammation.

The intravenous or intra-arterial injection of iodinated contrast material for pyelography, contrast-enhanced CT studies, and angiographic studies opens the door to a diverse assortment of contrast reactions, most of which are minor and easily treated. Minor reactions include arm pain, a feeling of general body warmth and discomfort, mild nausea and vomiting, a strong metallic taste in the mouth, and mild urticaria (hives). Minor reactions dissipate in a few minutes with patient reassurance and observation.

Intermediate or moderate reactions are those that require some form of therapy but are not life threatening. Depending on the contrast agent used and on how contrast reactions are defined in a given institution, moderate reactions occur in approximately 1% of contrast injections. They include difficulty breathing, severe hives, severe nausea and vomiting, mild hypotension, wheezing, and other similar reactions. Treatment ranges from administration of intravenous fluids to the use of intravenous diphenhydramine for hives. Epi-

nephrine may be administered, and atropine is used if there is a vasovagal reaction with hypotension and bradycardia.

Severe reactions are those that are life threatening. They include sudden cardiovascular collapse and death, as well as severe hypotension; severe shortness of breath, wheezing, or laryngoedema; loss of consciousness; massive hives and angioneurotic edema; ventricular cardiac arrhythmias; angina; and myocardial infarction. Their treatment depends on the patient's signs and symptoms and includes intravenous fluids, oxygen, various drugs (including epinephrine, diphenhydramine, and atropine), and possible cardiopulmonary resuscitation (CPR).

The incidence of adverse reactions to radiopharmaceuticals is estimated to be less than 0.006%. Most reactions are allergic and occur within minutes after intravenous injection. In the case of radiolabeled murine antibodies, an anaphylactic reaction may occur, although serious reactions of this type have not been reported.

Selected Products

Barium Sulfate. The many commercial preparations of barium sulfate differ in their density and their ability to coat the bowel wall. These characteristics are determined by the particle size of the barium suspension, its viscosity, and its pH, which in turn are determined by the addition of small amounts of flavoring agents, suspending agents, and so forth. These additives are the proprietary secret of the manufacturer and do improve the diagnostic properties of the barium colloidal suspension for GI radiological studies.

Barium sulfate preparations are used to study the esophagus, stomach, and duodenum as part of an esophagram or UGI series and are given orally. Most patients find the taste of these dense mixtures acceptable (they are usually given a strawberry or lemon flavor), but they dislike the heavy texture of the barium. Barium sulfate suspensions are also given orally to study the entire small bowel (SBFT) or rectally to examine the colon (BE) (Fig. 13-18).

Typical barium suspensions range from 30 to more than 120% weight/volume (w/v), and because they are colloidal suspensions, they cannot be given intravascularly; the colloidal particles would produce fatal pulmonary embolism. The barium suspensions used for UGI or BE studies are too dense to be used for gut opacification during CT studies of the abdomen, because they produce unacceptable radiographic artifacts. Instead, commercial barium preparations are diluted to 1 to 4% w/v.

Diatrizoate. Diatrizoate is classified as an ionic monomeric contrast agent and is available in the meglumine, sodium, or combination of meglumine and sodium salts of the fully substituted triiodobenzoic acid. It has a molecular weight of 614, and the organically bound iodine content is 62%. Its salts are used mainly for angiography and excretory urography. The diatrizoate meglumine (66%) and diatrizoate sodium (10%) combination may be used orally or rectally to delineate the GI tract. This preparation is indicated when the use of barium sulfate is potentially dangerous (i.e., whenever a suspected perforation of the GI tract exists), because water-soluble contrast agents are quickly absorbed through the peritoneal surface. The high osmolality prevents water absorption and leads to rapid transit through the GI tract.

Figure 13-19 ■ Lymphangiogram of a normal leg after Ethiodol administration.

The meglumine salt dilute solution (18% w/v) is used for cystography after sterile catheterization of the bladder.

Ethiodol. Ethiodol is a sterile preparation containing ethyl esters of the iodinated fatty acids of poppy-seed oil and it is used for lymphangiography. It contains 35 to 39% of organically bound iodine that has been added to the double bonds of the fatty acids. Because Ethiodol is an oily substance and not miscible with plasma, it cannot be administered intravascularly. For lymphangiography, it is injected into tiny lymphatics of the web space of the hand or foot. The lymphatics carry tiny globules of Ethiodol to regional lymph nodes, where they are partially filtered by the nodes and localized in them. The iodine in the Ethiodol makes the nodes sufficiently radiopaque to be visualized on plain film radiographs. A lymphangiogram typically is used to evaluate lymph nodes in the groin, pelvis, and abdomen in patients with Hodgkin's disease and sometimes other malignancies. A typical normal lymphangiogram of the lower leg is illustrated in Figure 13-19.

Iobitridol. Iobitridol is a low-osmolar nonionic monomeric contrast agent. It is similar to the other agents in its class and finds use in excretory urography, angiography, and CT.

Iocetamic Acid. Iocetamic acid is a high-osmolar ionic monomeric contrast agent and is used as an oral cholecystographic agent for the radiographic visualization of the biliary tract and gallbladder. It has a molecular weight of 614 and an organically bound iodine content of about 62%. A dose of 3.0 to 4.5 g is given orally 10 to 15 hours before radiographic examination, and about 60% of this dose is excreted in the urine within 48 hours. A typical radiograph of a gallbladder is illustrated in Figure 13-20.

Iohexol. Iohexol is a low-osmolar nonionic monomeric contrast agent. It finds widespread use in excretory urography, CT, myelography, and angiographic procedures.

Iodipamide Meglumine. Iodipamide meglumine is an ionic dimeric contrast agent and is given as the meglumine salt, which is highly water soluble. It has a molecular weight of 1,530 and an organically bound iodine content of 49.9%. Iodipamide meglumine is very strongly bound to serum albumin.

Figure 13-20 ■ Radiograph of a normal gallbladder after administration of iopanoic acid.

min and is excreted by the liver into the biliary system unmodified. Unfortunately, iodipamide meglumine produces a high incidence of adverse patient reactions, such as urticaria and hypotension, and intravenous cholangiography has generally been discontinued. Modern ultrafast helical (spiral) CT scanners, however, can produce exquisite high-contrast studies of the liver and biliary system, and these sophisticated CT scanning techniques have renewed interest in the use of intravenous cholangiography.

Iodixanol. Iodixanol is a low-osmolar nonionic *dimeric* contrast agent. It is designed for intravascular injection and is used for excretory urography, angiography, and CT.

Iopamidol. Iopamidol is a low-osmolar nonionic monomeric contrast agent. It has a molecular weight of 777 and an organically bound iodine content of 49%. Although the osmolality is much lower than that of the ionic contrast agents, the viscosity is very similar. It is used for a variety of angiographic procedures, excretory urography, arthrography, and oral and rectal visualization of the GI tract. It is available in solutions containing 30.6 to 75.5% iopamidol.

Iopanoic Acid. Iopanoic acid is an ionic monomeric contrast agent. It has a molecular weight of 571 and an organically bound iodine content of 66.7%. It is used as an oral cholecystographic agent for the radiographic visualization of the biliary tract and gallbladder. A dose of 3 g is given by mouth with ample water about 10 to 14 hours before radiographic examination. It frequently produces mild GI discomfort.

Iopromide. Iopromide is a low-osmolar nonionic monomeric contrast agent. It has a molecular weight of 791 and an organically bound iodine content of 48.12%. It is designed for intravascular injection.

Iotrol. Iotrol is a low-osmolar nonionic *dimeric* contrast agent. It has a molecular weight of 1,626 and contains six iodine atoms per particle in solution. It is designed for intravascular injection.

Ioversol. Ioversol is a low-osmolar nonionic monomeric contrast agent. It has a molecular weight of 807 and an iodine content of 47.2%. Its main uses are in angiography and excretory urography.

Ioxaglate. Ioxaglate is a *low-osmolal ionic dimeric* contrast agent that is formulated as a combined solution of its meglumine and sodium salts. It has a molecular weight of 1,269 and an organically bound iodine content of 60%. Ioxaglate is used in angiography, arthrography, urography, venography, and hysterosalpingography. This agent is not suitable for myelography.

Ioxilan. Ioxilan is a low-osmolar nonionic monomeric contrast agent. Like other agents in its class, it is mainly used by intravascular injection in excretory urography, angiography, and CT.

Metrizamide. Metrizamide is a low-osmolar nonionic monomeric contrast agent. It has a molecular weight of 789

Figure 13-21 ■ MRI of the brain of a 36-year-old patient with a single episode of acute weakness. **A.** T₁-weighted axial image without contrast agent taken 3 days later. **B.** T₁-weighted image after intravenous injection of gadopentetate dimeglumine, which has concentrated in the left frontal lobe (arrow). The patient was diagnosed as having a cerebrovascular accident. (Courtesy of Berlex Laboratories, Inc.)

and an organically bound iodine content of 48.2%. It is used mainly in the radiographic examination of the spinal cord and central nervous system (i.e., myelography, cisternography, and ventriculography). The most frequent adverse effects are headache, nausea, and vomiting. Metrizamide was the first commercially available nonionic contrast agent. On-site reconstitution of the lyophilized powder is necessary because of the instability of metrizamide in solution. It has largely been replaced in daily practice by the newer low-osmolar contrast agents.

MRI Agents. There are many types of MRI contrast agents. At the present time, only the extracellular gadolinium chelates have found widespread use. These agents, in general, are highly soluble in water and can be administered by intravenous injection. They are classified as ionic or non-ionic, and they are either linear or macrocyclic chelates. Gadolinium-based contrast agents are administered in a typical dose of 0.1 mmol/kg, which can be increased to a total dose of 0.3 mmol/kg for the nonionic agent gadoteridol in patients who have poorly enhancing tumors or equivocal scans. Figure 13-21 illustrates an MRI study of a brain before and after injection of gadopentetate dimeglumine.

Propylidone. Dionosil, a commercial preparation of propylidone, a pyridone ester, was once popular for use in bronchography. It consists of a white powder suspended in an oily medium and was used for bronchography and laryngography (examination of the larynx). Other methods of imaging, such as CT, ultrasonography, and MRI, as well as modern fiber optic bronchoscopy have largely replaced bronchography.

Tyropanoate Sodium. Tyropanoate sodium is a high-osmolar ionic monomeric contrast agent that is given by mouth for the radiographic visualization of the biliary tract and gallbladder. It has a molecular weight of 633 and an organically bound iodine content of 57.4%. A dose of 3.0 g is given with water 10 to 12 hours before radiographic examination. This agent is not recommended for children under 12 years of age.

Central Nervous System Depressants

EUGENE I. ISAACSON

The common denominator of the drug classes considered in this chapter is depression of neuronal activity in the central nervous system (CNS), that is, the brain and spinal cord. In most cases the brain is the intended target. In a few cases, as in skeletal muscle relaxants, the cord is also targeted.

The drug classes are the anxiolytics, sedative-hypnotics, general anesthetics, anticonvulsants, and antipsychotics. The primary clinical indication for anxiolytic drugs is in the treatment of the anxiety disorders, which are conditions characterized by excessive or inappropriate anxiety. Examples of these disorders are posttraumatic stress disorder, generalized anxiety disorder, panic attacks, social phobia, and obsessive-compulsive disorder. The major clinical indication for the sedative-hypnotic drugs is in the treatment of some of the insomnias, which are failures to get adequate sleep.

General anesthetic agents are used to produce unconsciousness and loss of perception to painful surgical procedures. Anticonvulsant drugs are used to prevent or lessen the sudden excessive electrical activity in brain neurons that is a characteristic of the epilepsies. Antipsychotics are used in the thought disorders (psychoses), most notably the schizophrenias.

The first four classes of drugs often have a number of structural features in common and likewise often share at least one mode of action, positive modulation of the action of γ -aminobutyric acid (GABA) at GABA_A receptors. Additionally, many anticonvulsants also have an overall bottle-stopper shape that has been associated with neuronal voltage-gated sodium channel block, leading to decreased neuronal excitation. Channel block of other inorganic cations, most notably Ca²⁺, may contribute significantly to overall action in some instances. Antipsychotics are grouped into typical and atypical categories. Both categories share a common feature, a dopamine-like structure, often hydrophobically substituted. This feature can be related to the most commonly cited action of these agents, competitive antagonism of dopamine (DA) at D₂ and D₃ receptors in the limbic system. In recombinant D₂ receptor cultures, antipsychotic drugs have been observed to act as inverse agonists. For inverse agonism to be a significant mode of action, there must be proof that there is a baseline level of dopaminergic activation in the limbic system. Preliminary indicators suggest that baseline activation will be found; so, inverse agonism is a clinical possibility.¹ The structures of present-day antipsychotics are not inconsistent with inverse antagonism of DA as a mode of antipsychotic action. A defective gating mechanism in the processing of incoming environmental stimuli by the limbic system appears to characterize schizophrenia. The resulting inability to distinguish relevant from irrelevant stimuli evokes the positive symptoms (e.g., illogical and disordered thought, delusions, and hallucinations).

The defective mechanism appears to result from excessive limbic D₂ and D₃ activation.

The fundamental differences between typical and atypical antipsychotics reportedly are that the atypical agents are (a) less prone to produce extrapyramidal symptoms (EPS), because they are less able to block striatal D₂ receptors vis-à-vis limbic D₂ and D₃ receptors, and (b) more active against negative symptoms (social withdrawal, apathy, anhedonia). These differences are examined in a greater detail under the heading, Antipsychotics.

The foregoing introductory condensation may be useful in organizing and clarifying major structural and biological activity relationships throughout this chapter. More details about, and some exceptions to, these generalizations are presented under the discussion headings that follow.

GENERAL ANESTHETICS

The classical inhalation anesthetics, the general anesthetic alcohols, the anesthetic phenol Diprivan, the barbiturates, the neurosteroids, and the benzodiazepines are positive modulators of the action of GABA on GABA_A receptors by binding to allosteric binding sites (different sites exist for each drug group listed).²⁻³ A unifying theory of anesthesia proposes that general anesthetics act by facilitation of GABA_A receptors to promote chloride ion conductance,² and at anesthetic concentrations, at least some of the agents (ethanol, phenobarbital) depress the function of ionotropic glutamate receptors (excitatory), which may contribute to the overall anesthetic effect in those cases.⁴

Lipid and protein components of neuronal cell membranes have long been implicated as the site(s) of action in the various theories of how the structurally diverse chemical agents produce general anesthesia. Implicating allosteric binding sites on GABA_A receptors as important in anesthesia does not mean that other proposed sites of action should be ignored. By their nature, many of the simple anesthetic agents could affect a broad range of neuronal components. Also, none of the existing theories of anesthesia is refuted. Inhibition of sodium ion channels by structurally disruptive hydrophobic binding to channel protein is considered likely by many investigators. Still, it is intriguing that the apolar sites of action implied by the Meyer-Overton relationship,⁵ theorized as long ago as Johnson and Eyring⁶ to be sites of a bioactive protein, might significantly be allosteric modulatory sites of the protein of GABA_A receptors.

Clinically, general anesthesia for surgery uses multiple drug regimens. Some drugs may be used to augment the general anesthetic agent (e.g., neuroleptics and opioid analgesics). Other drugs may add an action (e.g., the skeletal

muscle relaxants). Also, drugs such as anticholinergics may be used to decrease adverse effects. Consult a current medical textbook for the ways in which these agents are used together. Our purpose is to consider only the general anesthetic agent.

General anesthetic agents can be broadly categorized as those useful by the inhalation route and those useful by the intravenous (IV) route. These are dictated by the physical state of the agents.

Inhalation Anesthetics

The inhalation anesthetics in use are halothane, enflurane, isoflurane, methoxyflurane, sevoflurane, desflurane, and nitrous oxide. Older agents such as ethylene and cyclopropane are obsolete because of a fundamental chemical property—they are explosive and flammable when mixed with oxygen. This adds an unacceptable level of danger to the production of anesthesia.

Halothane, USP. Halothane, 2-bromo-2-chloro-1,1,1-trifluoroethane (Fluothane), $\text{CH}(\text{Cl})\text{CF}_3$, a volatile liquid-halogenated hydrocarbon (bp, 50°C), was introduced in 1956 and gained rapid acceptance, largely because of its nonflammability. Additionally, the drug has high potency and a relatively low blood/gas partition coefficient. Accordingly, induction of and recovery from anesthesia are relatively rapid. In actual practice, intravenous sodium thiopental is usually used to induce anesthesia.

Most of halothane is eliminated intact in the expired air. There is sufficient reactivity to oxidative processes, however, to allow up to 20% of the administered compound to undergo metabolism. The trifluoromethyl group is quite stable; the C–H bond, however, is destabilized and is the probable site of metabolic entry. Metabolites are chloride and bromide ions and trifluoroacetate. Additionally, loss of HF yields the olefin 1,1-difluoro-2-chloro-2-bromoethylene, which reacts with the SH group of glutathione.

A low incidence of hepatic necrosis is associated with halothane. This has greatly reduced its use. It is suggested that the olefin might lead to metabolites that produce an immunoreactive response.^{7,8} Halothane has a narrow margin of safety. Respiratory depression is notable, and mechanical ventilation and increased oxygen concentrations are often required. Opioids or nitrous oxide are often needed to obtain adequate surgical analgesia. Overall, halothane is not much used today.

Methoxyflurane, USP. Methoxyflurane, 2,2-dichloro-1,1-difluoroethyl methyl ether, $\text{CHCl}_2\text{CF}_2\text{-O-CH}_3$ (Penthane), is a volatile liquid (bp, 105°C). The agent does not have a high vapor pressure at room temperature, so concentrations in the inspired air are low. This, together with a large blood/gas partition coefficient, produces a slow induction of anesthesia, featuring an excitatory phase. Accordingly, induction may be made with intravenous sodium thiopental. The compound is very soluble in lipids; consequently, recovery is slow. The agent produces excellent analgesia and good muscle relaxation.

Methoxyflurane is as much as 70% metabolized. Apparently, all labile sites are attacked. Metabolites include dichloroacetate, difluoromethoxyacetate, oxalate, and fluoride

ions. The fluoride ion especially and oxalate are responsible for the renal damage the agent produces when used to produce deep anesthesia over prolonged periods. Because of the potential for renal damage, it has restricted application as an anesthetic.⁹ It is said to be safe when used by intermittent inhalation as an analgesic during labor.

Enflurane, USP. Enflurane, 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether, $\text{HF}_2\text{COCF}_2\text{-CHFCI}$ (Ethrane), is a volatile liquid with a vapor pressure at room temperature about three-fourths that of halothane and a blood/gas partition coefficient also about three-fourths that of halothane. Consequently, induction is relatively easy, although an ultra-short-acting barbiturate is generally used for this purpose. Enflurane is said to be relatively easy to work with and to have a relatively low frequency of adverse cardiovascular effects. Respiration is depressed, so mechanical ventilation and oxygen supplementation are used. At high doses in a small percentage of patients, tonic-clonic convulsive activity is seen. Accordingly, enflurane should not be used in patients with epileptic foci.

As much as 5% of administered drug is metabolized. Difluoromethoxydifluoroacetate and fluoride ion have been reported as metabolites. The fluoride concentration, however, is generally thought to lie within safe limits.¹⁰

Isoflurane, USP. Isoflurane, 1-chloro-2,2,2-trifluoroethyl difluoromethyl ether, $\text{F}_3\text{CC(H)ClOCF}_2$ (Forane), is a close structural relative of enflurane and shares many properties with it, although changes in the electroencephalogram (EEG) and tonic-clonic activity are not reported. It does differ considerably in extent of metabolism; only about 0.2% is metabolized.¹¹ Metabolites are fluoride ion and trifluoroacetate. Neither kidney nor liver damage has been reported for the drug.

Desflurane. Desflurane (Suprane), $\text{FC(H}_2\text{)-O-C(H)F-C(H)F}_2$, has an oil/gas partition coefficient about one-fifth and a blood/gas partition coefficient one-third that of isoflurane. Its physical properties confer pharmacokinetic properties claimed to be superior to those of isoflurane. Desflurane and isoflurane are metabolized to about the same extent.

Sevoflurane. Sevoflurane, $\text{FC(H}_2\text{)-O-CH(CF}_3\text{)}_2$, has an oil/gas partition coefficient about one-half that of isoflurane, and the blood/gas partition coefficient is about one-third that of isoflurane. Pharmacokinetically, it reportedly has the advantages of rapid uptake and rapid elimination. It is metabolized to about the same extent as enflurane.

Nitrous Oxide, USP. Nitrous oxide, nitrogen monoxide, N_2O , is a gas at room temperature and is supplied as a liquid under pressure in metal cylinders. It is a good analgesic, but such high concentrations are required in the inspired mixture (up to 80%) to achieve anesthesia that attendant dangers of hypoxia exist. Accordingly, it is rarely used as the sole anesthetic agent. It is often used in combination with other agents, permitting their use at lower concentrations. It has analgesic effects that have been reported to result from a general depressant effect on synaptic transmission of pain messages.¹² It is a positive modulator of GABA on GABA_A

receptors, which would constitute a basis for its general anesthetic action.³

Intravenous Anesthetics

The sodium salts of the ultra-short-acting barbiturates may be administered intravenously in aqueous solutions to induce anesthesia. Thereafter, the maintaining volatile anesthetic with or without nitrous oxide is used. Respiratory depression is marked with the barbiturates at anesthetic doses; consequently, these agents are not used to maintain surgical anesthesia. Unconsciousness is produced within seconds of intravenous injection, and the duration of action is about 30 minutes. The rapid onset of action is attributed to rapid partitioning from the blood, across the blood-brain barrier, into the sites of action in the brain. Thiobarbiturates (thiamylal, thiopental) have an exceptionally high lipid/water partition coefficient, which is considered to be the basis of this rapid partitioning. The very short duration of action is attributed to repartitioning from the brain into peripheral tissues—initially to well-perfused tissues and subsequently to body fat. Methohexital is not a thiobarbiturate, but its structure confers properties that produce an ultra-short action (see the discussion under the heading, Methohexital Sodium). The structures of the compounds are given in Table 14-1.

Methohexital Sodium. Methohexital, sodium-(±)-1-methyl-5-allyl-5-(1-methyl-2-pentynyl) barbiturate (Brevital Sodium), is an *N*-methyl barbiturate with a pK_a of 8.4, versus about 7.6 for the non-*N*-methylated compounds. This pK_a change increases the concentration of the lipid-soluble free acid form at physiological hydrogen ion concentrations. The compound also has extensive hydrophobic character (total of nine hydrocarbon carbons); consequently, the lipid/water partition coefficient of the free acid form is high. Finally, it has an accessible site of metabolic inactivation, the CH_2 α to the triple bond. Overall, the compound has the properties to rapidly penetrate the CNS after intravenous injection and then redistribute rapidly to other body sites and also undergo rapid metabolic inactivation.

Thiamylal Sodium. Thiamylal, sodium 5-allyl-5-(1-methylbutyl)-2-thiobarbiturate (Surital Sodium), is a highly hydrophobic thiobarbiturate that has structural features closely related to those of thiopental. It has biological properties similar to those of thiopental. Intravenous administration induces unconsciousness within seconds, and consciousness is regained within 30 minutes.

Thiopental Sodium, USP. Thiopental sodium, sodium 5-ethyl-5-(1-methylbutyl)-2-thiobarbiturate (Pentothal Sodium), is the most widely used ultra-short-acting anesthetic barbiturate. Additionally, the compound is the prototype for the ultra-short-acting barbiturates. Most discussions of how structure influences duration of action in this group of agents relate specifically to it. The compound's onset of action is about equal to the time required for it to travel to the brain from the site of administration. Consciousness is regained within 30 minutes.

Benzodiazepines. Benzodiazepines alone cannot produce surgical anesthesia. Some of the more CNS-depressant benzodiazepines (e.g., diazepam and midazolam), however, are used intravenously to induce anesthesia. Diazepam has a very high lipid/water partition coefficient and, consequently, is highly depotized and very long acting. So, it is usually not chosen for induction for short-term anesthetic procedures. Midazolam has a lower lipid/water partition coefficient, which improves pharmacokinetic properties. It has a marked amnesiac effect that is valued in this use. Its physical and biological properties make it a frequent choice for induction anesthesia. The sedative effect of these compounds can be reversed by flumazenil.

Etomidate. Etomidate (Amidate) contains a 4-carboxylic acid ester-substituted imidazole moiety, which is also present in a number of compounds that are structural variations of the triazolo and imidazolo benzodiazepines. It is a positive allosteric modulator of GABA_A receptors. Since it is a hydrophobically substituted imidazole, a side effect of

Thiopental sodium Pentothal Sodium	CH ₃ CH ₂ —	CH ₃ CH ₂ CH ₂ CH— CH ₃	H	S

the drug that can have serious clinical consequences is depression of steroidogenesis. The compound is a base, and water-soluble salts can be made for intravenous administration.

Propofol. Simple phenols are rarely seen among useful CNS depressants, possibly because of tissue destruction and general toxicity largely due to the phenolic hydroxy group. It is likely that the 2,6-isopropyl groups of propofol (Diprivan) favorably influence the biological properties of the hydroxyl group. Propofol is useful for induction and maintenance of anesthesia. It is not water soluble, so an emulsion is given intravenously. Penetration into the brain is rapid, as is redistribution to other tissues, characteristics of compounds with a high lipid/water partition coefficient. The drug binds allosterically to GABA_A receptors at a site different from the benzodiazepine site.²

Alphaxalone. Alphaxalone, 5 α -pregnane-3 α -ol, 11,20-dione, is a long-discontinued anesthetic, but it may be instructive. It was introduced into the clinic as a consequence of research begun after recognition of the anesthetic properties of cholesterol and then a number of 3-hydroxy steroidal metabolites. After the discontinuation of alphaxalone use, it was found that a number of such compounds, some endogenously produced, are positive allosteric modulators at GABA_A receptors. Negative allosteric modulating steroids are also known, and some steroids are positive or negative modulators, depending on their concentration. It is believed that modulation of GABA_A function may be a normal physiological role of such steroids. Collectively, they are called neurosteroids. Research in the area continues.

Ketamine Hydrochloride, USP. Ketamine, (\pm)-2-(*o*-chlorophenyl)-2-methylaminocyclohexanone hydrochloride (Ketalar), has a different mode of action from the other anesthetic agents in this review. Ketamine was designed as a structural relative of the medically discontinued agent phencyclidine (PCP) (see Chapter 15), with which it shares a number of biological properties. Blockage of glutamic acid *N*-methyl-D-aspartate (NMDA) receptors explains many of the actions of the two compounds. The incidence of hallucinations is much lower with ketamine than with phencyclidine. Ketamine produces a sense of dissociation from events being experienced, followed by anesthesia, analgesia, and sometimes amnesia. The anesthetic state produced by ketamine has also been described as cataleptic anesthesia. It is

also called *dissociative anesthesia*.² The prevalence of hallucinations and excitement is higher in adults than in children. The drug may be used as the sole agent (mainly for minor surgical procedures in children), or it can be used to induce anesthesia that is then maintained by one of the potent inhalation agents, or it and nitrous oxide may be used together for general anesthesia.

ANXIOLYTIC, SEDATIVE, AND HYPNOTIC AGENTS

The list of anxiolytic, sedative, and hypnotic drugs is a short one—benzodiazepines, barbiturates, and a miscellaneous group. In addition to the short list of agents reviewed, a number of drugs belonging to other pharmacological classes may possess one or more of the anxiolytic, sedative, and hypnotic properties. These classes include H₁-antihistamines, antiadrenergics, antipsychotics, and anticonvulsants as prominent examples. Additionally, other areas are being explored for sleep-promoting agents. Adenosine-2A receptor (A_{2A}) agonists and melatonin-2 receptor (MT₂) agonists are under study.¹¹ Both adenosine and melatonin are thought to be involved in natural mediation of sleep. Adenosine is considered a possible endogenous sleep-producing agent. Melatonin affects circadian rhythms and may be a weak sedative-hypnotic.

Linoleamide and 9,10-octadecenoamide have also been implicated recently as possible endogenous sleep-producing agents. They are positive modulators of GABA_A receptors.¹² Anandamide (and other endogenous cannabinoids) presumably do not bind to GABA_A receptors. Some of their roles in the CNS function are discussed in Chapter 15. Further work should clarify the exact role and importance in sleep of linoleamide and 9,10-octadecenoamide. As we review the agents classed as anxiolytics, sedatives, and hypnotics, note that these groups of CNS depressants have an especially close relationship with anticonvulsants. Strong evidence indicates that in many cases the neuronal effects associated with anxiolytic, sedative, and hypnotic effects, especially positive modulation of GABA_A receptors, also relate to anticonvulsant effects. In addition, other mechanisms of action, such as sodium channel blockade and calcium T channel blockade, may predominate among anticonvulsants; so, it is appropriate to discuss them separately.

Benzodiazepines and Related Compounds

Benzodiazepines and benzodiazepine-like drugs bind to a benzodiazepine recognition site, one of several allosteric sites that modulate the effect of GABA binding to GABA_A receptors.^{2,3,15} The GABA_A receptor is a ligand-gated chloride ion channel. It is a protein anchored in the cell mem-

brane and is pentameric, as are other ligand-gated ion channels. The five polypeptide subunits that together make up its structure come from the subunit families α , β , δ , ϵ , π , ρ , and θ . There are six isoforms of the α polypeptide (α_1 to α_6), four of the β with two splice variants, and three of the γ with two variants. Presently, one form of each of the others is known. Each subunit has an extracellular N-terminal domain, then three membrane-spanning domains, an intracellular loop, a fourth membrane-spanning domain, and an extracellular C terminus.

At least 16 different GABA_A receptors have so far been identified in rodent brain. The subunit composition of the receptors has great bearing on the response to benzodiazepines and other ligands. Most receptors consist of α , β , and γ combinations. Of these, α_1 , β_2 , and γ_2 are most common. Other highly expressed combinations are α_2 , β_2 , γ_2 and α_2 , β_3 , γ_2 .

The benzodiazepine recognition site is in the extracellular N-terminus of the α_1 , α_2 , α_3 , and α_5 subunits. GABA_A receptors with α_4 or α_6 subunits do not respond to benzodiazepines. α_3 and α_6 subunits have an arginine residue replacing histidine at position 101 of the extracellular N-terminal domain: α_1 subunits are required for sedative and hypnotic effects, and to a lesser extent, anticonvulsant effects of benzodiazepines; α_2 subunits are required for the anxiolytic effects of benzodiazepines; and α_3 and α_5 subunits may be involved in other actions of benzodiazepines. If an arginine replaces histidine in an α_2 subunit of the GABA receptor, the receptor is resistant to the sedative effects of benzodiazepines and zolpidem. If arginine replaces histidine in an α_2 subunit, the anxiolytic effect of benzodiazepines is lost.¹⁵

Although the binding domain of the benzodiazepines is considered to be in the N-terminal domain of the α unit, the benzodiazepines also require a γ_2 subunit for most positive allosteric effects. Amino acid residues in the α_1 subunit that have been identified as key binding sites within the benzodiazepine binding site are Tyr 161, Thr 162, Gly 200, Ser 204, Thr 206, and Val 211. In the γ subunit, Phe 77 has been identified.¹⁴⁻²¹

A number of compounds that have structural characteristics broadly related to the benzodiazepines, including neuroactive flavanoids, imidazopyridines, and pyrazolopyrimidines, can act as positive modulators at the benzodiazepine recognition site on one or more of the GABA_A receptor subtypes. Compounds may produce all the characteristic actions of benzodiazepines or be selective, as are, for example, anxiolytic flavanoids or the sedative-hypnotics zolpidem and zalephon.

Most classical benzodiazepines are positive modulators, many probably nonselectively for all the receptor subtypes that respond to benzodiazepines. Some have been claimed to be relatively selective as anticonvulsants. Such drugs, with only part of the spectrum of all possible benzodiazepine actions have been called *partial agonists*. This term can mislead, since in this use, it applies to drugs that do not have all the possible qualitative actions, rather than being at a point on a single activity scale between an agonist and an antagonist.

Some β -carbolines are negative modulators at benzodiazepine modulatory sites. Additionally, there are GABA_A receptor subtypes that recognize benzodiazepines but not β -carbolines and subtypes that recognize β -carbolines but not

benzodiazepines. Negative modulators diminish the positive effect of GABA on chloride flux. In whole animals, they appear to increase anxiety, produce panic attacks, and improve memory. β -Carbolines were once suspected of being the endogenous modulators of benzodiazepine binding sites. Now, this is not considered likely. Many experts in the field now think that there is no endogenous ligand for the benzodiazepine recognition site (allosteric modulatory site).

There are also compounds that can occupy benzodiazepine modulatory sites, have no effect on chloride flux themselves, and block positive and negative modulators. They have been called variously *antagonists*, *zero modulators*, and *neutralizing allosteric modulators*. One such compound, flumazenil, is used clinically to counteract the sedative effect of benzodiazepines.

As noted under the heading of general anesthetics, there are other allosteric sites that recognize respectively, neurosteroids, barbiturates, inhalation anesthetics, alcohols and the phenol Diprivan (separate sites). The convulsants picrotoxin and pentylenetetrazole have definite binding sites on GABA receptors.

The field of benzodiazepines was opened with the synthesis of chlordiazepoxide by Sternbach and the discovery of its unique pharmacological properties by Randall.²² Chlordiazepoxide (see the discussion of individual compounds) is a 2-amino benzodiazepine, and other amino compounds have been synthesized. When it was discovered that chlordiazepoxide is rapidly metabolized to a series of active benzodiazepine-2-ones (see the general scheme of metabolic relationships), however, emphasis shifted to the synthesis and testing of the latter group. Empirical structure-activity relationships (SARs) for antianxiety activity have been tabulated for this group (analogous statements apply for the older 2-amino group).^{22, 23} The following general structure helps to visualize them.

An electronegative substituent at position 7 is required for activity, and the more electronegative it is, the higher the activity. Positions 6, 8, and 9 should not be substituted. A phenyl at position 5 promotes activity. If this phenyl group is *ortho* (2') or *diortho* (2',6') substituted with electron-attracting substituents, activity is increased. On the other hand,

para substitution decreases activity greatly. Saturation of the 4,5 double bond or a shift of it to the 3,4 position decreases activity. Alkyl substitution at the 3 position decreases activity; substitution with a hydroxy does not. The presence or absence of the 3-hydroxyl is important pharmacokinetically. Compounds without the hydroxyl are nonpolar, have long half-lives, and undergo hepatic oxidation. Compounds with the hydroxyl are much more polar and are readily converted to the excreted glucuronide (see the overall metabolic relationship scheme). The 2-carbonyl function is optimal for activity, as is the nitrogen atom at position 1. The N-substituent should be small.

Additional research yielded compounds with a fused triazolo ring, represented by triazolam and alprazolam. Midazolam, with a fused imidazolo ring, also followed. These compounds are metabolized mainly by hydroxylation of the methyl substituent on the triazolo or imidazolo ring. The resulting hydroxy compound is active but is quickly conjugated. The compounds are also metabolized by 3-hydroxylation of the benzodiazepine ring. Interestingly, an electron-attracting group at position 7 is not required for activity in these compounds.

The metabolism of benzodiazepines has received much study.^{24, 25} Some of the major metabolic relationships are shown in the scheme below.

The benzodiazepines generally are well absorbed from the gastrointestinal (GI) tract, although the more polar compounds (e.g., those with a hydroxyl at the 3-position) tend to be absorbed more slowly than the more nonpolar compounds.

The drugs tend to be highly bound to plasma proteins; in general, the more nonpolar the drug, the greater the binding. They are also very effectively distributed to the brain. Generally, the more nonpolar the compound, the greater the distribution to the brain, at least initially. When diazepam is used as an anesthetic, it initially distributes to the brain and then redistributes to sites outside the brain.

Compounds without the 3-hydroxyl group usually have long half-lives and undergo conversion to the 3-hydroxy compounds by hepatic oxidation. Compounds with the 3-hydroxyl group have short half-lives because of rapid conjugation to the 3-glucuronide, which undergoes urinary excretion.

In addition to lower abuse potential, and a much greater margin of safety than the barbiturates, the drugs have fewer drug interactions. Especially noteworthy is that they do not promote the metabolism of other drugs.

Chlordiazepoxide Hydrochloride, USP. Chlordiazepoxide hydrochloride, 7-chloro-2-(methylamino)-5-phenyl-3H-1,4-benzodiazepine 4-oxide monohydrochloride (Librium), is absorbed well from the GI tract. Peak plasma levels are reached in 2 to 4 hours. N-demethylation and hydrolysis of the condensed amidino group are rapid and extensive, producing demoxepam as a major metabolite. Demoxepam, in turn, is converted principally to nordazepam. Nordazepam, in turn, is converted principally to oxepam, which undergoes conjugation to the excreted glucuronide. Other routes of metabolism can occur, for example, opening of the seven-membered ring by hydrolysis of the lactam group.

Chlordiazepoxide Hydrochloride

Diazepam, USP. Diazepam, 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzodiazepin-2-one (Valium), was

the first member of the benzodiazpin-2-one group to be introduced. It is very nonpolar and is rapidly absorbed. Diazepam is metabolized by N-demethylation to nordazepam, which is then metabolized according to the general scheme. It is widely used for several anxiety states and has an additional wide range of uses (e.g., as an anticonvulsant, a premedication in anesthesiology, and in various spastic disorders).

Oxazepam, USP. Oxazepam, 7-chloro-1,3-dihydro-3-hydroxy-5-phenyl-2H-1,4-benzodiazepin-2-one (Serax), can be considered a prototype for the 3-hydroxy compounds. For the stereochemistry of this and other 3-hydroxy compounds, see the chapter dealing with metabolism. It is much more polar than diazepam, for example. Metabolism is relatively uncomplicated, and the duration of action is short.

Clorazepate Dipotassium. Clorazepate dipotassium, 7-chloro-2,3-dihydro-2-oxo-5-phenyl-1H-1,4-benzodiazepine-3-carboxylic acid dipotassium salt monohydrate (Tranxene), can be considered a prodrug. Inactive itself, it undergoes rapid loss of water and then decarboxylation to nordazepam, which has a long half-life and undergoes hepatic conversion to oxazepam. Despite the polar character of the drug as administered, because it is quickly converted in the GI tract to a nonpolar compound, it has an overall long half-life.

Prazepam, USP. Prazepam, 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one (Vertran), has a long overall half-life. Extensive N-dealkyl-

ation occurs to yield nordazepam. 3-Hydroxylation of both prazepam and nordazepam occurs.

Lorazepam, USP. Lorazepam, 7-chloro-5-(2-chlorophenyl)-3-dihydro-3-hydroxy-2H-1,4-benzodiazepin-2-one (Ativan), can be recognized as the 2'-chloro substituted analogue of oxazepam. In keeping with overall SARs, the 2'-chloro substituent increases activity. Metabolism is relatively rapid and uncomplicated because of the 3-hydroxyl group in the compound.

Halazepam, USP. Halazepam, 7-chloro-1,3-dihydro-5-phenyl-1-(2,2,2-trifluoroethyl)-2H-1,4-benzodiazepin-2-one (Paxipam), is well absorbed. It is active and present in plasma, but much of its activity is due to the major metabolites nordazepam and oxazepam. The drug is marketed as an anxiolytic.

Temazepam. Temazepam, 7-chloro-1,3-dihydro-3-hydroxy-1-methyl-5-phenyl-2H-1,4-benzodiazepin-2-one (Restoril), also occurs as a minor metabolite of diazepam. It can be visualized as N-methyl oxazepam. A small amount of N-demethylation occurs. Metabolism proceeds mainly through conjugation of the 3-hydroxyl group, however. The duration of action is short. It is marketed as a hypnotic said to have little or no residual effect.

Temazepam

Flurazepam Hydrochloride, USP. Flurazepam hydrochloride, 7-chloro-1-[2-(diethylamino)ethyl]-5-(2-fluorophenyl)-1,3-dihydro-2H-1,4-benzodiazepin-2-one dihydrochloride (Dalmane), is notable as a benzodiazepine marketed almost exclusively for use in insomnia. Metabolism of the dialkyl aminoalkyl side chain is extensive. A major metabolite is *N*¹-dealkyl flurazepam, which has a very long half-life and persists for several days after administration.

Flurazepam Hydrochloride

Alprazolam, USP. Alprazolam, 8-chloro-1-methyl-6-phenyl-4*H*-s-triazolo[4,3-*a*][1,4]benzodiazepine (Xanax), is rapidly absorbed from the GI tract. Protein binding is lower (~70%) than with most benzodiazepines. Oxidative metabolism of the methyl group to the methyl alcohol followed by conjugation is rapid; consequently, the duration of action is short. The drug is a highly potent anxiolytic on a milligram basis.

Alprazolam

Triazolam, USP. Triazolam, 8-chloro-6-(*o*-chlorophenyl)-1-methyl-4*H*-s-triazolo[4,3-*a*][1,4]benzodiazepine (Halcion), has all of the characteristic benzodiazepine pharmacological actions. It is marketed as a sedative-hypnotic drug said to impair little, if any, daytime function. It is rapidly metabolized to the 1-methyl alcohol, which is then conjugated and excreted.

Triazolam

Midazolam. This drug is used intravenously as a sedative-hypnotic and as an induction anesthetic. Further information can be found in the section on anesthetics.

Midazolam

Quazepam. Quazepam (Doral) and its active metabolites reportedly are relatively selective for the benzodiazepine modulatory site on (ω -1) type 1 GABA_A receptors (i.e., receptors with an α_1 subunit) and are hypnotic agents. Quazepam is metabolized by oxidation to the 2-oxo compound and then *N*-dealkylation. Both metabolites are active, the first reportedly is the more potent and selective. Thereafter, 3-hydroxylation and glucuronidation occur.

Zolpidem. Zolpidem (Ambien) has attracted attention as a relatively selective positive modulator at the ω -1 benzodiazepine binding site. As such, it is a hypnotic. It is said to be relatively fast in action and to produce no active metabolites. Metabolism of the aryl methyl groups would be expected, however, the resulting compounds would not be long-lived.

Zaleplon. Zaleplon (Sonata) is another ω -1 sedative hypnotic with overall biological properties resembling those of zolpidem. It may have a more rapid onset and termination of action than zolpidem.

Metabolism involves the aldehyde dehydrogenase and the cytochrome system.

Barbiturates

The barbiturates appear to exert most of their characteristic CNS effects by binding to an allosteric recognition site on GABA_A receptors that positively modulates the effect of the GABA_A-GABA combination. In addition, by attaching to the barbiturate modulatory site, barbiturates can increase chloride ion flux without GABA attaching to its receptor site on GABA_A. This has been termed a *GABA mimetic effect*. It is thought to be related to the profound CNS depression that barbiturates can produce.

The first historical sedative-hypnotic barbiturate, 5,5-diethylbarbituric acid, was introduced in 1903. With time, many members were added, and the barbiturates dominated the sedative-hypnotic field until the advent of the benzodiazepines. The benzodiazepines are much safer to use and have replaced the barbiturates as the most broadly useful agents in sedative-hypnotic applications.

The barbiturates are 5,5-disubstituted barbituric acids. The following scheme shows how the 5,5-dialkyl compounds are synthesized. Substitution of thiourea for urea in the reaction produces the 2-thiobarbiturates, useful as induction anesthetics.

Consideration of the structure of 5,5-disubstituted barbituric acids reveals their acidic character. Those without methyl substituents on the nitrogen have pK_{a} s of about 7.6; those with a methyl substituent have pK_{a} s of about 8.4. The free acids have poor water solubility and good lipid solubility (the latter largely a function of the two hydrocarbon substituents on the 5 position, although in the 2-thiobarbiturates the sulfur atom increases lipid solubility).

Sodium salts of the barbiturates are readily prepared and are water soluble. Their aqueous solutions generate an alkaline pH. A classic incompatibility is the addition of an agent with an acidic pH in solution, which results in formation and precipitation of the free water-insoluble disubstituted barbituric acid. Sodium salts of barbiturates in aqueous solution decompose at varying rates by base-catalyzed hydrolysis, generating ring-opened salts of carboxylic acids.

The names of many barbiturates end in *al* (e.g., phenobarbital), appearing to denote an aldehydic compound, because chloral hydrate was widely recognized as a sedative-hypnotic agent when the first barbiturates were introduced. Hence, the suffix was an effort to indicate a therapeutic, not a chemical, class.

Structure-Activity Relationships

Extensive synthesis and testing of the barbiturates over a long time span have produced well-defined SARs, which have been summarized.²⁶

Both hydrogen atoms at the 5 position of barbituric acid must be replaced. This may be because if one hydrogen is available at position 5, tautomerization to a highly acidic trihydroxypyrimidine ($\text{pK}_{\text{a}} \sim 4$) can occur. Consequently, the compound is largely in the anionic form at physiological pHs, with little nonionic lipid-soluble compound available to cross the blood-brain barrier.

Beginning with lower alkyls, there is an increase in onset and a decrease in duration of action with increasing hydrocarbon content up to about seven to nine total carbon atoms substituted on the 5 position. Lipophilicity and an ability to penetrate the brain in the first case and an ability to penetrate liver microsomes in the second may be involved. Also, for more hydrophobic compounds, partitioning out of the brain to other sites can be involved in the second instance. There is an inverse correlation between the total number of carbon atoms substituted on the 5 position and the duration of action, which is even better when the character of these substituents is taken into account, for example, the relatively polar character of a phenyl substituent (approximates a three- to four-carbon aliphatic chain), branching of alkyls, presence of an isolated double or triple bond, and so on. Additionally, these groups can influence the ease of oxidative metabolism by effects on bond strengths as well as by influencing partitioning.

Metabolism of the barbiturates is discussed in Chapter 4. Suffice it to say that increasing the lipid/water partition coefficient generally increases the rate of metabolism, except for compounds with an extremely high lipid/water partition coefficient (e.g., thiopental), which tend to depotize and are thus relatively unavailable for metabolism. Metabolism generally follows an ultimate (ω) or penultimate ($\omega-1$) oxidation pattern. Ring-opening reactions are usually minor. N-methylation decreases duration of action, in large part, probably,

by increasing the concentration of the lipid-soluble free barbituric acid. 2-Thiobarbiturates have a very short duration of action because the lipid/water partition coefficient is extremely high, promoting depotization. Barbiturates find use as sedatives, as hypnotics, for induction of anesthesia, and as anticonvulsants. Absorption from the GI tract is good. Binding to blood proteins is substantial. Compounds with low lipid/water partition coefficients may be excreted intact in the urine. Those with higher lipid/water partition coefficients are excreted after metabolism to polar metabolites.

Some of the more frequently used barbiturates are described briefly in the following sections. For the structures, the usual dosages required to produce sedation and hypnosis, the times of onset, and the duration of action, see Table 14-2.

BARBITURATES WITH A LONG DURATION OF ACTION (OVER 6 HOURS)

Barbital. Barbital, 5,5-diethylbarbituric acid, although discontinued as a sedative-hypnotic, is interesting because of the biological consequence of its low lipid/water partition coefficient. It is slowly eliminated, mostly intact, by the kidney.

Phenobarbital, USP. Phenobarbital, 5-ethyl-5-phenylbarbituric acid (Luminal), is a long-acting sedative and hypnotic. It is also a valuable anticonvulsant, especially in generalized tonic-clonic and partial seizures (see the discussion on anticonvulsants). Metabolism to the *p*-hydroxy compound followed by glucuronidation accounts for about 90% of a dose.

Mephobarbital, USP. Mephobarbital, 3-methyl-5-ethyl-5-phenylbarbituric acid (Metharbital), is metabolically N-dealkylated to phenobarbital, which many consider to account for almost all of the activity. Its principal use is as an anticonvulsant.

BARBITURATES WITH AN INTERMEDIATE DURATION OF ACTION (3 TO 6 HOURS)

Barbiturates with an intermediate duration of action are used principally as sedative-hypnotics. They include **Amobarbital, USP**, 5-ethyl-5-isopentylbarbituric acid (Amytal), and its water-soluble sodium salt, **Amobarbital Sodium, USP**, 5-allyl-5-isopropylbarbituric acid (aprobital, Aluratek); **Butabarbital Sodium, USP**, the water-soluble sodium salt of 5-*sec*-butyl-5-ethylbarbituric acid (Butisol Sodium).

TABLE 14-2 Barbiturates Used as Sedatives and Hypnotics

General Structure

Generic Name Proprietary Name	Substituents			Sedative Dose (mg)	Hypnotic Dose (mg)	Usual Onset of Action (min)
	R ₅	R' ₅	R ₁			
A. Long Duration of Action (more than 6 hours)						
Mephobarbital, USP <i>Mobaral</i>	C ₂ H ₅		CH ₃	30-100 ^a	100	30-60
Phenobarbital, USP <i>Luminal</i>	C ₂ H ₅		H	15-30 ^a	100	20-40
B. Intermediate Duration of Action (3 to 6 hours)						
Amobarbital, USP <i>Amytal</i>	CH ₃ CH ₂ —	(CH ₃) ₂ CHCH ₂ CH ₂ —	H	20-40	100	20-30
Butabarbital, Sodium, USP <i>Butisol Sodium</i>	CH ₃ CH ₂ —		H	15-30	100	20-30
C. Short Duration of Action (less than 3 hours)						
Pentobarbital, Sodium, USP <i>Nembutal Sodium</i>	CH ₃ CH ₂ —		H	30	100	20-30
Secobarbital, USP <i>Seconal</i>	CH ₂ =CHCH ₂ —		H	15-30	100	20-30

^aDaytime sedative and anticonvulsant

BARBITURATES WITH A SHORT DURATION OF ACTION (UNDER 3 HOURS)

Barbiturates that have substituents in the 5 position promoting more rapid metabolism (e.g., by increasing the lipid/water partition coefficient) than the intermediate group include **Pentobarbital-Sodium, USP**, sodium 5-ethyl-5-(1-methylbutyl)barbiturate (Nembutal); **Secobarbital, USP**, 5-allyl-5-(1-methylbutyl)barbituric acid (Seconal); and the sodium salt sodium secobarbital.

Barbiturates with an ultra-short duration of action are discussed under anesthetic agents.

Miscellaneous Sedative-Hypnotics

A wide range of chemical structures (e.g., imides, amides, alcohols) can produce sedation and hypnosis resembling those produced by the barbiturates. Despite this apparent structural diversity, the compounds have generally similar structural characteristics and chemical properties: a hydrophobic portion and a semipolar portion that can participate in H bonding. In some cases, modes of action are undetermined. As a working hypothesis, most of the agents can be envisioned to act by mechanisms similar to those proposed for barbiturates and alcohols.

AMIDES AND IMIDES

Glutethimide, USP. Glutethimide, 2-ethyl-2-phenylglutaramide (Doriden), has many structural relationships with the barbiturates and resembles them in many respects biologically. It is an effective sedative-hypnotic. It is very hydrophobic, and absorption from the GI tract is somewhat erratic. Metabolism is extensive, and the drug is an enzyme inducer. In the therapeutic dosage range, adverse effects tend to be infrequent. Toxic effects in overdose are as severe as, and possibly more troublesome than, those of the barbiturates.

**Alcohols and Their Carbamate Derivatives**

The very simple alcohol ethanol has a long history of use as a sedative and hypnotic. Its modes of action were described under the anesthetic heading and are said to apply to other alcohols. It is widely used in self-medication as a sedative-hypnotic. Because this use has so many hazards, it is seldom a preferred agent medically.

As the homologous series of normal alcohols is ascended from ethanol, CNS depressant potency increases up to eight carbon atoms, with activity decreasing thereafter (the Meyer-Overton parabola, Chapter 2). Branching of the alkyl chain increases depressant activity and, in an isometric series, the order of potency is tertiary > secondary > primary. In part,

this may be because tertiary and secondary alcohols are not metabolized by oxidation to the corresponding carboxylic acids. Replacement of a hydrogen atom in the alkyl group by a halogen increases the alkyl portion and, accordingly, for the lower-molecular-weight compounds, increases potency. Carbamylation of alcohols generally increases depressant potency. Carbamate groups are generally much more resistant to metabolic inactivation than hydroxyl functions. Most of the alcohols and carbamates have been superseded as sedative-hypnotics. A number of difunctional compounds (e.g. diol carbamates) have depressant action on the cord in addition to the brain and are retained principally for their skeletal muscle relaxant properties.

Ethchlorvynol, USP. Ethchlorvynol, 1-chloro-3-ethyl-1-penten-4-yn-3-ol (Placidyl), is a sedative-hypnotic with a rapid onset and short duration of action. Metabolism, probably involving the hydroxyl group, accounts for about 90% of a dose. Acute overdose shares several features with barbiturate overdose.

Meprobamate, USP. Meprobamate, 2-methyl-2-propyltrimethylene dicarbamate, 2-methyl-2-propyl-1,3-propanediol dicarbamate (Equanil, Miltown), is officially indicated as an antianxiety agent. It is also a sedative-hypnotic agent. It has a number of overall pharmacological properties resembling those of benzodiazepines and barbiturates. The mechanism of action underlying anxiolytic effects is unknown but may involve effects on conductivity in specific brain areas.²⁷ It does not appear to act through effects on GABAergic systems. The drug is effective against absence seizures and may worsen generalized tonic-clonic seizures.

Meprobamate is also a centrally acting skeletal muscle relaxant. The agents in this group find use in a number of conditions, such as strains and sprains that may produce acute muscle spasm. They have interneuronal blocking properties at the level of the spinal cord, which are said to be partly responsible for skeletal muscle relaxation.²⁷ Also, the general CNS depressant properties they possess may contribute to, or be mainly responsible for, the skeletal muscle relaxant activity. Dihydric compounds and their carbamate (urethane) derivatives, as described above in the discussion of meprobamate, are prominent members of the group.

Chlorphenesin Carbamate. Chlorphenesin carbamate, 3-(*p*-chlorophenoxy)-1,2-propanediol 1-carbamate (Mao-

late), is the *p*-chloro substituted and 1-carbamate derivative of the lead compound in the development of this group of agents, mephensin.

Mephensin is weakly active and short-lived because of facile metabolism of the primary hydroxyl group. Carbamylation of this group increases activity. *p*-Chlorination increases the lipid/water partition coefficient and seals off the *para* position from hydroxylation.

Metabolism, still fairly rapid, involves glucuronidation of the secondary hydroxyl group. The biological half-life in humans is 3.5 hours.

Methocarbamol, USP. Methocarbamol, 3-(*o*-methoxyphenoxy)-1,2-propanediol 1-carbamate (Robaxin), is said to be more sustained in effect than mephensin. Likely sites for metabolic attack include the secondary hydroxyl group and the two ring positions opposite the ether functions. The dihydric parent compound, guaifenesin, is used as an expectorant.

Carisoprodol, USP. Carisoprodol, *N*-isopropyl-2-methyl-2-propyl-1,3-propanediol dicarbamate, 2-methyl-2-propyl-1,3-propanediol carbamate isopropylcarbamate (Soma), is the mono-*N*-isopropyl-substituted relative of meprobamate. The structure is given in the discussion of meprobamate. It is indicated in acute skeletomuscular conditions characterized by pain, stiffness, and spasm. As can be expected, a major side effect of the drug is drowsiness.

ALDEHYDES AND THEIR DERIVATIVES

For chemical reasons that are easily rationalized, few aldehydes are valuable hypnotic drugs. The aldehyde in use, chloral (as the hydrate), is thought to act principally through a metabolite, trichloroethanol. Acetaldehyde is used as the cyclic trimer derivative, paraldehyde, which could also be grouped as an ether.

Chloral Hydrate, USP. Chloral hydrate, trichloroacetaldehyde monohydrate, $CCl_3CH(OH)_2$ (Noctec), is an aldehyde hydrate stable enough to be isolated. The relative stability of this *gem*-diol is largely due to an unfavorable dipole-dipole repulsion between the trichloromethyl carbon and the carbonyl carbon present in the parent carbonyl compound.²⁸

Chloral hydrate is unstable in alkaline solutions, undergoing the last step of the haloform reaction to yield chloroform

and formate ion. In hydroalcoholic solutions, it forms the hemiacetal with ethanol. Whether or not this compound is the basis for the notorious and potentially lethal effect of the combination of ethanol and chloral hydrate (the "Mickey Finn") is controversial. Synergism between two different CNS depressants also could be involved. Additionally, ethanol, by increasing the concentration of NADH, enhances the reduction of chloral to the more active metabolite trichloroethanol, and chloral can inhibit the metabolism of alcohol because it inhibits alcohol dehydrogenase. Although it is suggested that chloral hydrate per se may act as a hypnotic,²⁹ chloral hydrate is very quickly converted to trichloroethanol, which is generally assumed to account for almost all of the hypnotic effect. It appears to have potent barbiturate-like binding to GABA_A receptors.

Triclofos Sodium. Triclofos sodium, 2,2,2-trichloroethanol dihydrogen phosphate monosodium salt (Triclos), is irritating to the GI mucosa. Its active metabolite, trichloroethanol, also has unpleasant GI effects when given orally. Triclofos is the nonirritating sodium salt of the phosphate ester of trichloroethanol and is readily converted to trichloroethanol. Accordingly, triclofos sodium produces CNS effects similar to those of oral chloral hydrate.

Paraldehyde, USP. Paraldehyde, 2,4,6-trimethyl-*s*-trioxane; paracetaldehyde, is recognizable as the cyclic trimer of acetaldehyde. It is a liquid with a strong characteristic odor detectable in the expired air and an unpleasant taste. These properties limit its use almost exclusively to an institutional setting (e.g., in the treatment of delirium tremens). In the past, when containers were opened and air admitted and then reclosed and allowed to stand, fatalities occurred because of oxidation of paraldehyde to glacial acetic acid.

ANTIPSYCHOTICS

Antipsychotics are drugs that ameliorate mental aberrations that are characteristic of the psychoses. The psychoses differ from the milder behavioral disorders, such as the anxiety disorders, in that thinking tends to be illogical, bizarre, and loosely organized. Importantly, patients have difficulty understanding reality and their own conditions. There are often hallucinations (usually auditory) and delusions.

In the schizophrenias, in addition to these symptoms,

called *positive symptoms*, there are negative symptoms represented by apathy, social withdrawal, and anhedonia. Cognitive deficits may also be observed.

Psychoses can be organic and related to a specific toxic chemical (e.g., delirium produced by central anticholinergic agents), an NMDA antagonist (e.g., phencyclidine), a definite disease process (e.g., dementia) or they can be idiopathic. Idiopathic psychoses may be acute or chronic. Idiopathic acute psychotic reactions have been reported to follow extremely severe short-term stress. Schizophrenia is a group of chronic idiopathic psychotic disorders with the overall symptomatology described above.

The term *antipsychotic* was slow in gaining acceptance. Now it is widely acknowledged that antipsychotics actually diminish the underlying thought disorder that is the chief characteristic of the schizophrenias. The agents often have a calming effect in agitated psychotic patients; hence, they also have been referred to as *major tranquilizers*. Finally, because they lessen reactivity to emotional stimuli, with little effect on consciousness, they are referred to as *neuroleptics*.

The most frequent uses of these agents are in manic disorders and the schizophrenias. In the manic disorders, the agents may block DA at limbic D_2 and D_3 receptors, reducing euphoria, delusional thinking, and hyperactivity. In the chronic idiopathic psychoses (schizophrenias), both conventional (typical) and newer (most are atypical) antipsychotics appear to act to benefit positive symptoms by blocking DA at D_2 and D_3 limbic receptors.¹ The bases of the atypical group's activity against negative symptoms may be serotonin- 2_A receptor (5-HT $_{2A}$) block, block at receptors yet to be determined, and possibly decreased striatal D_2 block.^{1, 30} A classic competitive antagonism has been demonstrated at D_2 and D_3 receptors. Also, in recombinantly expressed receptors, inverse agonism has been demonstrated. For this to apply in vivo, a ground state of dopaminergic activity must be shown. Some preliminary signs indicate this is likely.¹

In the schizophrenias, which have an extremely complex and multifactorial etiology,^{31, 32} the fundamental lesion appears to be a defect in the brain's informational gating mechanism. A slight abnormality in the startle response may be observed in infancy, but the disease does not emerge until late in the second decade or in the third decade of life. Basically the gating system has difficulty discriminating between relevant and irrelevant stimuli. Perception is illogical. Proceeding from this, thought and actions become illogical. Although the actual structural or anatomical lesions are not known, the basic defect appears to involve overactivity of dopaminergic neurons in the mesolimbic system. Some investigators suggest that this is the cause of most, if not all, of the common symptoms of the disease. Negative symptoms (e.g., social withdrawal) may be considered secondary symptoms. Others argue that all or part of the foregoing is excessively reductionist, and that other lesions cause some or all of the symptoms.

A major reason for the recent interest in the negative symptoms of schizophrenia has been the introduction of atypical, as opposed to typical, antipsychotics. Typical antipsychotics began with the serendipitous discovery of the antipsychotic activity of chlorpromazine. Many compounds were synthesized, usually with chlorpromazine as the model, and the antipsychotic potential assessed. A clear association between the ability to block DA at mesolimbic D_2 receptors

was established. During the same time, amphetamine-induced psychosis was determined to be caused by overactivation of mesolimbic D_2 receptors and judged to be the closest of the various chemically induced model psychoses to the schizophrenias.

The conventional typical antipsychotics are characterized by the production of EPS, roughly approximating the symptoms of Parkinson's disease. These are reversible on discontinuing or decreasing the dose of the drug and are associated with blockade of DA at D_2 striatal receptors. After sustained high-dose therapy with antipsychotics, a late-appearing EPS, tardive dyskinesia, may occur. The overall symptomatology resembles the symptoms of Huntington's chorea. The condition is thought to arise from biological compensation (increased D_2 activity) for the striatal D_2 block of antipsychotic drugs.

Atypical antipsychotics date from the discovery of clozapine, its antipsychotic properties and its much lower production of EPS. Some investigators express concern that typical antipsychotics, especially by producing EPS, introduce drug-induced effects that are hard to distinguish from negative symptoms. This leads to the view that diminishing EPS can account for perceived decreased negative symptoms. It is, however, reportedly also more active against negative symptoms of schizophrenia, independent of reduced EPS, and has a unique, notably expanded, receptor-blocking profile. Compounds are now under synthesis and being tested at the various CNS receptors at which clozapine acts to determine the role of these receptors in schizophrenia.

Also contributing to the development of typical antipsychotics was the introduction of risperidone. It has reduced EPS, has increased activity against negative symptoms, and, in addition to its DA blocking ability, is a 5-HT $_{2A}$ antagonist. One view of the drug is that it combines structurally the features of an antidepressant and an antipsychotic, and so the two drug effects are attained. Related to this is the view that at least some negative symptoms (e.g., depression, withdrawal) are secondary to the positive symptoms. The view has also been advanced, however, that 5-HT $_{2A}$ receptors are involved in part (the negative symptoms) or wholly in schizophrenia. So far, the evidence appears to be that 5-HT $_{2A}$ blocking agents do not relieve positive effects of schizophrenia.³⁰ The view that 5-HT $_{2A}$ overactivity is the source of negative symptoms (part of the basis psychosis) is not disproved at present, though some say it has been weakened.³⁰

One result of the development of atypical antipsychotics has been a renewed interest in models of psychosis other than the amphetamine model. In line with possible dual involvement of 5-HT and DA, the lysergic acid diethylamide model has been cited as better fitting schizophrenias than the amphetamine model. But, this has been disputed. Interest in serotonergic involvement is still high and involves elucidating the roles of 5-HT $_6$ and 5-HT $_7$ receptors.

Interest remains in understanding the psychosis produced by several central anticholinergics. Muscarinic (M_1 and M_4) agonists appear to offer the best approach at this time.³³ The role of the M_5 receptor awaits synthesis of M_5 -specific drugs.³⁴

Phencyclidine-induced psychosis has been proposed as a superior model for schizophrenia because it presents both positive and negative symptoms.³⁰ It suggests that deficits in glutaminergic function occur in schizophrenia. Results of

agonists of NMDA receptors overall have not been productive because of the excitatory and neurotoxic effects of the agents tested. Identification of susceptible receptor subtypes as targets, using glycine modulation or group II metabotropic receptor agonists to modulate NMDA receptors, has been proposed to circumvent the problems associated with the NMDA agonists.

The ionotropic glutamic acid α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors are activated by brain-penetrating ampakines. There are suggestions that these agents exert some antipsychotic actions by increasing glutamatergic activity.

The individual antipsychotic compounds are now considered. The substituted dopamine motif is useful as an organizational device. Atypical antipsychotics are indicated when they occur. Future growth in this area should be interesting.

Phenothiazines

Many potentially useful phenothiazine derivatives have been synthesized and evaluated pharmacologically. Consequently, the large body of information permits accurate statements about the structural features associated with activity. Many of the features were summarized and interpreted by Gordon et al.³⁵ The best position for substitution is the 2 position. Activity increases (with some exceptions) as electron-withdrawing ability of the substituent increases. Another possibly important structural feature in the more potent compounds is the presence of an unshared electron pair on an atom or atoms of the 2 substituent. Substitution at the 3 position can improve activity over nonsubstituted compounds but not as significantly as substitution at the 2 position. Substitution at position 1 has a deleterious effect on antipsychotic activity, as does (to a lesser extent) substitution at the 4 position.

Phenothiazine Antipsychotic Agents—General Structure

The significance of these substituent effects could be that the hydrogen atom of the protonated amino group of the side chain H bonds with an electron pair of an atom of the 2 substituent to develop a DA-like arrangement. Horn and Snyder, from x-ray crystallography, proposed that the chlorine-substituted ring of chlorpromazine base could be superimposed on the aromatic ring of dopamine base with the sulfur atom aligned with the *p*-hydroxyl of dopamine and the aliphatic amino groups of the two compounds also aligned.³⁶ The model used here is based on the interpretation of the SARs by Gordon et al.³⁵ and on the Horn and Snyder proposal³⁶ but involves the protonated species rather than the free base. The effect of the substituent at the 1 position might be to interfere with the side chain's ability to bring the protonated amino group into proximity with the 2 substituent. In the Horn and Snyder scheme,³⁶ the sulfur atom at

position 5 is in a position analogous to the *p*-hydroxyl of dopamine, and it was also assigned a receptor-binding function by Gordon et al.³⁵ A substituent at position 4 might interfere with receptor binding by the sulfur atom.

The three-atom chain between position 10 and the amino nitrogen is required. Shortening or lengthening the chain at this position drastically decreases activity. The three-atom chain length may be necessary to bring the protonated amino nitrogen into proximity with the 2-substituent.

As expected, branching with large groups (e.g., phenyl) decreases activity, as does branching with polar groups. Methyl branching on the β position has a variable effect on activity. More importantly, the antipsychotic potency of *lev* (the more active) and *dextro* isomers differs greatly. This has long been taken to suggest that a precise fit (i.e., receptor site occupancy) is involved in the action of these compounds.

Decreases in size from a dimethylamino group (e.g., going to a monomethylamino) greatly decrease activity, as do effective size increases, such as the one that occurs with *N,N*-diethylamino. Once the fundamental requirement of an effective size of about that equivalent to a dimethylamino is maintained, as in fusing *N,N*-diethyl substituents to generate a pyrrolidino group, activity can be enhanced with increasing chain length, as in N_2 -substituted piperizino compounds.

The critical size of groups on the amino atom suggests the importance of the amino group (here protonated) for receptor attachment. The effect of the added chain length, once the critical size requirement is met, could be increased affinity. It appears to have been reasonably proved that the protonated species of the phenothiazines can bind to DA receptors.³⁷

Metabolism of the phenothiazines is complex in detail, but simple overall. A major route is hydroxylation of the tricyclic system. The usual pattern, for which there are good chemical reasons, is hydroxylation *para* to the 10-nitrogen atom of the ring other than the ring bearing the electron-attracting substituent at the 2 position. Thus, the major initial metabolite is frequently the 7-hydroxy compound. This compound is further metabolized by conjugation with glucuronic acid, and the conjugate is excreted. Detailed reviews of the metabolites of phenothiazines (as well as SARs and pharmacokinetic factors) are available.³⁸

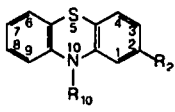

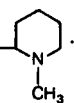

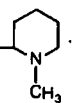

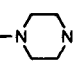

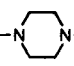

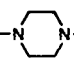

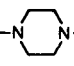

PRODUCTS

The structures of the phenothiazine derivatives described below are given in Table 14-3.

Promazine. Promazine, 10-[3-(dimethylamino)propyl]phenothiazine monohydrochloride (Sparine), was introduced into antipsychotic therapy after its 2-chloro-substituted relative. The 2H substituent *vis-a-vis* the 2G substituent gives a milligram potency decrease as an antipsychotic, as encompassed in Gordon's rule. Tendency to EPS is also lessened, which may be significant, especially if it is decreased less than antipsychotic potency.

Chlorpromazine Hydrochloride, USP. Chlorpromazine hydrochloride, 2-chloro-10-[3-(dimethylamino)propyl]phenothiazine monohydrochloride (Thorazine), was the first phenothiazine compound introduced into therapy. It is

TABLE 14-3 Phenothiazine Derivatives

			
Generic Name Proprietary Name	R ₁₀		R ₂
Propyl Dialkylamino Side Chain			
Promazine hydrochloride, USP <i>Sparine</i>	$-(CH_2)_3N(CH_3)_2 \cdot HCl$		H
Chlorpromazine hydrochloride, USP <i>Thorazine</i>	$-(CH_2)_3N(CH_3)_2 \cdot HCl$		Cl
Triflupromazine hydrochloride, USP <i>Vesprin</i>	$-(CH_2)_3N(CH_3)_2 \cdot HCl$		CF ₃
Alkyl Piperidyl Side Chain			
Thioridazine hydrochloride, USP <i>Mellaril</i>	$-(CH_2)_2-N(CH_3)-$ 	$\cdot HCl$	SCH ₃
Mesoridazine besylate, USP <i>Sereniti</i>	$-(CH_2)_2-N(CH_3)-$ 	$\cdot C_6H_5SO_3H$	$\begin{matrix} O \\ \\ SCH_3 \end{matrix}$
Propyl Piperazine Side Chain			
Prochlorperazine maleate, USP <i>Compazine</i>	$-(CH_2)_3-N(CH_3)-$ 	$\cdot 2C_4H_4O_4$	Cl
Trifluoperazine hydrochloride, USP <i>Stelazine</i>	$-(CH_2)_3-N(CH_3)-$ 	$\cdot 2HCl$	CF ₃
Perphenazine, USP <i>Trilafon</i>	$-(CH_2)_3-N(CH_3)-CH_2-CH_2-OH$ 		Cl
Fluphenazine hydrochloride, USP <i>Permitil, Prolixin</i>	$-(CH_2)_3-N(CH_3)-CH_2-CH_2-OH$ 	$\cdot 2HCl$	CF ₃

still useful as an antipsychotic. Other uses are in nausea and vomiting and hiccough. It is the reference compound in activity comparisons, that is, the compound to which others are compared. The drug has significant sedative and hypotensive properties, possibly reflecting central and peripheral α_1 -noradrenergic blocking activity, respectively. Effects of peripheral anticholinergic activity are common. As with the other phenothiazines, the effects of other CNS-depressant drugs, such as sedatives and anesthetics, can be potentiated.

Triflupromazine Hydrochloride, USP. Triflupromazine hydrochloride, 10-[3-(dimethylamino)propyl]-2-(trifluoromethyl)phenothiazine monohydrochloride (Vesprin), has lower sedative and hypotensive effects than chlorpromazine

and a greater milligram potency as an antipsychotic. EPS are higher. The 2-CF₃ versus the 2-Cl is associated with these changes. Overall, the drug has uses analogous to those of chlorpromazine.

Thioridazine Hydrochloride, USP. Thioridazine hydrochloride, 10-[2-(1-methyl-2-piperidyl)ethyl]-2-(methylthio)phenothiazine monohydrochloride (Mellaril), is a member of the piperidine subgroup of the phenothiazines. The drug has a relatively low tendency to produce EPS. The drug has high anticholinergic activity, and this activity in the striatum, counterbalancing a striatal DA block, may be responsible for the low EPS. It also has been suggested that there may be increased DA receptor selectivity, which may

be responsible. The drug has sedative and hypotensive activity in common with chlorpromazine and less antiemetic activity. At high doses, pigmentary retinopathy has been observed. A metabolite of the drug is mesoridazine (discussed next).

Mesoridazine Besylate, USP. Mesoridazine besylate, 10-[2-(methyl-2-piperidyl)ethyl]-2-(methylsulfinyl)phenothiazine monobenzenesulfonate (Sereniti), shares many properties with thioridazine. No pigmentary retinopathy has been reported, however.

Prochlorperazine Maleate, USP. Prochlorperazine maleate, 2-chloro-10-[3-(4-methyl-1-piperazinyl)propyl]-phenothiazine maleate (Compazine), is in the piperazine subgroup of the phenothiazines, characterized by high milligram antipsychotic potency, a high prevalence of EPS, and low sedative and autonomic effects. Prochlorperazine is more potent on a milligram basis than its alkylamino counterpart, chlorpromazine. Because of the high prevalence of EPS, however, it is used mainly for its antiemetic effect, not for its antipsychotic effect.

Perphenazine, USP. Perphenazine, 4-[3-(2-chlorophenothiazine-10-yl)propyl]piperazineethanol; 2-chloro-10-[3-[4-(2-hydroxyethyl)piperazinyl]propyl]phenothiazine (Trilafon), is an effective antipsychotic and antiemetic.

Fluphenazine Hydrochloride, USP. The member of the piperazine subgroup with a trifluoromethyl group at the 2-position of the phenothiazine system and the most potent antipsychotic phenothiazine on a milligram basis is fluphenazine hydrochloride, 4-[3-[2-(trifluoromethyl)phenazin-10-yl]propyl]-1-piperazineethanol dihydrochloride, 10[3-[4-(2-hydroxyethyl)piperazinyl]propyl]-2-trifluoromethylphenothiazine dihydrochloride (Permitil, Prolixin). It is also available as two lipid-soluble esters for depot intramuscular injection, the enanthate (heptanoic acid ester) and the decanoate ester. These long-acting preparations have use in treating psychotic patients who do not take their medication or are subject to frequent relapse.

Ring Analogues of Phenothiazines: Thioxanthenes, Dibenzoxazepines, and Dibenzodiazepines

The ring analogues of phenothiazines are structural relatives of the phenothiazine antipsychotics. Most share many clinical properties with the phenothiazines. The dibenzodiazepine clozapine has some important differences, however, notably low production of EPS and reduction of negative symptoms. It is an important atypical antipsychotic.

Thiothixene, USP. The thioxanthene system differs from the phenothiazine system by replacement of the N-H moiety with a carbon atom doubly bonded to the propylidene side chain. With the substituent in the 2 position, *Z* and *E* isomers are produced. In accordance with the concept that the presently useful antipsychotics can be superimposed on DA, the *Z* isomers are the more active antipsychotic isomers. The compounds of the group are very similar in pharmaco-

logical properties to the corresponding phenothiazines. Thus, thiothixene (*Z-N*-dimethyl-9-[3-(4-methyl-1-piperazinyl)propylidene]thioxanthene-2-sulfonamide (Navane), displays properties similar to those of the piperazine subgroup of the phenothiazines.

A dibenzoxazepine derivative in use is **loxapine succinate**, 2-chloro-11-(4-methyl-1-piperazinyl)dibenz[*b, f*]4oxazepine succinate (Daxolin). The structural relationship to the phenothiazine antipsychotics is apparent. It is an effective antipsychotic and has side effects similar to those reported for the phenothiazines.

The dibenzodiazepine derivative is **clozapine** (Clozaril). It is not a potent antipsychotic on a milligram basis (note the orientation of the *N*-methyl piperazino group relative to the chlorine atom). It is effective against both positive and negative symptoms of schizophrenia and has a low tendency to produce EPS. There are legal restrictions on its use because of a relatively high frequency of agranulocytosis. As a rule, two other antipsychotics are tried before recourse to therapy with clozapine.

Fluorobutyrophenones

The fluorobutyrophenones belong to a much-studied group of compounds, many of which possess high antipsychotic activity. Only a few of these are used in the United States, which can be misleading about the importance of the group and its evolved relatives. The structural requirements for

antipsychotic activity in the group are well worked out.³⁹ General features are expressed in the following structure.

Optimal activity is seen when AR₁ is an aromatic system. A *p*-fluoro substituent aids activity. When X = C=O, optimal activity is seen, although other groups, C(H)OH and C(H)aryl, also give good activity. When n = 3, activity is optimal; longer or shorter chains decrease activity. The aliphatic amino nitrogen is required, and highest activity is seen when it is incorporated into a cyclic form. AR₂ is an aromatic ring and is needed. It should be attached directly to the 4 position or (occasionally) separated from it by one intervening atom. The Y group can vary and assist activity. An example is the hydroxyl group of haloperidol.

The empirical SARs could be construed to suggest that the 4-aryl piperidino moiety is superimposable on the 2-phenylethylamino moiety of dopamine and, accordingly, could promote affinity for D₂ and D₃ receptors. The long Y-alkyl substituent could help promote receptor affinity and produce receptor antagonism activity and/or inverse agonism.

Some members of the class are extremely potent antipsychotic agents and D₂ and D₃ receptor antagonists. EPS are extremely marked in some members of this class, which may, in part, be due to a potent DA block in the striatum and almost no compensatory striatal anticholinergic block. Most of the compounds do not have the structural features associated with effective anticholinergic activity.

Haloperidol, USP. Haloperidol, 4-[4-(*p*-chlorophenyl)-4-hydroxypiperidine]-4'-*n*-fluorobutyrophenone (Haldol), is a potent antipsychotic useful in schizophrenia and in psychoses associated with brain damage. It is frequently chosen as the agent to terminate mania and often used in therapy for Gilles de la Tourette's syndrome.

Droperidol, USP. Droperidol, 1-[1-[3-(*p*-fluorobenzoyl)propyl]-1,2,3,6-tetrahydro-4-pyridyl]-2-benzimidazolone (Inapsine), may be used alone as a preanesthetic neuroleptic or as an antiemetic. Its most frequent use is in combination (Innovar) with the narcotic agent fentanyl (Sublimaze) preanesthetically.

Risperidone. Risperidone (Risperdal) has the structural features of a hybrid molecule between a butyrophenone antipsychotic and a trazodone-like antidepressant. It benefited refractory psychotic patients, with parkinsonism controlled at one-tenth the dose of antiparkinsonian drugs used with haloperidol.⁴⁰ Coexisting anxiety and depressive syndromes were also lessened. It is reported to decrease the negative (e.g., withdrawal, apathy) as well as the positive (e.g., delusions, hallucinations) symptoms of schizophrenia. This is reportedly a consequence of the compound's combination 5-HT₂-D₂ receptor antagonistic properties.⁴¹ Overall the reasons for the decreased EPS and effectiveness against negative symptom are still under investigation. It is an important atypical antipsychotic.

The diphenylbutylpiperidine class can be considered a modification of the fluoroxybutyrophenone class. Because of their high hydrophobic character, the compounds are inherently long acting. Penfluridol has undergone clinical trials in the United States, and pimozide has been approved for antipsychotic use. Overall, side effects for the two compounds resemble those produced by the fluoroxybutyrophenones.

β-Aminoketones

Several β-aminoketones have been examined as antipsychotics.³⁸ They evolved out of research on the alkaloid lobeline. The overall structural features associated with activity can be seen in the structure of molindone. In addition to the

β -aminoketone group, there must be an aryl group positioned as in molindone. It might be conjectured that the proton on the protonated amino group in these compounds H-bonds with the electrons of the carbonyl oxygen atom. This would produce a cationic center, two-atom distance, and an aryl group that could be superimposed on the analogous features of protonated dopamine.

Molindone Hydrochloride. Molindone hydrochloride, 3-ethyl-6,7-dihydro-2-methyl-5-morpholinomethylindole-4(5*H*)-one monohydrochloride (Molan), is about as potent an antipsychotic as trifluoperazine. Overall, side effects resemble those of the phenothiazines.

Benzamides

The benzamides evolved from observations that the gastroprokinetic and antiemetic agent metoclopramide has antipsychotic activity related to D_2 receptor block. It was hoped that the group might yield compounds with diminished EPS liability. This expectation appears to have been met. A H bond between the amido H and the unshared electrons of the methoxy group to generate a pseudo ring is considered important for antipsychotic activity in these compounds. Presumably, when the protonated amine is superimposed on that of protonated dopamine, this pseudo ring would superimpose on dopamine's aromatic ring.⁴² These features can be seen in sulpiride and remoxipride.

Remoxipride (Roxiam). Remoxipride is a D_2 receptor blocker.⁴⁰ It is said to be as effective as haloperidol with fewer EPS. Negative symptoms of schizophrenia are diminished. The drug is classed as an atypical antipsychotic. The substituents on the aliphatic amino nitrogen and the substituents on the aromatic ring are interesting.

Olanzapine and Quetiapine. Olanzapine (Zyprexa) and quetiapine (Seroquel) possess tricyclic systems with greater electron density than chlorpromazine. They thus resemble clozapine. The drugs are atypical antipsychotics.

Overall, these two compounds should bind less strongly to D_2 receptors and permit more receptor selectivity among receptor subtypes than typical antipsychotics. This could account for decreased striatal D_2 -blocking activity, which would produce less discomfort in patients. It would be interesting to see testing results of these drugs' activities over a broad range of receptors, as are presently being accumulated for clozapine.

With respect to the atypical antipsychotics, two events long in the past may shed some light on the events of today. The field of reuptake-inhibiting antidepressants arose when only a very small structural change was made in an antipsychotic drug, and the new activity noted. (The antipsychotic activity remained.) So, small changes in structure can produce antipsychotics that are active against depressive symptoms. Likewise, small changes in structure could provide selectivity among D_2 receptors.

Almost 40 years ago, it was noted that thioridazine was far less unpleasant for patients than its relatives.⁴³ Its tricyclic system is far more nucleophilic than that of most other drugs. The emphasis, at the time, however, was to increase milligram potency by increasing D_2 receptor affinity by lowering tricyclic electron density. The experience of clozapine, with increased electron density of the receptor-binding rings and thus lower affinity, appears to validate the observation about thioridazine and appears to allow more selectivity among D_2 receptors. Lessening blocks on, for example, striatal D_2 receptors, and possibly mesocortical D_2 receptors as well, could produce drugs that are much less unpleasant for the patient. Additionally, a less intense D_2 block could allow the effects of other blocks to make up more of the drug's total action (e.g., 5-HT transporter block). Several atypical

antipsychotics have rings with enhanced nucleophilicity. Of course, other structural features could be influencing receptor selectivity, for example, increasing steric hindrance to receptor binding by the protonated amino group or to the nng binding.

Antimanic Agents

LITHIUM SALTS

The lithium salts used in the United States are the carbonate (tetrahydrate) and the citrate. Lithium chloride is not used because of its hygroscopic nature and because it is more irritating than the carbonate or citrate to the GI tract.

The active species in these salts is the lithium ion. The classic explanation for its antimanic activity is that it resembles the sodium ion (as well as potassium, magnesium, and calcium ions) and can occupy the sodium pump. Unlike the sodium ion, it cannot maintain membrane potentials. Accordingly, it might prevent excessive release of neurotransmitters (e.g., dopamine) that characterize the manic state. Many of the actions of lithium ion have been reviewed.⁴⁴ The indications for lithium salts are acute mania (often with a potent neuroleptic agent for immediate control, since lithium is slow to take effect) and as a prophylactic to prevent recurrence of the mania of bipolar manic-depressive illness. Lithium salts are also used in severe recurrent unipolar depression. One effect of the drug that might be pertinent is an increase in the synthesis of presynaptic serotonin. Some have speculated that simply evening out transmission, preventing downward mood swing, for example, could be a basis for antidepressant action.

Because of its water solubility, the lithium ion is extensively distributed in body water. It tends to become involved in the many physiological processes involving sodium, potassium, calcium, and magnesium ions, hence, many side effects and potential drug interactions exist. The margin of safety is low; therefore lithium should be used only when plasma levels can be monitored routinely. In the desired dose range, side effects can be adequately controlled.

Because of the toxicity of lithium, there is substantial interest in design of safer compounds. As more is learned about lithium's specific actions, the likelihood of successful design of compounds designed to act on specific targets is increased. Actually, carbamazepine and valproic acid, which target sodium channels, are proving to be effective.⁴⁵ These two drugs are discussed in the anticonvulsant section.

Lithium Carbonate, USP, and Lithium Citrate. Lithium carbonate (Eskalith, Lithane) and lithium citrate (Cibalith-S) are the salts commercially available in the United States.

ANTICONVULSANT OR ANTIEPILEPTIC DRUGS

As is customary, the terms *anticonvulsant* and *antiepileptic* are used interchangeably in this discussion. Strictly speaking, however, an anticonvulsant is an agent that blocks experimentally produced seizures in laboratory animals, and

an antiepileptic drug is a drug used medically to control the epilepsies, not all of which are convulsive, in humans.

A classification of the types of epilepsy has been widely accepted because its accuracy facilitates diagnosis, drug selection, and precise discussion of seizure disorders.^{46, 47} The major classification types are (a) generalized seizures, which essentially involve the entire brain and do not have an apparent local onset; (b) unilateral seizures, which involve one entire side of the body; (c) partial (or focal) seizures that have a focus (i.e., begin locally); (d) erratic seizures of the newborn; and (e) unclassified seizures (severe seizures associated with high mortality such that time does not permit a precise categorization).

Two major types of generalized seizures are the generalized tonic-clonic seizure (grand mal) and the nonconvulsive seizures or absence (petit mal) seizures. The typical generalized tonic-clonic seizure is often preceded by a series of bilateral muscular jerks; followed by loss of consciousness, which in turn is followed by a series of tonic and then clonic spasms. The typical absence seizure (classic petit mal) consists of a sudden brief loss of consciousness, sometimes with no motor activity, although often some minor clonic motor activity exists.

Major types of focal (partial) epilepsy are simple focal and complex focal seizures. A prototypic simple partial seizure is jacksonian motor epilepsy in which the jacksonian march may be seen. As the abnormal discharge proceeds over the cortical site involved, the visible seizure progresses over the area of the body controlled by the cortical site. The complex partial seizure is represented by the psychomotor or temporal lobe seizure. There is an aura, then a confused or bizarre but seemingly purposeful behavior lasting 2 to 3 minutes, often with no memory of the event. The seizure may be misdiagnosed as a psychotic episode. This is an extremely difficult epilepsy to treat. Much effort has been made in recent years to develop drugs to control it.

For broad consideration of how structure relates to antiepileptic activity, the classification of the epilepsies is traditionally further condensed (generalized tonic-clonic seizures, simple partial seizures, complex partial seizures, and absence seizures). The broad general pattern of structural features associated with antigeneralized tonic-clonic seizure activity is discernible for barbiturates, hydantoins, oxazolidinediones, and succinimides. This SAR also applies to simple partial seizures. It applies with less certainty to complex partial seizures, which are relatively resistant to treatment. With fewer effective drug entities, overall structural conclusions are more tenuous. The other general seizure type for which a broad SAR pattern among the cited compounds can be seen is the absence seizure. These features are cited under the heading, SARs Among Anticonvulsants.

Likewise, animal models characteristically discern three types of activity: activity against electrically induced convulsions correlates with activity against generalized tonic-clonic and partial seizures, and activity against pentylenetetrazole (PTZ)-induced seizures correlates with antiabsence activity. Of late, a fourth model, activity against pilocarpine and kainic acid seizures, is said to predict protection against temporal lobe epilepsy (a complex partial seizure).

Each of the epilepsy types is characterized by a typical abnormal pattern in the EEG. The EEG indicates sudden, excessive electrical activity in the brain. Antiepileptic drugs

act to prevent, stop, or lessen this activity. The precise causes of the sudden, excessive electrical discharges may be many, and not all are understood. A working hypothesis is that there is a site or focus of damaged or abnormal and, consequently, hyperexcitable neurons in the brain. These can fire excessively and sometimes recruit adjacent neurons that in turn induce other neurons to fire. The location and the extent of the abnormal firing determine the epilepsy. An addition to this theory is based on the kindling model.⁴⁸ Experimentally, a brief and very localized electrical stimulus is applied to a site in the brain, with long intervals between applications. As the process is repeated, neuronal afterdischarges grow both longer and more intense at the original site and at new sites far from the original site. It is thought that changes occur in neurons at the discharge site, and these neurons in turn induce changes in neurons far from the site. Progressively more severe seizures can be induced, and these can arise from secondary foci that have been kindled far from the site of stimulation.

A major mode of action of anticonvulsants can be positive allosteric modulation of GABA_A receptors. This is probably the mode of action of benzodiazepines and a major mode of action of barbiturates. On the basis of the structure of barbiturates, some inorganic cation blocking action would be expected as well—voltage-gated sodium channel for phenobarbital and calcium T channel block for 5,5-dialkyl members. Oxazolidine-2,4-diones (only trimethadione remains) and succinimides appear to act via calcium T-type channel block. Some sodium channel block could be expected among phenyl-substituted succinimides. The major mode of action for phenytoin (and probably monophenyl substituted hydantoin), carbamazepine, oxcarbazepine, valproic acid, felbamate, topiramate, lamotrigine and zonisamide is reported to be voltage-gated sodium channel block and is in accord with their structures. This does not exclude other expected actions in some of the examples.

Direct block of ionotropic glutamate receptors has so far not yielded clinically useful drugs. Some voltage-gated sodium channel drugs are reported to be antiglutamate as well by blocking glutamate release. Side effects of direct ionotropic glutamate receptor blocking has been a serious problem. Because of this, present approaches are to use the modulatory route. That is, lessen ionotropic glutamate activity by (a) using drugs that act at the glycine modulatory site on NMDA and (b) developing antagonists of members group II and group III metabotropic receptors and agonists of metabotropic group I glutamate acid receptors. These drugs would lower ionotropic glutamatergic activity.

Adenosine, which may be an endogenous anticonvulsant, continues to serve as a model but, for reasons such as poor brain distribution and an array of cardiovascular effects of agonists, has not yet yielded useful drugs. Elaboration of roles of receptor subtypes may give leads for drug design.

SARs Among Anticonvulsants

Several major groups of drugs have the common structure shown below.

Structure common to anticonvulsant drugs.

An overall pattern in the foregoing is that R and R' should both be hydrocarbon radicals. If both R and R' are lower alkyls, the tendency is to be active against absence seizures (petit mal) and not active against generalized tonic-clonic (grand mal) or partial seizures. If one of the hydrocarbon substituents is an aryl group, activity tends to be directed toward generalized tonic-clonic and partial seizures and not antiabsence activity.⁴⁹

A conformational analysis of the aryl-containing antiepileptic drugs indicates that the conformational arrangement of the hydrophobic groups is important.⁵¹

Barbiturates

Although sedative-hypnotic barbiturates commonly display anticonvulsant properties, only phenobarbital and mephobarbital display enough anticonvulsant selectivity for use as antiepileptics. For the structures of these agents, consult Table 14-2, and for discussion of chemical properties see the section on barbiturates under sedative-hypnotic-anxiolytic agents. The metabolism of phenobarbital involves p-hydroxylation, followed by conjugation.

Mephobarbital is extensively N-demethylated in vivo and is thought to owe most of its activity to the metabolite phenobarbital. In keeping with their structures, both agents are effective against generalized tonic-clonic and partial seizures.

Hydantoins

The hydantoins are close structural relatives of the barbiturates, differing in lacking the 6-oxo group. They are cyclic mononucleureas rather than cyclic diacylureas. As a consequence of losing a carbonyl group, they are weaker organic acids than the barbiturates (e.g., phenytoin $pK_a = 8.3$). The aqueous solutions of sodium salts, such as of phenytoin sodium, generate strongly alkaline solutions.

TABLE 14-4 Anticonvulsant Hydantoin Derivatives

Generic Name Proprietary Name	Substituents		
	R ₅	R' ₃	R ₃
Phenytoin, USP Dilantin, Diphenoin			H
Mephenytoin, USP Mesantoin		CH ₃ —CH ₂ —	CH ₃ —
Ethotoin Peganone		H	CH ₃ —CH ₂ —

The compounds have a trophism toward antigeneralized tonic-clonic rather than antiabsence activity. This is not an intrinsic activity of the hydantoin ring system. All of the clinically useful antigeneralized tonic-clonic compounds (Table 14-4) possess an aryl substituent on the 5 position, corresponding to the branched atom of the general pharmacophore. Hydantoins with lower alkyl substituents reportedly have antiabsence activity.

Phenytoin and Phenytoin Sodium, USP. Phenytoin, 5,5-diphenylhydantoin (Dilantin), is the first anticonvulsant in which it was clearly demonstrated that anticonvulsant activity could definitely be separated from sedative-hypnotic activity. It is often cited as the prime example of an anticonvulsant acting as a sodium channel blocker.^{13, 51} One effect of neuronal sodium channel block is to decrease presynaptic glutamic acid release, giving anticonvulsant activity.^{50, 51} Another consequence is to reduce glutamate-induced ischemic damage to neurons.^{51, 52} The drug is useful against all seizure types except absence. It is sometimes noted that the drug is incompletely or erratically absorbed from sites of administration. This is due to its very low water solubility. Metabolism proceeds by stereospecific p-hydroxylation of an aromatic ring, followed by conjugation.

Mephenytoin, USP. Mephenytoin, 5-ethyl-3-methyl-5-phenylhydantoin (Mesantoin), is metabolically N-dealkylated to 5-ethyl-5-phenylhydantoin, believed to be the active agent. Interestingly, 5-ethyl-5-phenylhydantoin, the hydantoin counterpart of phenobarbital, was one of the first hydantoins introduced into therapy. It was introduced as a sedative-hypnotic and anticonvulsant under the name Nirvanol, but it was withdrawn because of toxicity. Presumably, mephenytoin may be considered a prodrug that ameliorates some of the toxicity—serious skin and blood disorders—of the delivered active drug.

Metabolic inactivation of mephenytoin and its demethyl metabolite is by p-hydroxylation and then conjugation of the

hydroxyl group. The drug has a spectrum of activity similar to that of phenytoin. It may worsen absence seizures.

Ethotoin. Ethotoin, 3-ethyl-5-phenylhydantoin (Peganone), is N-dealkylated and p-hydroxylated; the N-dealkyl metabolite, presumably the active compound, is likewise metabolized by p-hydroxylation. The hydroxyl group is then conjugated.

The compound is used against generalized seizures, but usually on an adjunctive basis, owing to its low potency. In general, agents that are not completely branched on the appropriate carbon have lower potency than their more completely branched counterparts.

Oxazolinediones

Replacement of the N-H group at position 1 of the hydantoin system with an oxygen atom yields the oxazolidine-2,4-dione system. The oxazolidinedione system is sometimes equated with antiabsence activity, but this trophism probably is more dictated by the fact that the requisite branched atom of these compounds is substituted with lower alkyls. Aryl-substituted oxazolidine-2,4-diones have shown activity against generalized tonic-clonic seizures. The oxazolidinedione group of anticonvulsants used clinically has shrunk to one clinically useful member. Toxicities associated with the group may be the problem.

Trimethadione, USP. Trimethadione, 3,5,5-trimethyl-2,4-oxazolidinedione, 3,5,5-trimethadione (Tridione), was the first drug introduced specifically for treating absence seizures. It is important as a prototype structure for antiabsence compounds. Dermatological and hematological toxicities limit its clinical use.

The drug is metabolized by N-demethylation to the putative active metabolite dimethadione.⁵³ Dimethadione is a calcium T channel blocker. Dimethadione is a water-soluble and lowly lipophilic compound and thus is excreted as such without further metabolism.

Succinimides

In view of the activity of antiepileptic agents such as the oxazolidine-2,4-diones, substituted succinimides (CH₂ replaces O) were a logical choice for synthesis and evaluation. Three are now in clinical use.

Phensuximide, USP. Some trophism toward antiabsence activity is attributed to the succinimide system. The —CH₂— could be viewed as an α-alkyl branch condensed into the ring. Phensuximide, N-methyl-2-phenylsuccinimide (Milontin), is used primarily against absence seizures, but it has low potency and is relegated to secondary status. The

phenyl substituent confers some activity against generalized tonic-clonic and partial seizures. N-demethylation occurs to yield the putative active metabolite. Both phensuximide and the N-demethyl metabolite are inactivated by p-hydroxylation and conjugation.

Methsuximide. N-demethylation and p-hydroxylation of parent and metabolite occur. Methsuximide, N,2-dimethyl-2-phenylsuccinimide (Celontin), has some use against absence and complex partial seizures.

Ethosuximide, USP. Ethosuximide, 2-ethyl-2-methylsuccinimide (Zarontin), conforms very well to the general structural pattern for antiabsence activity. The drug is more active and less toxic than trimethadione. It is a calcium T channel-blocking drug. Toxicity primarily involves the skin and blood.

Some of the drug is excreted intact. The major metabolite is produced by oxidation of the ethyl group.

Ureas and Monoacylureas

The two chemical classes, ureas and monoacylureas, have a long history of producing compounds with anticonvulsant activity. The numerical yield of clinically useful compounds has not been great, however. Most of the simpler compounds have gone by the way. For convenience of grouping, carbamazepine and oxcarbazepine can be considered N,N-diacylureas.

Carbamazepine, USP. Carbamazepine, 5H-dibenz[b,f]azepine-5-carboxamide (Tegretol), for SAR discussion purposes, can be viewed either as an ethylene-bridged 1,1-diphenylurea or an amido-substituted tricyclic system. The two phenyls substituted on the urea nitrogen fit the pattern of antigeneralized tonic activity. The overall shape of the molecule suggests the mode of action, sodium channel block. Carbamazepine is useful in generalized tonic-clonic and partial seizures.

The drug has the potential for serious hematological toxicity, and it is used with caution.

Metabolism proceeds largely through the epoxide formed

at the (Z)-stilbene double bond. In humans, the epoxide reportedly is converted largely to the 10S,11S-trans-diol.⁵⁴ The epoxide is a suspect in the idiosyncratic reactions carbamazepine may produce (e.g., aplastic anemia). With this in mind, compounds designed to avoid the epoxide such as oxcarbazepine (Trileptal) were developed.

Oxcarbazepine is reduced to the monohydroxy compound, undoubtedly stereospecifically. The monohydroxy compound is considered the major active metabolite. The drug is used against partial seizures. The major mechanism of action is sodium channel block.

Miscellaneous Agents

Primidone. Primidone, 5-ethyl-5-phenyl-4,6-(1H,5H)-pyrimidinedione (Mysoline), is sometimes described as a 2-deoxybarbiturate. It appears to act as such and through conversion to phenobarbital and to phenylethylmethylolamide (PEMA).⁵⁵ The efficacy is against all types of seizures except absence. The agent has good overall safety but rare serious toxic effects do occur.

Valproic Acid. Many carboxylic acids have anticonvulsant activity, although often of low potency, possibly in part because extensive dissociation at physiological pH produces poor partitioning across the blood-brain barrier. Valproic acid, 2-propylpentanoic acid (Depakene), has good potency and is used against several seizure types. They include typical and atypical absence seizures and absence seizure with generalized tonic-clonic seizure. Mechanistically, the drug is a sodium channel blocker. This is in accordance with its structural features. It is also reported to increase GABA levels, again in conformity with its structure. Metabolism is by conjugation of the carboxylic acid group and oxidation of one of the hydrocarbon chains. Many of the side effects are mild. A rare, but potentially fatal, fulminant hepatitis has caused concern, however. One tends to look to the hydrogen atom α to the carboxyl acid as being labile and generating a toxiphore.

Gabapentin. Despite the fact that gabapentin (Neurontin) is a relative of GABA with increased hydrophobic character, its mechanism of action does not appear to involve an interaction with GABA_A receptors. A binding site on calcium channels has been identified, but the mode of action of the drug is considered unclear. The drug is said to have a good pharmacokinetic profile and to cross the blood-brain barrier well. It was introduced for adjunctive therapy of refractory partial seizures and, secondarily, generalized tonic-clonic seizures. It was studied as a single drug therapy for various seizures.⁵⁶

Tiagabine (Gabitril). A glance at tiagabine's structure suggests an uptake inhibitor. Reportedly, it blocks GABA reuptake as a major mode of its anticonvulsant activity. Its use is against partial seizures.

Felbamate. Felbamate (Felbatol) has been used successfully in refractory patients with generalized tonic-clonic seizures and complex partial seizures. The mechanism of action may involve an interaction with the strychnine-insensitive receptor on the NMDA receptor.⁵⁶ It is also a sodium channel blocker. The drug is associated with a serious risk of aplastic anemia. It is used with extreme caution after other anticonvulsants have been tried and a careful risk-to-benefit assessment has been made.

Lamotrigine. Lamotrigine (Lamictal) has been found effective against refractory partial seizures. It is said to act by blocking sodium channels and preventing glutamate release.⁵² It is a member of a group of drugs that reduce glutamate release and thus reduce neuronal cell death in ischemia. One trial with lamotrigine did not detect slowing of the progression of amyotrophic lateral sclerosis (ALS). Another member of the group (sodium channel blockers with antiglutamate effect), riluzole (Rilutek) (2-amino-6-(trifluoroethoxy)-benzothiazole) is used to slow progression. The bottle-stopper shape of both drugs is readily apparent.

Zonisamide (Zonegran) and Topiramate (Topamax). Zonisamide and Topiramate have, respectively, the sulfonamide and sulfate amido as the small diameter end polar group and an extensive hydrophobic group as the large diameter end of the bottle stopper. Both are sodium channel blockers. Zonisamide also blocks calcium-T channels and Topamax increases the effect of GABA and antagonizes glutamate kainic acid/AMPA receptors. Each of the drugs is employed adjunctively against partial seizures.

Benzodiazepines

For details of the chemistry and SARs of the benzodiazepines, see the discussion of anxiolytic-sedative-hypnotic drugs. Among the present clinically useful drugs, the structural features associated with anticonvulsant activity are identical with those associated with anxiolytic-sedative-hypnotic activity.²² Animal models predict that benzodiazepines are modestly effective against generalized tonic-clonic and partial seizures and very highly active

against absence seizures. This difference in seizure control tropism differs markedly from that of the barbiturates, hydantoins, and most other chemical compounds when they are aryl- or diaryl-substituted. Despite the high effectiveness of benzodiazepines as a group in animal models, only a few benzodiazepines have achieved established positions in anticonvulsant therapy. Because selective anticonvulsants should be attainable among agents acting at GABA_A benzodiazepine allosteric modulatory sites, the number may increase in the future. A problem with the benzodiazepines has been decreased effectiveness over time. When physiological adaptation of this type occurs, it usually happens with sedative agents. If sedation were divorced from anticonvulsant action, possibly the latter might be sustained.

Clonazepam, USP. Clonazepam 5-(2-chlorophenyl)-3-dihydro-7-nitro-2H-1,4-benzodiazepin-2-one (Klonopin), partially selective at benzodiazepine allosteric binding sites on GABA_A receptors, is useful in absence seizures and in myoclonic seizures. Tolerance to the anticonvulsant effect often develops, a common problem with the benzodiazepines. Metabolism involves hydroxylation of the 3 position, followed by glucuronidation and nitro group reduction, followed by acetylation.

Diazepam. For details on diazepam (Valium) see its discussion under anxiolytics and sedative-hypnotic agents. The drug is mainly useful in treating generalized tonic-clonic status epilepticus, which is an ongoing and potentially fatal generalized tonic-clonic seizure.

Chlorazepate. See the detailed discussion of chlorazepate (Tranxene) in the sedative-hypnotic-anxiolytic section. Its principal anticonvulsant use is adjunctively in complex partial seizures.

Conclusion

Overall, there has been progress in recent years in the introduction of antiseizure drugs. Most of the progress has involved voltage-gated sodium channel blocking drugs.⁵⁶ Good reviews are available.^{57, 58}

Central Nervous System Stimulants

EUGENE I. ISAACSON

This chapter discusses a broad range of agents that stimulate the central nervous system (CNS). The *analeptics* classically are a group of agents with a limited range of use because of the general nature of their effects. The *methylxanthines* have potent stimulatory properties, mainly cortical at low doses but with more general effects as the dose is increased. The *central sympathomimetic agents* amphetamine and close relatives have alerting and antidepressant properties but medically are used more often as anorexigants. The *antidepressant drugs* are used most frequently in depressive disorders and can be broadly grouped into the monoamine oxidase inhibitors (MAOIs), the monoamine reuptake inhibitors, and agents acting on autoreceptors. A small group of miscellaneous acting drugs, which includes a number of hallucinogens, cocaine, and cannabinoids, concludes the chapter.

ANALEPTICS

The traditional analeptics are a group of potent and relatively nonselective CNS stimulants. The convulsive dose lies near their analeptic dose. They can be illustrated by picrotoxinin and pentyleneetetrazole. Both are obsolete as drugs but remain valuable research tools in determining how drugs act. Newer agents, modafinil and doxapram, are more selective and have use in narcolepsy and as respiratory stimulants.

Picrotoxin. Picrotoxinin, the active ingredient of picrotoxin, has the following structure:

Picrotoxinin

According to Jarboe et al.,¹ the encircled hydroxylactonyl moiety is mandatory for activity, with the encircled 2-propenyl group assisting. Picrotoxinin exerts its effects by interfering with the inhibitory effects of γ -aminobutyric acid (GABA) at the level of the GABA_A receptor's chloride channel. The drug is obsolete medically. Pharmacologically, it has been useful in determining mechanisms of action of sedative-hypnotics and anticonvulsants. Butyrolactones bind to the picrotoxinin site.

Pentyleneetetrazole. Pentyleneetetrazole, 6,7,8,9-tetrahydro-5H-tetrazolo[1,5-a]azepine, 1,5-pentamethylenetetrazole (Metrazol), has been used in conjunction with the electroencephalograph to help locate epileptic foci. It is used as a laboratory tool in determining potencies of potential anticonvulsant drugs in experimental animals. The drug acts as a convulsant by interfering with chloride conductance. It binds to an allosteric site on the GABA_A receptor and acts as a negative modulator. Overall, it appears to share similar effects on chloride conductance with several other convulsive drugs, including picrotoxinin.

Pentyleneetetrazole

Modafinil. Modafinil (Provigil) has overall wakefulness-promoting properties similar to those of central sympathomimetics. It is considered an atypical α_1 -norepinephrine (NE) receptor stimulant and is used to treat daytime sleepiness in narcolepsy patients. Adverse reactions at therapeutic doses are reportedly not severe and may include nervousness, anxiety, and insomnia.

Modafinil

Doxapram Hydrochloride, USP. Doxapram, 1-ethyl-4-(2-morpholinoethyl)-3,3-diphenyl-2-pyrrolidinone hydrochloride hydrate (Dopram), has an obscure molecular mechanism of action. Overall, it stimulates respiration by action on peripheral carotid chemoreceptors. It has use as a respiratory stimulant postanesthetically, after CNS depressant drug overdose, in chronic obstructive pulmonary diseases, and in the apneas.

METHYLYXANTHINES

The naturally occurring methylxanthines are caffeine, theophylline, and theobromine. See Table 15-1 for their structures and occurrence and Table 15-2 for their relative potencies.

Caffeine is a widely used CNS stimulant. Theophylline has some medical use as a CNS stimulant, but its CNS-stimulant properties are encountered more often as sometimes severe, and potentially life-threatening, side effects of its use in bronchial asthma therapy. Theobromine has very little CNS activity (probably because of poor physicochemical properties for distribution to the CNS).

Caffeine is often used as it occurs in brewed coffee, brewed tea, and cola beverages. In most subjects, a dosage of 85 to 250 mg of caffeine acts as a cortical stimulant and facilitates clear thinking and wakefulness, promotes an ability to concentrate on the task at hand, and lessens fatigue. As the dose is increased, side effects indicating excessive stimulation (e.g., restlessness, anxiety, nervousness, and tremulousness) become more marked. (They may be present in varying degrees at lower dose levels.) With further increases in dosage, convulsions can occur. A review of the actions of caffeine in the brain with special reference to factors that contribute to its widespread use appears to be definitive.³

The CNS effects of theophylline at low dose levels have

been little studied. At high doses, the tendency to produce convulsions is greater for theophylline than for caffeine. In addition to being cortical stimulants, theophylline and caffeine are medullary stimulants, and both are used as such. Caffeine may be used in treating poisoning from CNS-depressant drugs, though it is not a preferred drug.

The important use of theophylline and its preparations in bronchial asthma is discussed elsewhere. Caffeine also is reported to have valuable bronchodilating properties in asthma. Finally, because of central vasoconstrictive effects, caffeine has value in treating migraine and tension headaches and may have actual analgesic properties in the latter use.

The CNS-stimulating effects of the methylxanthines were once attributed to their phosphodiesterase-inhibiting ability. This action is probably irrelevant at therapeutic doses. Evidence indicates that the overall CNS-stimulant action is related more to the ability of these compounds to antagonize adenosine at A₁ and A_{2A} receptors.³⁻⁶ All of the roles of these receptors are still under study. The adenosine receptor subtypes and their pharmacology have been reviewed.^{3, 7-9} Problems with the present compounds, such as caffeine and theophylline, are lack of receptor selectivity and the ubiquitous nature of the various receptor subtypes.

Caffeine and theophylline have pharmaceutically important chemical properties. Both are weak Brønsted bases. The reported pK_a values are 0.8 and 0.6 for caffeine and 0.7 for theophylline. These values represent the basicity of the imino nitrogen at position 9. As acids, caffeine has a pK_a above 14, and theophylline, a pK_a of 8.8. In theophylline, a proton can be donated from position 7 (i.e., it can act as a Brønsted acid). Caffeine cannot donate a proton from position 7 and does not act as a Brønsted acid at pH values under 14. Caffeine does have electrophilic sites at positions 1, 3, and 7. In addition to its Brønsted acid site at 7, theophylline has electrophilic sites at 1 and 3. In condensed terms, both compounds are electron-pair donors, but only theophylline is a proton donor in most pharmaceutical systems.

Although both compounds are quite soluble in hot water (e.g., caffeine 1:6 at 80°C), neither is very soluble in water at room temperature (caffeine about 1:40, theophylline about 1:120). Consequently, a variety of mixtures or complexes designed to increase solubility are available (e.g., citrated caffeine, caffeine and sodium benzoate, and theophylline ethylenediamine compound [aminophylline]).

Caffeine in blood is not highly protein bound; theophylline is about 50% bound. Differences in the substituent at the 7 position may be involved. Additionally, caffeine is

more lipophilic than theophylline and reputedly achieves higher brain concentrations. The half-life of caffeine is 5 to 8 hours, and that of theophylline, about 3.5 hours. About 1% of each compound is excreted unchanged. The compounds are metabolized in the liver. The major metabolite of caffeine is 1-methyluric acid, and that of theophylline, 1,3-dimethyluric acid.¹⁰ Neither compound is metabolized to uric acid, and they are not contraindicated in gout.

CENTRAL SYMPATHOMIMETIC AGENTS (PSYCHOMOTOR STIMULANTS)

Sympathomimetic agents, whose effects are manifested mainly in the periphery, are discussed in Chapter 16. A few simple structural changes in these peripheral agents produce compounds that are more resistant to metabolism, more non-polar, and better able to cross the blood-brain barrier. These effects increase the ratio of central to peripheral activity, and the agents are designated, somewhat arbitrarily, as *central sympathomimetic agents*.

In addition to CNS-stimulating effects, manifested as excitation and increased wakefulness, many central sympathomimetics exert an anorexiant effect. Central sympathomimetic (noradrenergic) action is often the basis for these effects. Other central effects, notably dopaminergic and serotonergic effects, can be operative, however.¹¹ In some agents, the ratio of excitation and increased wakefulness to anorexiant effects is decreased, and the agents are marketed as anorexiant. Representative structures of this group of compounds are given in Table 15-3. The structures of the anorexiant phendimetrazine and sibutramine and the alerting agents methylphenidate and pemoline, useful in attention-deficient disorders, are given in the text.

Structural features for many of the agents can be visualized easily by considering that within their structure they

contain a β -phenethylamine moiety, and this grouping can give some selectivity for presynaptic or postsynaptic noradrenergic systems. β -Phenethylamine, given peripherally, lacks central activity. Facile metabolic inactivation by monoamine oxidases (MAOs) is held responsible. Branching with lower alkyl groups on the carbon atom adjacent (α) to the amino nitrogen increases CNS rather than peripheral activity (e.g., amphetamine, presumably by retarding metabolism). The α branching generates a chiral center. The *dextro(S)* isomer of amphetamine is up to 10 times as potent as the *levo(R)* isomer for alerting activity and about twice as active as a psychotomimetic agent. Hydroxylation of the ring or hydroxylation on the β carbon (to the nitrogen) decreases activity, largely by decreasing the ability to cross the blood-brain barrier. For example, phenylpropanolamine, with a β -OH, has about 1/100th the ability to cross the blood-brain barrier of its deoxy congener, amphetamine.

Halogenation (F, Cl, Br) of the aromatic ring decreases sympathomimetic activity. Other activities may increase. *p*-Chloroamphetamine has strong central serotonergic activity (and is a neurotoxin, destroying serotonergic neurons in experimental animals).^{12, 13}

Methoxyl or methylenedioxy substitution on the ring tends to produce psychotomimetic agents, suggesting tropism for dopaminergic (D_2) receptors.

N-methylation increases activity (e.g., compare methamphetamine with dextroamphetamine). Di-N-methylation decreases activity. Mono-N substituents larger than methyl decrease excitatory properties, but many compounds retain anorexiant properties. Consequently, some of these agents are used as anorexiant, reportedly with less abuse potential than amphetamine.

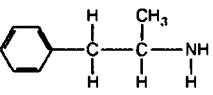

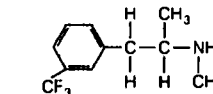

There can be some departure from the basic β -phenethylamine structure when compounds act by indirect noradrenergic mechanisms. A β -phenethylamine-like structure, however, can be visualized in such compounds.

The abuse potential of the more euphoriant and stimulatory of the amphetamines and amphetamine-like drugs is well documented. They produce an exceedingly destructive addiction. Apparently, both a euphoric "high" (possibly related to effects on hedonistic D_2 receptors) and a post-euphoric depression (especially among amine-depleting drugs, contribute to compulsive use of these agents. Abuse of these drugs (especially methamphetamine) in recent years has reached disastrous proportions.

Recognized medical indications for dextroamphetamine and some very close congeners include narcolepsy, Parkinson's disease, attention-deficient disorders, and, although not the preferred agents for obesity, appetite suppression. In some conditions, such as Parkinson's disease, for which its main use is to decrease rigidity, the antidepressant effect of dextroamphetamine can be beneficial. It is also reportedly an effective antidepressant in terminal malignancies. In almost all cases of depression, and especially in major depressive disorders of the unipolar type, however, dextroamphetamine has long been superseded by other agents, notably the MAOIs and the monoamine reuptake inhibiting antidepressants.

The compounds and their metabolites can have complex multiple actions. In a fundamental sense, the structural basis for action is quite simple. The compounds and their metabolites resemble NE and can participate in the various neuro-

and postsynaptic processes involving NE, such as synthesis, release, reuptake, and presynaptic and postsynaptic receptor activation. Also, because dopamine (DA) and, to a lesser extent, serotonin (5-hydroxytryptamine [5-HT]) bear a structural resemblance to NE, processes in DA- and 5-HT-activated systems can be affected. To illustrate the potential complexity, the receptor activations that can be associated with just one parameter, reduction in food intake, reportedly are α_1 , β_1 , β_2 , 5HT_{1B}, 5HT_{2A}, 5HT_{2C}, D₁, and D₂.

PRODUCTS

Amphetamine Sulfate, USP. Amphetamine, (\pm)-1-phenyl-2-aminopropane (Benzedrine), as the racemic mixture has a higher proportion of cardiovascular effects than the *dextro* isomer. For most medical uses, the dextrorotatory isomer is preferred.

Dextroamphetamine Sulfate, USP, and Dextroamphetamine Phosphate. Dextroamphetamine, (+)-(*S*)-methylphenethylamine, forms salts with sulfuric acid (Dexedrine) and with phosphoric acids. The phosphate is the more water-soluble salt and is preferred if parenteral administration is required. The dextrorotatory isomer has the (*S*) configuration and fewer cardiovascular effects than the levorotatory (*R*) isomer. Additionally, it may be up to 10 times as potent as the (*R*) isomer as an alerting agent and about twice as potent a psychotomimetic agent. Although it is a more potent psychotomimetic agent than the (*R*) isomer, it has a better ratio of alerting to psychotomimetic effects.

The major mode of action of dextroamphetamine is release of NE from the mobile pool of the nerve terminal. Other mechanisms, such as inhibition of uptake, may make a small contribution to the overall effects. The alerting actions relate to increased NE available to interact with postsynaptic receptors (α_1). Central β -receptor activation has classically been considered the basis for most of the anorexiant effect.

The psychotomimetic effects are linked to release of DA and activation of postsynaptic receptors. D₂ and mesolimbic D₁ receptors would be involved. Effects on 5-HT systems also have been linked to some behavioral effects of dextroamphetamine. Effects via 5-HT receptors would include 5HT_{1A} receptors and, theoretically, all additional receptors through 5HT₇.

Dextroamphetamine is a strongly basic amine, with values from 9.77 to 9.94 reported. Absorption from the gastrointestinal tract occurs as the lipid-soluble amine. The drug is not extensively protein bound. Varying amounts of the drug are excreted intact under ordinary conditions. The amount is insignificant under conditions of alkaline urine. Under conditions producing systemic acidosis, 60 to 70% of the drug can be excreted unchanged. This fact can be used to advantage in treating drug overdose.

The α -methyl group retards, but does not terminate, metabolism by MAO. Under most conditions, the bulk of a dose of dextroamphetamine is metabolized by N-dealkylation to phenylacetone and ammonia. Phenylacetone is degraded further to benzoic acid.

In experimental animals, about 5% of a dose accumulates in the brain, especially the cerebral cortex, the thalamus, and the corpus callosum. It is first p-hydroxylated and then β -hydroxylated to produce *p*-hydroxynorephedrine, which has

been reported to be the major active metabolite involved in NE and DA release.¹⁴

Methamphetamine Hydrochloride. Methamphetamine, (+)-1-phenyl-2-methylaminopropane hydrochloride desoxyephedrine hydrochloride (Desoxyn), is the *N*-methyl analogue of dextroamphetamine. It has more marked central and less peripheral action than dextroamphetamine. It has a very high abuse potential, and by the intravenous route, its salts are known as "speed." The overall abuse problem presented by the drug is a national disaster. Medicinally acceptable uses of methamphetamine are analogous to those of dextroamphetamine.

Phentermine Ion-Exchange Resin and Phentermine Hydrochloride, USP. The free base is α,α -dimethylphenethylamine, 1-phenyl-2-methylaminopropane. In the resin preparation (Ionamin), the base is bound with an ion-exchange resin to yield a slow-release product; the hydrochloride (Willpowr) is a water-soluble salt.

Phentermine has a quaternary carbon atom with one methyl oriented like the methyl of (*S*)-amphetamine and one methyl oriented like the methyl of (*R*)-amphetamine, and it reportedly has pharmacological properties of both the (*R*) and (*S*) isomers of amphetamine. The compound is used as an appetite suppressant and is a Schedule IV agent, indicating less abuse potential than dextroamphetamine.

Benzphetamine Hydrochloride. Benzphetamine hydrochloride, (+)-*N*-benzyl-*N*, α -dimethylphenethylamine hydrochloride, (+)-1-phenyl-2-(*N*-methyl-*N*-benzylamine)-propane hydrochloride (Didrex), is *N*-benzyl-substituted methamphetamine. The large (benzyl) *N*-substituent decreases excitatory properties, in keeping with the general structure-activity relationship (SAR) for the group. Anorexiant properties are retained. Classically, amphetamine-like drugs with larger than *N*-methyl substituents are cited as anorexiant through central β agonism. No claims for selectivity among β -receptor subtypes have been made in such citations. The compound shares mechanism-of-action characteristics with methylphenidate. Overall, it is said to reduce appetite with fewer CNS excitatory effects than dextroamphetamine.

Diethylpropion Hydrochloride, USP. Because it has two large (relative to H or methyl) *N*-alkyl substituents, diethylpropion hydrochloride, 1-phenyl-2-diethylaminopropane-1-one hydrochloride (Tenuate, Tepanil), has fewer sympathomimetic, cardiovascular, and CNS-stimulatory effects than amphetamine. It is reportedly an anorexiant agent that can be used for the treatment of obesity in patients with hypertension and cardiovascular disease. According to the generalization long used for this group of drugs, increasing *N*-alkyl size reduces central α_1 effects and increases β effects, even though the effects are likely mediated principally by indirect NE release.

Fenfluramine Hydrochloride. Fenfluramine hydrochloride, (\pm)-*N*-ethyl- α -methyl-*m*-(trifluoromethyl)phenethylamine hydrochloride (Pondimin), is unique in this group of drugs, in that it tends to produce sedation rather than

excitation. Effects are said to be mediated principally by central serotonergic, rather than central noradrenergic, mechanisms. In large doses in experimental animals, the drug is a serotonin neurotoxin.¹⁵ It was withdrawn from human use after reports of heart valve damage and pulmonary hypertension. From its structure, more apolar or hydrophobic character than amphetamine, tropism for serotonergic neurons would be expected. Likewise, the structure suggests an indirect mechanism. If an indirect mechanism were operative, then all postsynaptic 5-HT receptors could be activated. Evidence from several studies indicates that the 5HT_{1B} and the 5HT_{2C} receptors are most responsible for the satiety effects of 5-HT. 5-HT may also influence the type of food selected (e.g., lower fatter food intake).¹¹ The (+) isomer, dexfenfluramine (Redux), has a greater tropism for 5-HT systems than the racemic mixture. It, too, was withdrawn because of toxicity.

Phendimetrazine Tartrate, USP. The optically pure compound phendimetrazine tartrate, (2*S*,3*S*)-3,4-dimethyl-2-phenylmorpholine-1-(-)-tartrate (Plegine), is considered an effective anorexiant that is less abuse prone than amphetamine. The stereochemistry of (+)phendimetrazine is as shown.¹⁶

Phendimetrazine Tartrate

Sibutramine. Sibutramine (Meridia) is said to be an uptake inhibitor of NE and 5-HT. These mechanisms fit its structure. It is reportedly an antidepressant and an anorexiant drug. This mechanism implies that activation of all presynaptic and postsynaptic receptors in NE and 5-HT systems is possible. The data are not completely clear, but studies to date indicate that the receptors principally involved are α_1 , β_1 , and 5HT_{2C}.¹¹

Sibutramine

Methylphenidate Hydrochloride, USP. Because methylphenidate (Ritalin) has two asymmetric centers, there are four possible isomers. The *threo* racemate is the mar-

keted compound and is about 400 times as potent as the *erythro* racemate.¹⁷ The absolute configuration of each of the *threo*-methylphenidate isomers has been determined.¹⁸ Considering that the structure is fairly complex (relative to amphetamine), it is likely that one of the two components of the *threo* racemate contains most of the activity. Evidence indicates that the (+) -(2*R*,2'*R*)*threo* isomer is involved principally in the behavioral and pressor effects of the racemate.¹⁹ As is likely with many central psychomotor stimulants, there are multiple modes of action.

Methylphenidate, probably largely via its *p*-hydroxy metabolite, blocks NE reuptake, acts as a postsynaptic agonist, depletes the same NE pools as reserpine, and has effects on dopaminergic systems, such as blocking DA reuptake.

Methylphenidate is an ester drug with interesting pharmacokinetic properties arising from its structure. The pK_a values are 8.5 and 8.8. The protonated form in the stomach reportedly resists ester hydrolysis. Absorption of the intact drug is very good. After absorption from the gastrointestinal tract, however, 80 to 90% of the drug is hydrolyzed rapidly to inactive ritalinic acid.²⁰ (The extent of hydrolysis may be about 5 times that for (+) versus (-).²¹) Another 2 to 5% of the racemate is oxidized by liver microsomes to the inactive cyclic amide. About 4% of a dose of the racemate reportedly reaches the brain in experimental animals and there is *p*-hydroxylation to yield the putative active metabolite.

Methylphenidate is a potent CNS stimulant. Indications include narcolepsy and attention-deficit disorder. The structure of the (2*R*,2'*R*) isomer of the *threo* racemic mixture is shown.

Methylphenidate Hydrochloride

Pemoline. The unique structure of pemoline, 2-amino-5-phenyl-4(5*H*)-oxazoline (Cylert), is shown below.

Pemoline

The compound is described as having an overall effect on the CNS like that of methylphenidate. Pemoline requires 1 to 4 weeks of administration, however, to take effect. A partial explanation for the delayed effect may be that one of the actions of the agent, as observed in rats, is to increase the rate of synthesis of DA.

ANTIDEPRESSANTS

Monoamine Oxidase Inhibitors (MAOIs)

Antidepressant therapy usually implies therapy directed against major depressive disorders of the unipolar type:

is centered around three groups of chemical agents: the MAOIs, the monoamine reuptake inhibitors, and autoreceptor desensitizers and antagonists. Electroshock therapy is another option. The highest cure or remission rate is achieved with electroshock therapy. In some patients, especially those who are suicidal, this may be the preferred therapy. MAOIs and monoamine reuptake inhibitors have about the same response rate (~60 to 70%). In the United States, the latter group is usually chosen over MAOIs for antidepressant therapy.

A severe problem associated with the MAOIs that has been a major factor in relegating them to second-line drug status is that the original compounds inhibit liver MAOs irreversibly in addition to brain MAOs, thereby allowing dietary pressor amines that normally would be inactivated to exert their effects systemically. A number of severe hypertensive responses, some fatal, have followed ingestion of foods high in pressor amines. It was hoped that the development of agents such as selegiline that presumably spare liver MAO might solve this problem. The approach of using MAO selectivity did solve the hypertensive problem, but the compound was not an antidepressant (it is useful in Parkinson's disease). Another approach using a reversible MAOI has yielded antidepressants that lacked the hypertensive "cheese" effect. Another prominent side effect of MAOIs is orthostatic hypotension, said to arise from a block of NE released in the periphery. Actually, one MAOI, pargyline, was used clinically for its hypotensive action. Finally, some of the first compounds produced serious hepatotoxicity. Compounds available today reportedly are safer in this regard but suffer the stigma of association with the older compounds.

The history of MAOI development illustrates the role of serendipity. Isoniazid is an effective antitubercular agent but is a very polar compound. To gain better penetration into the *Mycobacterium tuberculosis* organism, a more hydrophobic compound, isoniazid substituted with an isopropyl group on the basic nitrogen (iproniazid), was designed and synthesized. It was introduced into clinical practice as an effective antitubercular agent. CNS stimulation was noted, however, and the drug was withdrawn. Later, it was determined in experimental animals and in vitro experiments with a purified MAO that MAO inhibition, resulting in higher synaptic levels of NE and 5-HT, could account for the CNS effects. The compound was then reintroduced into therapy as an antidepressant agent. It stimulated an intense interest in hydrazines and hydrazides as antidepressants and inaugurated effective drug treatment of depression.²² It continued to be used in therapy for several years but eventually was withdrawn because of hepatotoxicity.

The present clinically useful irreversible inactivators can be considered mechanism-based inhibitors of MAO.²³ They are converted by MAO to agents that inhibit the enzyme. They can form reactants that bond covalently with the enzyme or its cofactor. A consequence of irreversible inactivation is that the action of the agents may continue for up to 2 weeks after administration is discontinued. Consequently, many drugs degraded by MAO or drugs that elevate levels of MAO substrates cannot be administered during that time.

For a long time, because the agents that opened the field and then dominated it were irreversible inactivators, MAO

inhibition was almost always regarded as irreversible. From the beginning, however, it was known that it was possible to have agents that act exclusively by competitive enzyme inhibition. For example, it has long been known that the harmful alkaloids harmine and harmaline act as CNS stimulants by competitive inhibition of MAO. Reversible (competitive) inhibitors selective for each of the two major MAO subtypes (A and B) are reportedly forthcoming.

Moclobemide has received considerable attention abroad. A reversible inhibitor of MAO-A, it is considered an effective antidepressant and permits metabolism of dietary tyramine.²⁴ Metabolites of the drug are implicated in the activity. Reversible inhibitors of MAO-A (RIMAs) reportedly are antidepressants without producing hypertensive crises. Reversible inhibitors of MAO-B have also been studied. Presently, selective MAO-B inhibition has failed to correlate positively with antidepressant activity; selegiline, however, has value in treating Parkinson's disease.

The clinically useful MAOI antidepressants are nonselective between inhibiting metabolism of NE and 5-HT. Agents selective for a MAO that degrades 5-HT have been under study for some time. The structures of phenelzine and tranylcypromine are given in Table 15-4.

Phenelzine Sulfate, USP. Phenelzine sulfate, 2-(phenylethyl)hydrazine sulfate (Nardil), is an effective antidepressant agent. A mechanism-based inactivator, it irreversibly inactivates the enzyme or its cofactor, presumably after oxidation to the diazine, which can then break up into molecular nitrogen, a hydrogen atom, and a phenethyl free radical. The latter would be the active species in irreversible inhibition.²⁵

Tranylcypromine Sulfate, USP. Tranylcypromine sulfate, (±)-trans-2-phenylcyclopropylamine sulfate (Parnate), was synthesized to be an amphetamine analogue (visualize the α-methyl of amphetamine condensed onto the β-carbon atom).²⁶ It does have some amphetamine-like properties, which may be why it has more immediate CNS stimulant effects than agents that act by MAO inhibition alone. For MAO inhibition, there may be two components to the

TABLE 15-4 Monoamine Oxidase Inhibitors

Generic Name Proprietary Name	Structure
Phenelzine sulfate, USP Nardil	
Tranylcypromine sulfate, USP Parnate	

action of this agent. One is thought to arise because tranylcypromine has structural features (the basic nitrogen and the quasi- π character of the α - and β -cyclopropane carbon atoms) that approximate the transition state in a route of metabolism of β -arylamines.^{27, 28} As α - and β -hydrogen atoms are removed from the normal substrate of the enzyme, the quasi- π character develops over the α, β -carbon system. Duplication of the transition state permits extremely strong, but reversible, attachment to the enzyme. Additionally, tranylcypromine is a mechanism-based inactivator. It is metabolized by MAO, with one electron of the nitrogen pair lost to flavin. This, in turn, produces homolytic fission of a carbon-carbon bond of cyclopropane, with one electron from the fission pairing with the remaining lone nitrogen electron to generate an imine (protonated) and with the other residing on a methylene carbon. Thus, a free radical is formed that reacts to form a covalent bond with the enzyme or with reduced flavin to inactivate the enzyme.²⁹

Monoamine Reuptake Inhibitors

Originally, the monoamine reuptake inhibitors were a group of closely related agents, the tricyclic antidepressants, but now they are quite diverse chemically. Almost all of the agents block neuronal reuptake of NE or 5-HT or both (i.e., are selective).

Reuptake inhibition by these agents is at the level of the respective monoamine transporter via competitive inhibition of binding of the monoamine to the substrate-binding compartment. Probably the same site on the protein is involved for inhibitor and monoamine, but this has not yet been proved. The mechanism of reuptake by monoamine transporters has been reviewed.³⁰

The net effect of the drug is to increase the level of the monoamine in the synapse. Sustained high synaptic levels of 5-HT, NE, or both appear to be the basis for the antidepressant effect of these agents. There is a time lag of 2 or more weeks before antidepressant action develops. It is considered that (in the case of 5-HT) 5HT_{1A} receptors and (in the case of NE) α_2 receptors undergo desensitization and transmitter release is maintained. Of course activation of postsynaptic receptors and sustained transmission is the ultimate result of sustained synaptic levels of neurotransmitter.³¹

Tricyclic Antidepressants

The SARs for the TCAs are compiled in detail in the eighth edition of this text.³² The interested reader is referred to this compilation. In summary, there is a large, bulky group encompassing two aromatic rings, preferably held in a skewed arrangement by a third central ring, and a three- or, sometimes, two-atom chain to an aliphatic amino group that is monomethyl- or dimethyl-substituted. The features can be visualized by consulting the structures of imipramine and desipramine as examples. The overall arrangement has features that approximate a fully extended *trans* conformation of the β -arylamines. To relate these features to the mechanism of action, reuptake block, visualize that the basic arrangement is the same as that found in the β -arylamines, plus an extra aryl bulky group that enhances affinity for

the substrate-binding compartment of the transporter. The overall concept of a β -arylamine-like system with added structural bulk, usually an aryl group, appears to be applicable to many newer compounds—selective serotonin reuptake inhibitors (SSRIs), selective norepinephrine reuptake inhibitors (SNRIs)—that do not have a tricyclic grouping.

The TCAs are structurally related to each other and, consequently, possess related biological properties that can be summarized as characteristic of the group. The dimethylamino compounds tend to be sedative, whereas the monomethyl relatives tend to be stimulatory. The dimethyl compounds tend toward higher 5-HT to NE reuptake block ratios: in the monomethyl compounds, the proportion of NE uptake block tends to be higher and in some cases is considered selective NE reuptake. The compounds have anticholinergic properties, usually higher in the dimethylamino compounds. When treatment is begun with a dimethyl compound, a significant accumulation of the monomethyl compound develops as N-demethylation proceeds.

The TCAs are extremely lipophilic and, accordingly, very highly tissue bound outside the CNS. Since they have anticholinergic and noradrenergic effects, both central and peripheral side effects are often unpleasant and sometimes dangerous. In overdose, the combination of effects, as well as a quinidine-like cardiac depressant effect, can be lethal. Overdose is complicated because the agents are so highly protein bound that dialysis is ineffective.

PRODUCTS

Imipramine Hydrochloride, USP. Imipramine hydrochloride, 5-[3-(dimethylamino)propyl]-10,11-dihydro-5H-dibenz[*b,f*]azepine monohydrochloride (Tofranil), is the lead compound of the TCAs. It is also a close relative of the antipsychotic phenothiazines (replace the 10–11 bridge with sulfur, and the compound is the antipsychotic agent promazine). It has weaker D₂ postsynaptic blocking activity than promazine and mainly affects amines (5-HT, NE, and DA) via the transporters. As is typical of dimethylamino compounds, anticholinergic and sedative (central H₁ block) effects tend to be marked. The compound per se has a tendency toward a high 5-HT-to-NE uptake block ratio and probably can be called a serotonin transport inhibitor (SERTI). Metabolic inactivation proceeds mainly by oxidative hydroxylation in the 2 position, followed by conjugation with glucuronic acid of the conjugate. Urinary excretion predominates (about 75%), but some biliary excretion (up to 25%) can occur, probably because of the large nonpolar grouping. Oxidative hydroxylation is not as rapid or complete as that of the more nucleophilic ring phenothiazine antipsychotics; consequently, appreciable N-demethylation occurs, with a buildup of norimipramine (or desimipramine).

The demethylated metabolite is less anticholinergic, less sedative, and more stimulatory and is a SNRI.³¹ Consequently, a patient treated with imipramine has two compounds that contribute to activity. Overall, the effect is nonselective 5-HT versus NE reuptake. The activity of des- or norimipramine is terminated by 2-hydroxylation, followed by conjugation and excretion. A second N-demethylation

can occur, which in turn is followed by 2-hydroxylation, conjugation, and excretion.

Desipramine Hydrochloride, USP. The structure and salient properties of desipramine hydrochloride, 10,11-dihydro-*N*-methyl-5*H*-dibenzo[*b,f*]azepine-5-propanamine monohydrochloride, 5-(3-methylaminopropyl)-10,11-dihydro-5*H*-dibenzo[*b,f*]azepine hydrochloride (Norpramin, Perto-frane), are discussed under the heading, Imipramine, above. Among tricyclics, desipramine would be considered when few anticholinergic effects or a low level of sedation are important. It is a SNERI.³¹

Clomipramine Hydrochloride. Clomipramine (Anafranil) is up to 50 times as potent as imipramine in some bioassays. This does not imply clinical superiority, but it might be informative about tricyclic and, possibly, other reuptake inhibitors. The chloro replacing the H substituent could increase potency by increasing distribution to the CNS, but it is unlikely that this would give the potency magnitude seen. It might be conjectured that a H bond between the protonated amino group (as in vivo) and the unshared electrons of the chloro substituent might stabilize a β -arylamine-like shape and give more efficient competition for the transporter. The drug is an antidepressant. It is used in obsessive-compulsive disorder, an anxiety disorder that may have an element of depression.

Amitriptyline Hydrochloride, USP. Amitriptyline, 3-(10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-ylidene)-*N,N*-dimethyl-1-propanamine hydrochloride, 5-(3-dimethylaminopropylidene)-10,11-dihydro-5*H*-dibenzo[*a,d*]cycloheptene hydrochloride (Elavil), is one of the most anticholinergic and sedative of the TCAs. Because it lacks the ring electron-enriching nitrogen atom of imipramine, metabolic inactivation mainly proceeds not at the analogous 2 position but at the benzylic 10 position (i.e., toluene-like metabolism predominates). Because of the 5-exocyclic double bond, *E*- and *Z*-hydroxy isomers are produced by oxidation metabolism. Conjugation produces excretable metabolites. As is typical of the dimethyl compounds, *N*-demethylation occurs, and nortriptyline is produced, which has a less anticholinergic, less sedative, and more stimulant action than amitripty-

line. Nortriptyline is a SNERI³¹; the composite action of drug and metabolite is nonselective.

Nortriptyline Hydrochloride, USP. Pertinent biological and chemical properties for nortriptyline, 3-(10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-ylidene)-*N*-methyl-1-propanamine hydrochloride, 5-(3-methylaminopropylidene)-10,11-dihydro-5*H*-dibenzo[*a,d*]cycloheptene hydrochloride (Aventyl, Pamelor), are given above in the discussion of amitriptyline. Metabolic inactivation and elimination are like those of amitriptyline. Nortriptyline is a selective NE transporter (NET) inhibitor.³¹

Protriptyline Hydrochloride, USP. Protriptyline hydrochloride, *N*-methyl-5*H*-dibenzo[*a,d*]cycloheptene-5-propylamine hydrochloride, 5-(3-methylaminopropyl)-5*H*-dibenzo[*a,d*]cycloheptene hydrochloride (Vivactil), like the other compounds under consideration, is an effective antidepressant. The basis for its chemical naming can be seen by consulting the naming and the structure of imipramine. Protriptyline is a structural isomer of nortriptyline. Inactivation can be expected to involve the relatively localized double bond. Because it is a monomethyl compound, its sedative potential is low.

Trimipramine Maleate. For details of chemical nomenclature, consult the description of imipramine. Replacement of hydrogen with an α -methyl substituent produces a chiral carbon, and trimipramine (Surmontil) is used as the racemic mixture. Biological properties reportedly resemble those of imipramine.

Doxepin Hydrochloride, USP. Doxepin, 3-dibenzo[*b,e*]-oxepin-11(6*H*)ylidene-*N,N*-dimethyl-1-propanamine

hydrochloride. *N,N*-dimethyl-3-(dibenz[*b,e*]oxepin-11(6*H*)-ylidene)propylamine (Sinequan, Adapin), is an oxa congener of amitriptyline, as can be seen from its structure.

The oxygen is interestingly placed and should influence oxidative metabolism as well as postsynaptic and presynaptic binding affinities. The (*Z*) isomer is the more active, although the drug is marketed as the mixture of isomers. The drug overall is a NE and 5-HT reuptake blocker with significant anticholinergic and sedative properties. It can be anticipated that the nor- or des- metabolite will contribute to the overall activity pattern.

Doxepin Hydrochloride

Maprotiline Hydrochloride, USP. Maprotiline hydrochloride, *N*-methyl-9,10-ethanoanthracene-9(10*H*)-propanamine hydrochloride (Ludiomil), is sometimes described as a tetracyclic rather than a tricyclic antidepressant. The description is chemically accurate, but the compound, nonetheless, conforms to the overall TCA pharmacophore. It is a dibenzobicyclooctadiene and can be viewed as a TCA with an ethylene-bridged central ring. The compound is not strongly anticholinergic and has stimulant properties. It can have effects on the cardiovascular system. It is a SNRI.³¹

Maprotiline Hydrochloride

Amoxapine. Consideration of the structure of amoxapine, 2-chloro-11-(1-piperazinyl)dibenz-[*b,f*] [1,4]oxazepine (Asendin), reinforces the fact that many antidepressants are very closely related to antipsychotics. Indeed, some, including amoxapine, have significant effects at D₂ receptors. The *N*-methyl-substituted relative of amoxapine is the antipsychotic loxapine (Loxitane). The 8-hydroxy metabolite of amoxapine is reportedly active as an antidepressant and as a D₂ receptor blocker.

Amoxapine

Selective Serotonin Reuptake Inhibitors

Structurally, the SSRIs differ from the tricyclics, in that the tricyclic system has been taken apart in the center. (This

abolishes the center ring, and one ring is moved slightly forward from the tricyclic "all-in-a-row" arrangement.) The net effect is that the β -arylamino-like grouping is present, as in the tricyclics, and the compounds can compete for the substrate-binding site of the serotonin transporter protein (SERT). As in the tricyclics, the extra aryl group can add extra affinity and give favorable competition with the substrate, serotonin.

Many of the dimethylamino tricyclics are, in fact, SSRIs. Since they are extensively *N*-demethylated in vivo to nor-compounds, which are usually SNERIs, however, the overall effect is not selective. Breaking up the tricyclic system breaks up an anticholinergic pharmacophoric group and gives compounds with diminished anticholinergic effects. Overall, this diminishes unpleasant CNS effects and increases cardiovascular safety. Instead, side effects related to serotonin predominate.

Fluoxetine. In fluoxetine (Prozac), protonated in vivo the protonated amino group can H-bond to the ether oxygen electrons, which can generate the β -arylamino-like group, with the other aryl serving as the characteristic "extra" aryl. The *S* isomer is much more selective for SERT than for NET. The major metabolite is the *N*-demethyl compound, which is as potent as the parent and more selective (SERT versus NET).

Therapy for 2 or more weeks is required for the antidepressant effect. Somatodendritic 5HT_{1A} autoreceptor desensitization with chronic exposure to high levels of 5-HT is the accepted explanation for the delayed effect for this and other serotonin reuptake inhibitors.

To illustrate a difference between selectivity for a SERT and a NET, if the *para* substituent is moved to the *ortho* position (and is less hydrophobic, typically), a NET is obtained. This and other SERTs have anxiolytic activity. One of several possible mechanisms would be agonism of 5HT_{1A} receptors, diminishing synaptic 5-HT. Presumably, synaptic levels of 5-HT might be high in an anxious state.

Fluoxetine

Paroxetine. In the structure of paroxetine (Paxil), a amino group, protonated in vivo could H-bond with the -CH₂-O- unshared electrons. A β -arylamino-like structure with an extra aryl group results. The compound is a very highly selective SERT. As expected, it is an effective antidepressant and anxiolytic.

Paroxetine

Sertraline. Inspection of sertraline (Zoloft) (15.45) reveals the pharmacophore for SERT inhibition. The Cl substituents also predict tropism for a 5-HT system. The depicted stereochemistry is important for activity.

Fluvoxamine. The *E* isomer of fluvoxamine (Luvox) (shown) can fold after protonation to the β -arylamine-like grouping. Here the "extra" hydrophobic group is aliphatic.

Citalopram. Citalopram (Celexa) is a racemic mixture and is very SERT selective. The N-monodemethylated compound is slightly less potent but is as selective. The aryl substituents are important for activity. The ether function is important and probably interacts with the protonated amino group to give a suitable shape for SERT binding.

Selective Norepinephrine Reuptake Inhibitors

The discussion of fluoxetine opened the subject of SNERIs. That is, movement of a *para* substituent of fluoxetine (and relatives) to an *ortho* position produces a SNERI.

Nisoxetine is a SNERI and is an antidepressant. Most activity resides in the β isomer.

Reboxetine. Most of the activity of reboxetine resides in the *S,S* isomer (The marketed compound is *RR* and *SS*.) It is claimed to be superior to fluoxetine in severe depression. It is marketed in Europe. At least three tricyclic compounds, desipramine, nortriptyline, and the technically tetracyclic maprotiline are SNERIs. They, of course, have typical characteristic TCA side effects but lower anticholinergic and H_1 -antihistaminic (sedative) effects than dimethyl compounds. SNERIs are clinically effective antidepressants.

It would be expected that in the case of SNERIs, α_2 presynaptic receptors would be desensitized, after which sustained NE transmission would be via one or more postsynaptic receptors: α_1 , β_1 , and β_2 receptors are possibilities.

Newer (Nontricyclic) Nonselective 5-HT and NE Reuptake Inhibitors

Presently, one such compound is clinically used in the United States.

Venlafaxine. The structure and activity of venlafaxine (Effexor) are in accord with the general SARs for the group. As expected, it is an effective antidepressant.

Selective Serotonergic Reuptake Inhibitors and 5HT_{2A} Antagonists

The SSRIs and 5HT_{2A} antagonists are represented by trazodone (Desyrel) and nefazodone (Serzone).

The structures of these two compounds derive from those of the fluorobutyrophenone antipsychotics. They have β -arylamine-like structures that permit binding to the SERT

and inhibit 5-HT reuptake. In these compounds, the additional hydrophobic substituent can be viewed as being attached to the nitrogen of the β -arylamine-like group. Additionally, they are 5HT_{2A} antagonists. That antagonism may or may not afford antipsychotic effectiveness is discussed under antipsychotics. 5HT_{2A} antagonists appear to have antidepressant and anxiolytic activities. They may act, at least in part, by enhancing 5HT_{1A} activities.³³ Also, some of the effects may be mediated through 5HT_{2C} agonism (perhaps generally so for 5-HT-acting antidepressants.) Some of the side effects of SSRIs are considered to be mediated through 5HT_{2A} receptors, so a 5HT_{2A} blocker would reduce them.³³ The two compounds yield the same compound on N-dealkylation. It is a serotonin reuptake inhibitor.

5HT_{1A} Agonists and Partial Agonists

Buspirone. The initial compound in this series, buspirone (BuSpar), has anxiolytic and antidepressant activities and is a partial 5HT_{1A} agonist. Its anxiolytic activity is reportedly due to its ability to diminish 5-HT release (via 5HT_{1A} agonism). High short-term synaptic levels of 5-HT are characteristic of anxiety. Also, since it is a partial agonist, it can stimulate postsynaptic receptors when 5-HT levels are low in the synapse, as is the case in depression. A number of other spiroenes are in development as anxiolytics and antidepressants.³⁴

α_2 Antagonists

Mirtazapine. Mirtazapine (Remeron) was recently introduced for clinical use in the United States; its parent mianserin (pyridyl N replaced with C-H) was long known to be an antidepressant. It is reported to be faster acting and more potent than certain SSRIs. The mode of action gives increased NE release via α_2 -NE receptor antagonism and increased 5-HT release via antagonism of NE α_2 heteroreceptors located on serotonergic neurons.^{33, 34}

Miscellaneous Antidepressants

Bupropion. The mechanism of action of bupropion (Wellbutrin) is considered complex and reportedly involves a block of DA reuptake via the dopamine transporter (DAT), but the overall antidepressant action is noradrenergic. A metabolite that contributes to the overall action and its formation can be easily rationalized.

MISCELLANEOUS CNS-ACTING DRUGS

This section deals with a collection of drugs that do not fit easily under other topic headings in this chapter or the chapter on CNS depressants. All of the drugs are drugs of abuse and could be organized under that heading.

The β -arylamino hallucinogens arose because of interest in the naturally occurring hallucinogens psilocin and mescaline and in modifying the amphetamines, which were popular drugs at the time. Lysergic acid diethylamide was accidentally discovered during research on ergot alkaloids. It is of scientific interest because it serves as one model for clinical psychosis. Phenacyclidine is scientifically interesting because it gives information about the ionotropic *N*-methyl-D-aspartate glutamic acid receptor, and its CNS effects serve as a model for schizophrenia.

Cocaine as a CNS stimulant is a pernicious drug of abuse. Research on why it is so strongly addictive and on drug measures that might mitigate its effects has been intense in the past two decades.

Δ^9 -Tetrahydrocannabinol and its relatives were studied for many years to determine the SARs. The field was greatly stimulated with the discovery of the endogenous cannabinoid receptors. Presently, the endogenous cannabinoid system is under investigation.

1 β -Arylamino Hallucinogens

A property of the 1 β -arylamino hallucinogens is alteration of the perception of stimuli. Reality is distorted, and the user may undergo depersonalization. Literally, the effects are those of a psychosis. Additionally, the drugs can produce anxiety, fear, panic, frank hallucinations, and additional symptoms that may be found in a psychosis. Accordingly, they are classed as hallucinogens and psychotomimetics.

This group can be subgrouped into those that possess an indolethylamine moiety, those that possess a phenylethylamine moiety, and those with both. In the first group, there is a structural resemblance to the central neurotransmitter 5-HT, and in the second, there is a structural resemblance to NE and DA. This resemblance is suggestive, and there may be some selectivity of effects on the respective transmitter systems. With structures of the complexity found in many of these agents, however, a given structure may possibly affect not just the closest structurally related neurotransmitter systems but other systems as well. Thus, a phenethylamine system could affect not only NE and DA systems but also 5-HT systems, and an indolethylamine system could affect not only 5-HT but also NE and DA systems.

INDOLETHYLAMINES

Dimethyltryptamine. Dimethyltryptamine is a very weak hallucinogen, active only by inhalation or injection, with a short duration of action. It possesses pronounced sympathomimetic (NE) side effects.

Psilocybin and Psilocin. Psilocybin is the phosphoric acid ester of psilocin and appears to be converted to psilocin as the active species in vivo. It occurs in a mushroom, *Psilocybe mexicana*. Both drugs are active orally, with a short duration of action.

Synthetic α -methyl-substituted relatives have a much longer duration of action and enhanced oral potency.³⁵ This suggests that psilocin is metabolized by MAOs.

Dimethyltryptamine $R_4 = R_5 = H$
 Psilocybin $R_4 = OPO(OH)_2$, $R_5 = H$
 Psilocin $R_4 = OH$, $R_5 = H$

2-PHENYLETHYLAMINES

Mescaline. Mescaline, 3,4,5-trimethoxyphenethylamine, is a much-studied hallucinogen with many complex effects on the CNS. It occurs in the peyote cactus. The oral dose required for its hallucinogenic effects is very high, as much as 500 mg of the sulfate salt. The low oral potency probably results from facile metabolism by MAO. α -Methylation increases CNS activity. Synthetic α -methyl-substituted relatives are more potent.^{35, 36} The drugs DOM, MDA, and MDMA (ecstasy) are extremely potent, dangerous drugs of abuse.

Mescaline

1-(2,5-Dimethoxy-4-methylphenyl)-2-aminopropane
(DOM, STP)

3,4-Methylenedioxyamphetamine
(MDA)

MDMA (ecstasy)

The presence of methoxy or dioxymethylene (methylenedioxy) substituents on a 2-phenethylamine system is a characteristic of many psychotomimetic compounds and strongly suggests DA involvement.

AGENT POSSESSING BOTH AN INDOLETHYLAMINE AND A PHENYLETHYLAMINE MOIETY

(+)-Lysergic Acid Diethylamide. Both an indolethylamine group and a phenylethylamine group can be seen in the structure of the extraordinarily potent hallucinogen lysergic acid diethylamide (LSD). The stereochemistry is exceedingly important. Chirality, as shown, must be maintained or activity is lost; likewise, the location of the double bond, as shown, is required.³⁷ Experimentally, LSD has marked effects on serotonergic and dopaminergic neurons. The bases for all of its complex CNS actions are not completely understood, however. Recently, its actions have been suggested as being more typical of schizophrenic psychotic reactions than the model based on amphetamine. For more on this, see the discussion of atypical antipsychotics (Chapter 14).

Lysergic Acid Diethylamide

Dissociative Agents

Phencyclidine. Phencyclidine (PCP) was introduced as a dissociative anesthetic for animals. Its close structural relative ketamine is still so used and may be used in humans (Chapter 14). In humans, PCP produces a sense of intoxication, hallucinogenic experiences not unlike those produced by the anticholinergic hallucinogens, and often amnesia.

The drug affects many systems, including those of NE, DA, and 5-HT. It has been proposed that PCP (and certain other psychotomimetics) produces a unique pattern of activation of ventral tegmental area dopaminergic neurons.³⁸ It blocks glutamergic *N*-methyl-D-aspartate receptors.³⁹ This action is the basis for many of its CNS effects. PCP itself appears to be the active agent. The psychotic state produced by this drug is also cited as a better model than amphetamine psychosis for the psychotic state of schizophrenia.⁴⁰

Phencyclidine Hydrochloride

Euphoriant-Stimulant

Cocaine. Cocaine as a euphoriant-stimulant, psychotomimetic, and drug of abuse could as well be discussed with amphetamine and methamphetamine, with which it shares many biological properties. At low doses, it produces feelings of well-being, decreased fatigue, and increased alertness. Cocaine tends to produce compulsive drug-seeking behavior, and a full-blown toxic psychosis may emerge. Many of these effects appear to be related to the effects of increased availability of DA for interaction with postsynaptic receptors. (D_2 and D_1 receptors are pertinent). Cocaine is a potent DA reuptake blocker, acting by competitive inhibition of the DAT. A phenethylamine moiety with added steric bulk may suffice for this action. An interaction between a hydrogen atom on the nitrogen of the protonated form of cocaine and an oxygen of the benzoyl ester group, or alternatively, an interaction between the unshared electron pair of the free-base nitrogen and the carbonyl of the benzoyl ester group, could approximate this moiety.

Cocaine

Considerable research on drugs affecting the DAT has been published in recent years. A review of pharmacotherapeutic agents for cocaine abuse is available.⁴¹

Depressant-Intoxicant

Δ^1 -Tetrahydrocannabinol or Δ^9 -THC. There are two conventions for numbering THC: that arising from terpenoid chemistry produces Δ^1 -THC, and that based on the dibenzopyran system results in a Δ^9 -THC designation. The terpenoid convention is used here.

1-(-)- Δ^1 -trans-Tetrahydrocannabinol

THC is a depressant with apparent stimulant sensations arising from depression of higher centers. Many effects, reputedly subjectively construed as pleasant, are evident at low doses. The interested reader may consult a pharmacology text for a detailed account. At higher doses, psychotomimetic actions, including dysphoria, hallucinations, and paranoia, can be marked. Structural features associated with activity among cannabis-derived compounds have been reviewed.⁴² Notably, the phenolic OH is required for activity. Certain SARs (especially separation of potency between enantiomers) for cannabinoids suggested action at receptors.⁴³ Two receptors for THC have been discovered. The relevant receptor for CNS actions is CB_1 .⁴⁴ CB_2 occurs in immune tissues. The first natural ligand found for the receptor is the amide derivative of arachidonic acid, anandamide.⁴⁵ Other natural cannabinoids are arachidonic acid 2-glycerol ester and 2-arachidonyl glycerol ether.⁴⁶ The endogenous cannabinoid system appears to function as a retrograde messenger system at both stimulatory synapses and depressant synapses. The synaptic transmitter causes postsynaptic synthesis of endocannabinoids that are then transported to CB_1 receptors located presynaptically where they fine-tune both excitatory and inhibitory neurons.⁴⁷⁻⁵¹ Because CB_1 receptors appear to be present in all brain areas and affect both excitatory and inhibitory systems, the prospect of developing selective cannabinoid drugs acting at receptors is considered the most promising research route.

Endocannabinoids, as regulated by leptin, are also involved in maintaining food intake and in other behaviors.⁵²⁻⁵³

Adrenergic Agents

RODNEY L. JOHNSON

Adrenergic drugs are chemical agents that exert their principal pharmacological and therapeutic effects by either enhancing or reducing the activity of the various components of the sympathetic division of the autonomic nervous system. In general, substances that produce effects similar to stimulation of sympathetic nervous activity are known as *sympathomimetics* or *adrenergic stimulants*. Those that decrease sympathetic activity are referred to as *sympatholytics*, *antiadrenergics*, or *adrenergic-blocking agents*. Because of the important role that the sympathetic nervous system plays in the normal functioning of the body, adrenergic drugs find wide use in the treatment of a number of diseases. In addition to their effects on sympathetic nerve activity, a number of adrenergic agents produce important effects on the central nervous system (CNS). In this chapter, those agents that affect adrenergic neurotransmission and those that act directly on the various types of adrenergic receptors are discussed.

ADRENERGIC NEUROTRANSMITTERS

Structure and Physicochemical Properties

Norepinephrine (NE) is the neurotransmitter of the postganglionic sympathetic neurons. As a result of sympathetic nerve stimulation, it is released from sympathetic nerve endings into the synaptic cleft, where it interacts with specific presynaptic and postsynaptic adrenergic receptors. Another endogenous adrenergic receptor agonist is epinephrine. This compound is not released from peripheral sympathetic nerve endings, as is NE. Rather, it is synthesized and stored in the adrenal medulla, from which it is released into the circulation. Thus, epinephrine is often referred to as a neurohormone. Epinephrine is also biosynthesized in certain neurons of the CNS, where both it and NE serve as neurotransmitters.

Norepinephrine: R = H

Epinephrine: R = CH₃

Epinephrine and NE belong to the chemical class of substances known as the *catecholamines*. This name was given to these compounds because they contain an amino group attached to an aromatic ring that contains two hydroxyl

groups situated *ortho* to each other, the same arrangement of hydroxyl groups as found in catechol. Aromatic compounds that contain such an arrangement of hydroxyl substituents are highly susceptible to oxidation. Catecholamines, such as epinephrine and NE, undergo oxidation in the presence of oxygen (air) or other oxidizing agents to produce *ortho*-quinone-like compounds, which undergo further reactions to give mixtures of colored products. Hence, solutions of catecholamine drugs often are stabilized by the addition of an antioxidant (reducing agent) such as ascorbic acid or sodium bisulfite.

Catechol

ortho-Quinone

Epinephrine and NE each possess a chiral carbon atom, thus, each can exist as an enantiomeric pair of isomers. The enantiomer with the (*R*) configuration is biosynthesized by the body and possesses the biological activity.

Catecholamines are polar substances that contain both acidic (the aromatic hydroxyls) and basic (the aliphatic amine) functional groups. For example, the pK_a values for the epinephrine cation are 8.7 and 9.9 and are attributed to the phenolic hydroxyl group and the protonated amino group, respectively. Ganellin¹ calculated the relative populations of the various ionized and nonionized species of NE and epinephrine at pH 7.4 and found that the cation form (Fig. 16-1A) is present to an extent slightly greater than 95% for both catecholamines. The zwitterionic form (Fig. 16-1B), in which the aliphatic amine is protonated and one of the phenolic hydroxyl groups is ionized, is present to about 3%. Thus, at physiological pH, less than 2% of either epinephrine or NE exists in the nonionized form. This largely accounts for the high water solubility of these compounds as well as other catecholamines, such as isoproterenol and dopamine.

Biosynthesis

The biosynthesis of the catecholamines dopamine, NE, and epinephrine involves a sequence of enzymatic reactions, as illustrated in Figure 16-2. Catecholamine biosynthesis takes place in adrenergic and dopaminergic neurons in the CNS in sympathetic neurons of the autonomic nervous system, and in the adrenal medulla. The amino acid L-tyrosine serves as the precursor for the catecholamines. It is transported actively into the axoplasm, where it is acted on by tyrosine 3-monooxygenase (tyrosine hydroxylase) to form L-3,4-dihydroxyphenylalanine (L-dopa). Tyrosine hydroxylase is a Fe²⁺-containing enzyme that requires molecular oxygen as

Figure 16-1 ■ Cationic (**A**) and zwitterionic (**B**) forms of norepinephrine ($R = H$) and epinephrine ($R = CH_3$)

Figure 16-2 ■ Biosynthesis of the catecholamines dopamine, norepinephrine, and epinephrine.

uses tetrahydrobiopterin as a cofactor. The enzyme plays a key role in the regulation of catecholamine biosynthesis, as it is the rate-limiting step. For example, adrenergic nerve stimulation leads to activation of a protein kinase that phosphorylates tyrosine hydroxylase, thereby increasing its activity.³ In addition, through end-product inhibition, NE markedly reduces tyrosine hydroxylase activity. The basis of this feedback inhibition is believed to be a competition between the catecholamine product and the pterin cofactor.

The second enzymatic step in catecholamine biosynthesis is the decarboxylation of L-dopa to give dopamine. The enzyme that carries out this transformation is L-aromatic amino acid decarboxylase (dopa decarboxylase). It is a cytoplasmic enzyme that uses pyridoxal phosphate as a cofactor. In addition to being found in catecholaminergic neurons, L-aromatic amino acid decarboxylase is found in high concentrations in many other tissues, including the liver and kidneys. It exhibits broad substrate specificity, in that aromatic amino acids, such as L-tyrosine, L-phenylalanine, L-histidine, and L-tryptophan, in addition to L-dopa and L-5-hydroxytryptophan, serve as substrates.

The dopamine formed in the cytoplasm of the neuron is actively transported into storage vesicles, where it is hydroxylated stereospecifically by the Cu^{2+} -containing enzyme dopamine β -monooxygenase (dopamine β -hydroxylase) to give NE. Dopamine β -hydroxylase requires molecular oxygen and uses ascorbic acid as a cofactor. It exhibits rather wide substrate specificity. The NE formed is stored in the vesicles until depolarization of the neuron initiates the process of vesicle fusion with the plasma membrane and extrusion of NE into the synaptic cleft. Adenosine triphosphate (ATP) and the protein chromogranin A are released along with NE.

In the adrenal medulla, NE is converted to epinephrine. This reaction, which involves the transfer of a methyl group from S-adenosyl methionine to NE, is catalyzed by phenylethanolamine-N-methyltransferase (PNMT). It occurs in the cytoplasm, and the epinephrine formed is transported into the storage granules of the chromaffin cells. Although PNMT is highly localized in the adrenal medulla, it is also present in small amounts in heart and brain tissues.

Uptake and Metabolism

The action of NE at adrenergic receptors is terminated by a combination of processes, including uptake into the neuron and into extraneuronal tissues, diffusion away from the synapse, and metabolism. Usually, the primary mechanism for termination of the action of NE is reuptake of the catecholamine into the nerve terminal. This process is termed *uptake-1* and involves a Na^+/Cl^- -dependent transmembrane transporter that has a high affinity for NE.⁴ This uptake system also transports certain amines other than NE into the

nerve terminal, and it can be blocked by such drugs as cocaine and some of the tricyclic antidepressants. Some of the NE that reenters the sympathetic neuron is transported into storage granules, where it is held in a stable complex with ATP and protein until sympathetic nerve activity or some other stimulus causes it to be released into the synaptic cleft. The transport of NE from the cytoplasm into the storage granules is carried out by an H^+ -dependent transmembrane vesicular transporter.⁵

In addition to the neuronal uptake of NE discussed above, there exists an extraneuronal uptake process, uptake-2. This uptake process is present in a wide variety of cells, including glial, hepatic, and myocardial cells. It has relatively low affinity for NE. Although its physiological significance is unknown, it may play a role in the disposition of circulating catecholamines, since catecholamines that are taken up into extraneuronal tissues are metabolized rapidly.

The two principal enzymes involved in catecholamine metabolism are monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT).^{6, 7} Both of these enzymes are distributed throughout the body, with high concentrations found in the liver and kidneys. MAO is associated primarily

with the outer membrane of the mitochondria, while COMT is found primarily in the cytoplasm. The wide tissue distribution of MAO and COMT indicates that both act on catecholamines that enter the circulation and the extraneuronal tissues after being released from nerves or the adrenal gland or after being administered exogenously. In addition, the fact that COMT is not present in sympathetic neurons whereas the neuronal mitochondria do contain MAO indicates that MAO also has a role in the metabolism of intraneuronal catecholamines.

Neither COMT nor MAO exhibits high substrate specificity. MAO oxidatively deaminates a variety of compounds that contain an amino group attached to a terminal carbon. There are two types of MAOs, and these exhibit different substrate selectivity.⁸ For example, MAO-A shows substrate preference for NE and serotonin, while MAO-B shows substrate selectivity for β -phenylethylamine and benzylamine. Similarly, COMT catalyzes the methylation of a variety of catechol-containing molecules. The lack of substrate specificity of COMT and MAO is manifested in the metabolic disposition of NE and epinephrine, shown in Figure 16-3. Not only do both MAO and COMT use NE and epinephrine

Figure 16-3 ■ Metabolism of norepinephrine and epinephrine by MAO and COMT.

as substrates, but each also acts on the metabolites produced by the other.

The results of extensive research on catecholamine metabolism indicate that in the adrenergic neurons of human brain and peripheral tissues, NE is deaminated oxidatively by MAO to give 3,4-dihydroxyphenylglycolaldehyde, which then is reduced by aldehyde reductase to 3,4-dihydroxyphenylethylene glycol. It is primarily this glycol metabolite that is released into the circulation, where it undergoes methylation by the COMT that it encounters in nonneuronal tissues. The product of methylation, 3-methoxy-4-hydroxyphenylethylene glycol, is oxidized by alcohol dehydrogenase and aldehyde dehydrogenase to give 3-methoxy-4-hydroxymandelic acid. This metabolite commonly is referred to as vanillylmandelic acid (VMA), and although it can be the end product of several pathways of NE metabolism, 3-methoxy-4-hydroxyphenylethylene glycol is its principal precursor. In the oxidative deamination of NE and epinephrine at extraneuronal sites such as the liver, the aldehyde that is formed is oxidized usually by aldehyde dehydrogenase to give 3,4-dihydroxymandelic acid.

Methylation by COMT occurs almost exclusively on the *meta*-hydroxyl group of the catechol, regardless of whether the catechol is NE, epinephrine, or one of the metabolic products. For example, the action of COMT on NE and epinephrine gives normetanephrine and metanephrine, respectively. A converging pattern of NE metabolism of NE and epinephrine in which 3-methoxy-4-hydroxymandelic acid and 3-methoxy-4-hydroxyphenylethylene glycol are common end products thus occurs, regardless of whether the first metabolic step is oxidation by MAO or methylation by COMT.

Under normal circumstances, 3-methoxy-4-hydroxymandelic acid is the principal urinary metabolite of NE, though substantial amounts of 3-methoxy-4-hydroxyphenylethylene glycol are excreted along with varying quantities of other metabolites, both in the free form and as sulfate or glucuronide conjugates. Endogenous epinephrine is excreted primarily as metanephrine and 3-methoxy-4-hydroxymandelic acid.

ADRENERGIC RECEPTORS

α -Adrenergic Receptors

Ahlquist⁹ was the first to propose the existence of two general types of adrenergic receptors (adrenoceptors) in mammalian tissues. He designated these adrenergic receptors α and β . His hypothesis was based on the differing relative potencies of a series of adrenergic receptor agonists on various smooth muscle preparations. In the early 1970s, the discovery that certain adrenergic agonists and antagonists exhibited various degrees of selectivity for presynaptic and postsynaptic α -adrenergic receptors led to the proposal that postsynaptic α receptors be designated α_1 and that presynaptic α receptors be referred to as α_2 .¹⁰ Later, a functional classification of the α receptors was proposed wherein α_1 receptors were designated as those that were excitatory, while α_2 receptors purportedly mediated inhibitory responses.¹¹ Further developments revealed, however, that both α_1 and α_2 receptors could be either presynaptic or post-

synaptic and either excitatory or inhibitory in their responses. Thus, it became clear that neither an anatomical nor a functional classification system was as generally useful in classifying adrenergic receptors as a pharmacological classification based on the relative potency of a series of receptor agonists and antagonists.¹² Pharmacological and molecular biological methods have shown that it is possible to subdivide the α_1 and α_2 receptors into additional subtypes. Although the subtyping of adrenergic receptors continues to evolve, at present, the α_1 and α_2 receptors each have been divided into at least three subtypes, which have been designated α_{1A} , α_{1B} , α_{1D} and α_{2A} , α_{2B} , α_{2C} , respectively.¹³⁻¹⁵

The molecular basis by which activation of α -adrenergic receptors produces the appropriate tissue responses has been studied extensively. Both receptor subtypes belong to a superfamily of membrane receptors whose general structure consists of seven transmembrane α -helical segments and whose signal-transduction mechanisms involve coupling to guanine nucleotide-regulatory proteins (G proteins). They differ from each other, however, in the second-messenger system that is affected.^{16, 17} The α_1 -adrenergic receptor is coupled to the enzyme phospholipase C via a G protein, G_q . When stimulated by activation of the α_1 -adrenergic receptor, phospholipase C hydrolyzes phosphatidylinositol-4,5-bisphosphate to give the second messengers inositol-1,4,5-trisphosphate [$\text{Ins}(1,4,5)\text{P}_3$] and 1,2-diacylglycerol (DAG). $\text{Ins}(1,4,5)\text{P}_3$ stimulates the release of Ca^{2+} from the sarcoplasmic reticulum, while DAG activates protein kinase C, an enzyme that phosphorylates proteins. α_1 -Receptor activation also can increase the influx of extracellular Ca^{2+} via voltage-dependent as well as non-voltage-dependent Ca^{2+} channels. Activation of α_2 -adrenergic receptors leads to a reduction in the catalytic activity of adenylyl cyclase, which in turn results in a lowering of intracellular levels of cyclic-3,5-adenosine monophosphate (cAMP). The α_2 -adrenergic receptor-mediated inhibition of adenylyl cyclase is regulated by the G protein G_i .

α -Adrenergic receptors of the CNS and in peripheral tissues affect a number of important physiological functions.¹⁶ In particular, α receptors are involved in control of the cardiovascular system. For example, constriction of vascular smooth muscle is mediated by both postjunctional α_1 - and α_2 -adrenergic receptors, though the predominant receptor mediating this effect is α_1 .¹⁸ In the heart, activation of α_1 receptors results in a selective inotropic response with little or no change in heart rate.¹⁹ This is in contrast to the β_1 receptor, which is the predominant postjunctional receptor in the heart, mediating both inotropic and chronotropic effects. In the brain, activation of postjunctional α_2 receptors reduces sympathetic outflow from the CNS, which in turn causes a lowering of blood pressure.²⁰ The prototypical α_2 receptor is the presynaptic α receptor found on the terminus of the sympathetic neuron.^{10, 11, 21} Interaction of this receptor with agonists such as NE and epinephrine results in inhibition of NE release from the neuron. The α_2 receptors not only play a role in the regulation of NE release but also regulate the release of other neurotransmitters, such as acetylcholine and serotonin. Both α_1 - and α_2 -adrenergic receptors also play an important role in the regulation of a number of metabolic processes, such as insulin secretion and glycogenolysis.²²

β -Adrenergic Receptors

In 1967, almost 20 years after Ahlquist's landmark paper proposing the existence of α - and β -adrenergic receptors, Lands et al.²³ suggested that β receptors also could be subdivided into β_1 and β_2 types. Seventeen years later, Arch et al.²⁴ identified a third subtype of β receptor in brown adipose tissue. They initially referred to this as an atypical β receptor, but it later became designated the β_3 subtype.¹³ These β -adrenergic receptor subtypes differ in terms of the rank order of potency of the adrenergic receptor agonists NE, epinephrine, and isoproterenol. The β_1 receptors exhibit the agonist potency order isoproterenol > epinephrine = NE, while β_2 receptors exhibit the agonist potency order isoproterenol > epinephrine >> NE. For the β_3 receptor, the agonist potency order is isoproterenol = NE > epinephrine.

The β receptors are located mainly in the heart, where they mediate the positive inotropic and chronotropic effects of the catecholamines. They are also found on the juxtaglomerular cells of the kidney, where they are involved in increasing renin secretion. The β_2 receptors are located on smooth muscle throughout the body, where they are involved in relaxation of the smooth muscle, producing such effects as bronchodilation and vasodilation. They are also found in the liver, where they promote glycogenolysis. The β_3 receptor is located on brown adipose tissue and is involved in the stimulation of lipolysis.

Like the α_1 -adrenergic receptors, the β -adrenergic receptors belong to the superfamily of membrane receptors whose general structure consists of seven transmembrane α -helical segments and whose signal-transduction mechanisms involve coupling to G proteins. All three β -receptors are coupled to adenylyl cyclase, which catalyzes the conversion of ATP to cAMP. This coupling is via the guanine nucleotide protein G_i .^{25, 26} In the absence of agonist, guanosine diphosphate (GDP) is bound reversibly to the G_i protein. Interaction of the agonist with the receptor is believed to bring about a conformational change in the protein receptor, which causes a reduction in the affinity of the G_i protein for GDP and a concomitant increase in affinity for guanosine triphosphate (GTP). The α_i subunit of the G_i protein, with GTP bound to it, dissociates from the receptor-G protein ternary complex, binds to adenylyl cyclase, and activates the enzyme. The bound GTP then undergoes hydrolysis to GDP, and the receptor-G_i protein complex returns to the basal state.

The intracellular function of the second-messenger cAMP appears to be activation of protein kinases, which phosphorylate specific proteins, thereby altering their function. Thus, the phosphorylated proteins mediate the actions of cAMP, which functions as the mediator of the action of the drug or neurotransmitter that originally interacted with the β -receptor.²⁷ The action of cAMP is terminated by a class of enzymes known as phosphodiesterases, which catalyze the hydrolysis of cAMP to AMP.

Cloning of the gene and complementary DNA (cDNA) for the mammalian β -adrenergic receptor has made it possible to explore through single point mutations and the construction of chimeric receptors the structure-function relationships of the receptor.²⁸ Through such studies, it has been proposed that the adrenergic agonist-binding site is within the transmembrane-spanning regions, while the cytoplasmic regions

of the receptor interact with the G_i protein. Specifically, aspartic acid residue 113 in transmembrane region III acts as the counterion to the cationic amino group of the adrenergic agonist, while two serine residues, at positions 204 and 207 in transmembrane region V, form hydrogen bonds with the catechol hydroxyls of the adrenergic agonists. The β -hydroxyl group of adrenergic agonists is thought to form a hydrogen bond with the side chain of asparagine 293 in transmembrane region VI, while the phenylalanine residue at position 290 in the same transmembrane region is believed to interact with the catechol ring. Information such as this will no doubt aid in the future design and synthesis of new and improved adrenergic receptor agonists and antagonists.

Molecular biological techniques have shown the existence of adrenergic receptor polymorphism for both the α - and β -adrenergic receptors. It is postulated that such polymorphisms may be an important factor behind individual differences in responses to drugs acting at these receptors. Also, there may be an association between the polymorphisms of adrenergic receptor genes and disease states.²⁹ This will certainly be an active area of research in the future, and the results could have a great impact on the development and therapeutic use of not only the current adrenergic agents but also those that are yet to be developed.

DRUGS AFFECTING ADRENERGIC NEUROTRANSMISSION

Drugs Affecting Catecholamine Biosynthesis

Metyrosine. Many agents that affect catecholamine biosynthesis are known, but only a few are used as therapeutic agents. Metyrosine (α -methyl-*p*-tyrosine, Demser) is one example of a catecholamine-biosynthesis inhibitor in clinical use.³⁰ Metyrosine differs structurally from tyrosine only in the presence of an α -methyl group. It is a competitive inhibitor of tyrosine hydroxylase, the first and rate-limiting step in catecholamine biosynthesis. As such, metyrosine is a much more effective inhibitor of epinephrine and NE production than agents that inhibit any of the other enzymes involved in catecholamine biosynthesis. Although metyrosine is used as a racemic mixture, it is the (–) isomer that possesses the inhibitory activity. Metyrosine, which is given orally in dosages ranging from 1 to 4 g/day, is used principally for the preoperative management of pheochromocytoma. This condition involves chromaffin cell tumors that produce large amounts of NE and epinephrine. Although these tumors, which occur in the adrenal medulla, are often benign, patients frequently suffer hypertensive episodes. Metyrosine reduces the frequency and severity of these episodes by significantly lowering catecholamine production (35 to 80%). The drug is excreted mainly unchanged in the urine. Because of its limited solubility in water, crystalline is a potential serious side effect. Sedation is the most common side effect of metyrosine.

Metyrosine

Drugs Affecting Catecholamine Storage and Release

Reserpine. Reserpine is the prototypical drug affecting the vesicle storage of NE in sympathetic neurons and neurons of the CNS and of epinephrine in the adrenal medulla. Its actions are not limited to NE and epinephrine, however, as it also affects the storage of serotonin and dopamine in their respective neurons in the brain. Reserpine is an indole alkaloid obtained from the root of *Rauwolfia serpentina*, a climbing shrub found in India. Other alkaloid constituents of this plant that possess pharmacological activity similar to that of reserpine are **deserpine** and **rescinnamine**. Reserpine binds extremely tightly with the ATP-driven monoamine transporter that transports NE and other biogenic amines from the cytoplasm into the storage vesicles.³¹ This binding leads to a blockade of the transporter. Thus in sympathetic neurons, NE, which normally is transported into the storage vesicles, is instead metabolized by mitochondrial MAO in the cytoplasm. In addition, there is a gradual loss of vesicle-stored NE as it is used up by release resulting from sympathetic nerve activity. It is thought that the storage vesicles eventually become dysfunctional. The end result is a depletion of NE in the sympathetic neuron. Analogous effects are seen in the adrenal medulla with epinephrine and in serotonergic neurons.

When reserpine is given orally, its maximum effect is seen after a couple of weeks. A sustained effect up to several weeks is seen after the last dose has been given. Reserpine is extensively metabolized through hydrolysis of the ester function at position 18. This yields methyl reserpate and 3,4,5-trimethoxybenzoic acid. As is typical of many indole alkaloids, reserpine is susceptible to decomposition by light and oxidation. Both the pure alkaloid and the powdered

whole root of *R. serpentina* are used in the treatment of hypertension. Preparations in which reserpine is combined with a diuretic also are available, as diuretics increase the efficacy of reserpine.

Guanethidine and Guanadrel. Neuronal blocking agents are drugs that produce their pharmacological effects primarily by preventing the release of NE from sympathetic nerve terminals. Drugs of this type enter the adrenergic neuron by way of the uptake-1 process and accumulate within the neuronal storage vesicles. There, they stabilize the neuronal storage vesicle membranes, making them less responsive to nerve impulses. The ability of the vesicles to fuse with the neuronal membrane is diminished, resulting in inhibition of NE release into the synaptic cleft. Some of these agents on long-term administration also can produce a depletion of NE stores in sympathetic neurons.

Structurally, the neuronal blocking drugs typically possess a guanidino moiety [$\text{CNHC}(=\text{NH})\text{NH}_2$], which is attached to either an alicyclic or an aromatic lipophilic group. These structural features are seen in guanethidine (Ismelin) and guanadrel (Hylorel), which are used clinically in the treatment of hypertension. The presence of the very basic guanidino group ($\text{pK}_a > 12$) in these drugs means that at physiological pH they are essentially completely protonated. Thus, these agents do not get into the CNS.

Although guanethidine and guanadrel have virtually the same mechanism of action on sympathetic neurons, they differ in their pharmacokinetic properties. For example, while guanethidine is absorbed incompletely after oral administration (3 to 50%), guanadrel is well absorbed, with a bioavailability of 85%.³² These two agents also differ in terms of half-life: Guanethidine has a half-life of about 5 days, whereas guanadrel has a half-life of 12 hours. Both agents are partially metabolized (~50%) by the liver, and both are used to treat moderate-to-severe hypertension, either alone or in combination with another antihypertensive agent.

Bretylium Tosylate. Another neuronal blocking agent is the aromatic quaternary ammonium compound bretylium tosylate (Bretylol). This agent is used as an antiarrhythmic drug. Its antiarrhythmic actions are not believed to be due to its neuronal blocking effects, however. This agent is discussed in more detail in Chapter 19.

SYMPATHOMIMETIC AGENTS

Sympathomimetic agents produce effects resembling those produced by stimulation of the sympathetic nervous system. They may be classified as agents that produce effects by a direct, indirect, or mixed mechanism of action. Direct-acting agents elicit a sympathomimetic response by interacting directly with adrenergic receptors. Indirect-acting agents produce effects primarily by causing the release of NE from adrenergic nerve terminals; the NE that is released by the indirect-acting agent activates the receptors to produce the response. Compounds with a mixed mechanism of action interact directly with adrenergic receptors and cause the release of NE. As described below, the mechanism by which an agent produces its sympathomimetic effect is related intimately to its chemical structure.

Direct-Acting Sympathomimetics

STRUCTURE-ACTIVITY RELATIONSHIPS

Structure-activity relationships for α - and β -adrenergic receptor agonists have been reviewed.³³⁻³⁵ The parent structure for many of the sympathomimetic drugs is β -phenylethylamine. The manner in which β -phenylethylamine is substituted on the *meta* and *para* positions of the aromatic ring and on the amino, α , and β positions of the ethylamine side chain influences not only the mechanism of sympathomimetic action but also the receptor selectivity of the drug. For the direct-acting sympathomimetic amines, maximal activity is seen in β -phenylethylamine derivatives containing hydroxyl groups in the *meta* and *para* positions of the aromatic ring (a catechol) and a β -hydroxyl group of the correct stereochemical configuration on the ethylamine portion of the molecule. Such structural features are seen in the prototypical direct-acting compounds NE, epinephrine, and isoproterenol.

A critical factor in the interaction of adrenergic agonists with their receptors is stereoselectivity. Direct-acting sympathomimetics that exhibit chirality by virtue of the presence of a β -hydroxyl group (phenylethanolamines) invariably exhibit high stereoselectivity in producing their agonistic effects; that is, one enantiomeric form of the drug has greater

affinity for the receptor than the other form has. This is true for both α - and β -receptor agonists. For epinephrine, NE, and related compounds, the more potent enantiomer has the (*R*) configuration. This enantiomer is typically several 100-fold more potent than the enantiomer with the (*S*) configuration. It appears that for all direct-acting, β -phenylethylamine-derived agonists that are structurally similar to NE, the more potent enantiomer is capable of assuming a conformation that results in the arrangement in space of the catechol group, the amino group, and the β -hydroxyl group in a fashion resembling that of (–)-(*R*)-NE. This explanation of stereoselectivity is based on the presumed interaction of these three critical pharmacophoric groups with three complementary binding areas on the receptor and is known as the Easson-Stedman hypothesis.^{17, 36} This three-point interaction is supported by recent site-directed mutagenesis studies²⁸ on the adrenergic receptor and is illustrated in Figure 16-4.

The presence of the amino group in phenylethylamines is important for direct agonist activity. The amino group should be separated from the aromatic ring by two carbon atoms for optimal activity. Both primary and secondary amines are found among the potent direct-acting agonists, but tertiary or quaternary amines tend to be poor direct agonists. The nature of the amino substituent dramatically affects the receptor selectivity of the compound. In general, as the bulk of the nitrogen substituent increases, α -receptor agonist activity decreases and β -receptor activity increases. Thus NE, which is an effective β_1 -receptor agonist, is also a potent α agonist, while epinephrine is a potent agonist at α , β_1 , and β_2 receptors. Isoproterenol, however, is a potent β_1 - and β_2 -receptor agonist but has little affinity for α receptors. The nature of the substituent can also affect β_1 - and β_2 -receptor selectivity. In several instances, it has been shown that an *N-tert*-butyl

Figure 16-4 ■ Illustration of the Easson-Stedman hypothesis: representing the interaction of three critical pharmacophoric groups of norepinephrine with the complementary binding areas on the adrenergic receptor as suggested by site-directed mutagenesis studies.

group enhances β_2 selectivity. For example, *N*-*tert*-butylnorepinephrine (Colterol) is 9 to 10 times as potent an agonist at tracheal β_2 receptors than at cardiac β_1 receptors. Large substituents on the amino group also protect the amino group from undergoing oxidative deamination by MAO.

Methyl or ethyl substitution on the α -carbon of the ethylamine side chain reduces direct receptor agonist activity at both α and β receptors. Importantly, however, an α -alkyl group increases the duration of action of the phenylethylamine agonist by making the compound resistant to metabolic deamination by MAO. Such compounds often exhibit enhanced oral effectiveness and greater CNS activity than their counterparts that do not contain an α -alkyl group. α -Substitution also significantly affects receptor selectivity. In the case of β receptors, for example, α -methyl or ethyl substitution results in compounds with selectivity toward the β_2 receptor, while in the case of α receptors, α -methyl substitution gives compounds with selectivity toward the α_2 receptor. Another effect of α -substitution is the introduction of a chiral center, which has pronounced effects on the stereochemical requirements for activity. For example, with α -methylnorepinephrine, it is the *erythro* (1*R*,2*S*) isomer that possesses significant activity at α receptors.

Although the catechol moiety is an important structural feature in terms of yielding compounds with maximal agonist activity at adrenergic receptors, it can be replaced with other substituted phenyl moieties to provide selective adrenergic agonists. In particular, this approach has been used in the design of selective β_2 -receptor agonists. For example, replacement of the catechol function of isoproterenol with the resorcinol structure gives the drug metaproterenol, which is a selective β_2 -receptor agonist. Furthermore, since the resorcinol ring is not a substrate for COMT, β agonists that contain this ring structure tend to have better absorption characteristics and a longer duration of action than their catechol-containing counterparts. In another approach, replacement of the *meta*-hydroxyl of the catechol structure with a hydroxymethyl group gives agents, such as albuterol, which

show selectivity to the β_2 receptor. As in the case of the resorcinol modification, this type of substitution gives agents that are not metabolized by COMT and thus show improved oral bioavailability.

Modification of the catechol ring can also bring about selectivity at α receptors as it appears that the catechol moiety is more important for agonist activity at α_2 receptors than at α_1 receptors. For example, removal of the *p*-hydroxyl group from epinephrine gives phenylephrine, which, in contrast to epinephrine, is selective for the α_1 -adrenergic receptor.

In addition to the β -phenylethylamine class of adrenergic receptor agonists, there is a second chemical class of compounds, the imidazolines, that give rise to α -adrenergic receptor agonists. These imidazolines can be nonselective, or they can be selective for either the α_1 - or α_2 -adrenergic receptors. Structurally, imidazolines for the most part have the heterocyclic imidazoline nucleus linked to a substituted aromatic moiety via some type of bridging unit (Fig. 16-5).³⁴ Although modification of the imidazoline ring generally results in compounds with significantly reduced agonist activity, there are examples of so-called open-ring imidazolines that are highly active. The optimum bridging unit (X) is usually a single amino or methylene group. The nature of the aromatic moiety, as well as how it is substituted, is quite

Figure 16-5 ■ General structural features of the imidazoline α -adrenergic receptor agonists.

flexible. However, agonist activity is enhanced when the aromatic ring is substituted with halogen substituents like Cl or small alkyl groups like methyl, particularly when they are placed in the two *ortho* positions. Since the structure-activity relationships of the imidazolines are quite different from those of the β -phenylethylamines, it has been postulated that the imidazolines interact with α -adrenergic receptors differently from the way the β -phenylethylamines do, particularly with regard to the aromatic moiety.³⁷

ENDOGENOUS CATECHOLAMINES

The three naturally occurring catecholamines dopamine, NE, and epinephrine are used as therapeutic agents.

Dopamine. Dopamine is used in the treatment of shock. It is ineffective orally, in large part because it is a substrate for both MAO and COMT. Thus, it is used intravenously. In contrast with the catecholamines NE and epinephrine, dopamine increases blood flow to the kidney in doses that have no chronotropic effect on the heart or that cause no increase in blood pressure. The increased blood flow to the kidneys enhances glomerular filtration rate, Na^+ excretion, and, in turn, urinary output. The dilation of renal blood vessels produced by dopamine is the result of its agonist action on the D_1 -dopamine receptor.

Dopamine

In doses slightly higher than those required to increase renal blood flow, dopamine stimulates the β_1 receptors of the heart to increase cardiac output. Some of the effects of dopamine on the heart are also due to NE release. Infusion at a rate greater than $10 \mu\text{g/kg}$ per minute results in stimulation of α_1 receptors, leading to vasoconstriction and an increase in arterial blood pressure.

Norepinephrine (NE). NE (Levophed) is used to maintain blood pressure in acute hypotensive states resulting from surgical or nonsurgical trauma, central vasomotor depression, and hemorrhage. Like the other endogenous catecholamines, it is a substrate for both MAO and COMT and thus is not effective by the oral route of administration. It is given by intravenous injection.

Epinephrine. Epinephrine (Adrenalin) finds use in a number of situations because of its potent stimulatory effects on both α - and β -adrenergic receptors. Like the other catecholamines, epinephrine is light sensitive and easily oxidized on exposure to air because of the catechol ring system. The development of a pink to brown color indicates oxidative breakdown. To minimize oxidation, solutions of the drug are stabilized by the addition of reducing agents such as sodium bisulfite. As the free amine, it is used in aqueous solution for inhalation. Like other amines, it forms salts with acids; for example, those now used include the hydrochloride and the bitartrate. Epinephrine is destroyed readily in alkaline solutions and by metals (e.g., Cu, Fe, Zn), weak

oxidizing agents, and oxygen of the air. It is not effective by the oral route because of poor absorption and rapid metabolism by MAO and COMT.

Although intravenous infusion of epinephrine has pronounced effects on the cardiovascular system, its use in the treatment of heart block or circulatory collapse is limited because of its tendency to induce cardiac arrhythmias. It increases systolic pressure by increasing cardiac output, and it lowers diastolic pressure by causing an overall decrease in peripheral resistance; the net result is little change in mean blood pressure.

Epinephrine is of value as a constrictor in hemorrhage or nasal congestion. Also, it is used to enhance the activity of local anesthetics. Its use in these two situations takes advantage of the drug's potent stimulatory effects on α receptors. The ability of epinephrine to stimulate β_2 receptors has led to its use by injection and by inhalation to relax bronchial smooth muscle in asthma and in anaphylactic reactions. Several over-the-counter preparations (e.g., Primatene, Bronkaid) used for treating bronchial asthma use epinephrine.

Epinephrine is used in the treatment of open-angle glaucoma, where it apparently reduces intraocular pressure by increasing the rate of outflow of aqueous humor from the anterior chamber of the eye. The irritation often experienced on instillation of epinephrine into the eye has led to the development of other preparations of the drug that potentially are not as irritating. One such example is dipivefrin.

Dipivefrin. Dipivefrin (dipivalyl epinephrine, Propine) is a prodrug of epinephrine that is formed by the esterification of the catechol hydroxyl groups of epinephrine with pivalic acid. Dipivefrin is much more lipophilic than epinephrine, and it achieves much better penetration of the eye when administered topically as an aqueous solution for the treatment of primary open-angle glaucoma. It is converted to epinephrine by esterases in the cornea and anterior chamber. Dipivefrin offers the advantage of being less irritating to the eye than epinephrine, and because of its more efficient transport into the eye, it can be used in lower concentrations than epinephrine.

α -ADRENERGIC RECEPTOR AGONISTS

Phenylephrine. Phenylephrine (Neo-Synephrine; structure shown above under "Structure-Activity Relationships") is the prototypical selective direct-acting α_1 -receptor agonist. It is a potent vasoconstrictor but is less potent than

epinephrine and norepinephrine (NE). It is active when given orally, and its duration of action is about twice that of epinephrine. It is metabolized by MAO, but since it lacks the catechol moiety, it is not metabolized by COMT. It is relatively nontoxic and produces little CNS stimulation. When applied to mucous membranes, it reduces congestion and swelling by constricting the blood vessels of the membranes. Thus, one of its main uses is in the relief of nasal congestion. In the eye, it is used to dilate the pupil and to treat open-angle glaucoma. It also is used in spinal anesthesia, to prolong the anesthesia and to prevent a drop in blood pressure during the procedure. Another use is in the treatment of severe hypotension resulting from either shock or drug administration.

Methoxamine. Another selective direct-acting α_1 -receptor agonist used therapeutically is methoxamine (Vasoxyl). This drug is a vasoconstrictor that has no stimulant action on the heart. In fact, it tends to slow the ventricular rate because of activation of the carotid sinus reflex. It is less potent than phenylephrine as a vasoconstrictor. Methoxamine is used primarily during surgery to maintain adequate arterial blood pressure, especially in conjunction with spinal anesthesia. It does not stimulate the CNS.

Methoxamine

Midodrine. Midodrine (ProAmatine) represents another example of a dimethoxy- β -phenylethylamine derivative that is used therapeutically for its vasoconstrictor properties. Specifically, it is used in the treatment of symptomatic orthostatic hypotension. Midodrine is the *N*-glycyl prodrug of the selective α_1 -receptor agonist desglymidodrine. Removal of the *N*-glycyl moiety from midodrine occurs readily in the liver as well as throughout the body, presumably by amidases.

Midodrine

Desglymidodrine

Naphazoline, Tetrahydrozoline, Xylometazoline, and Oxymetazoline.

The 2-alkylimidazolines naphazoline (Privine), tetrahydrozoline (Tyzine, Visine), xylometazoline (Otrivin), and oxymetazoline (Afrin) are agonists at both α_1 - and α_2 -adrenergic receptors. These agents are used for their vasoconstrictive effects as nasal and ophthalmic decongestants. They have limited access to the CNS, since they essentially exist in an ionized form at physiological pH because of the very basic nature of the imidazoline ring (pK_a 9 to 10).

Clonidine. Clonidine (Catapres) is an example of a (phenylimino)imidazolidine derivative that possesses selectivity for the α_2 -adrenergic receptor. The α_1 : α_2 ratio is 300:1. Under certain conditions, such as intravenous infusion, clonidine can briefly exhibit vasoconstrictive activity as a result of stimulation of peripheral α -adrenergic receptors. However, this hypertensive effect, if it occurs, is followed by a much longer lasting hypotensive effect as a result of the ability of clonidine to enter into the CNS and stimulate α_2 receptors located in regions of the brain, such as the nucleus tractus solitarius. Stimulation of these α_2 receptors brings about a decrease in sympathetic outflow from the CNS, which in turn leads to decreases in peripheral vascular resistance and blood pressure.^{26, 38} Bradycardia is also produced by clonidine as a result of a centrally induced facilitation of the vagus nerve and stimulation of cardiac prejunctional α_2 -adrenergic receptors.³⁹ These pharmacological actions have made clonidine quite useful in the treatment of hypertension.

Clonidine: R = H

4-Hydroxyclohidine: R = OH

Apraclonidine: R = NH₂

The ability of clonidine and its analogues to exert an antihypertensive effect depends on the ability of these compounds not only to interact with the α_2 receptor but also to gain entry into the CNS. For example, in the case of clonidine, the basicity of the guanidine group (typically pK_a 13.6) is decreased to 8.0 (the pK_a of clonidine) because of its direct attachment to the dichlorophenyl ring. Thus, at physiological pH, clonidine will exist to a significant extent in the nonionized form required for passage into the CNS.

Substitutions on the aromatic ring also affect the ability of clonidine and its analogues to gain entry into the CNS to produce an antihypertensive effect. Although various halogen and alkyl substitutions can be placed at the two *ortho* positions of the (phenylimino)imidazolidine nucleus without affecting the affinity of the derivatives toward α_2 receptors, such substitutions have a marked effect on the lipophilicity of the compound. Halogen substituents such as chlorine seem to provide the optimal characteristics in this regard.⁴⁰ This distributive phenomenon is seen with one of the metabolites of clonidine, 4-hydroxyclohidine. This compound has good affinity for α_2 receptors, but since it is too polar to get into the CNS, it is not an effective antihypertensive agent.

In addition to binding to the α_2 adrenergic receptor, clonidine, as well as some other imidazolines, shows high affinity for what has been termed the "imidazoline" receptor.⁴¹⁻⁴² Some studies have implicated a role for the imidazoline receptors in the antihypertensive effects of clonidine.^{43, 44} However, other studies involving both site-directed mutagenesis of the α_{2A} -adrenergic receptor subtype and genetically engineered knockout mice deficient in either the α_{2B} - or α_{2A} -adrenergic receptor subtypes provide evidence that the hypotensive response of the α_2 -receptor agonists like clonidine primarily involves the α_{2A} -adrenergic receptor subtype.^{45, 46}

Guanabenz and Guanfacine. Two analogues of clonidine, guanabenz (Wyntensin) and guanfacine (Tenex), are also used as antihypertensive drugs. Their mechanism of action is the same as that of clonidine. Structurally, these two compounds can be considered "open-ring imidazolines." In these compounds, the 2,6-dichlorophenyl moiety found in clonidine is connected to a guanidino group by a two-atom bridge. In the case of guanabenz, this bridge is a $-\text{CH}=\text{N}-$ group, while for guanfacine it is a $-\text{CH}_2\text{CO}-$ moiety. For both compounds, conjugation of the guanidino moiety with the bridging moiety helps to decrease the pK_a of this normally very basic group so that at physiological pH a significant portion of each drug exists in its nonionized form. Differences between clonidine and its two analogues are seen in their elimination half-life values and in their metabolism and urinary excretion patterns. The elimination

half-life of clonidine ranges from 20 to 25 hours, while that for guanfacine is about 17 hours. Guanabenz has the shortest duration of action of these three agents, with a half-life of about 6 hours. Clonidine and guanfacine are excreted unchanged in the urine to the extent of 60 and 50%, respectively. Very little of guanabenz is excreted unchanged in the urine.

Guanabenz

Guanfacine

Apraclonidine and Brimonidine. In addition to its therapeutic use as an antihypertensive agent, clonidine has been found to provide beneficial effects in a number of other situations.⁴⁷ These include migraine prophylaxis, glaucoma, opiate withdrawal syndrome, and anesthesia. This has prompted the development of analogues of clonidine for specific use in some of the above areas. Two such examples are apraclonidine (Iopidine) and brimonidine (Alphagan). Both are selective α_2 -receptor agonists with $\alpha_1:\alpha_2$ ratios of 30:1 and 1,000:1, respectively. They both lower intraocular pressure by decreasing aqueous humor production and increasing aqueous humor outflow. Apraclonidine is used specifically to control elevations in intraocular pressure that occur during laser surgery on the eye. Brimonidine also is used in such a manner; in addition, it is approved for use in treating glaucoma. Another example is tizanidine (Zanaflex), which finds use in treating spasticity associated with multiple sclerosis or spinal cord injury. By stimulating α_2 -adrenergic receptors, it is believed to decrease the release of excitatory amino acid neurotransmitters from spinal cord interneurons.⁴⁸

Brimonidine

Tizanidine

Methyldopa. A phenylethylamine derivative that shows selectivity toward the α_2 receptor is α -methylnorepinephrine (Fig. 16-6). As discussed above under "Structure-Activity Relationships," the presence of an α -methyl group in the correct configuration on the phenylethylamine nucleus yields compounds with increased potency at α_2 receptors and decreased potency at α_1 receptors. Although α -methylnorepinephrine is not given as a drug, it is the metabolic product of the drug methyldopa (L - α -methyl-3,4-dihydroxyphenylalanine, Aldomet). Since methyldopa is a close structural analogue of L -dopa, it is treated as an alternate substrate by the enzyme L -aromatic amino acid decarboxylase. The product of this initial enzymatic reaction is α -methyldopamine. This intermediate, in turn, is acted on by dopamine β -hydroxylase to give the diastereoisomer of α -methylnorepinephrine, which possesses the (*R*) configuration at the carbon with the β -hydroxyl group and the (*S*) configuration at the carbon with the α -methyl substituent (Fig. 16-6). It is postulated that α -methylnorepinephrine acts on α_2 receptors in the CNS in the same manner as clonidine,

to decrease sympathetic outflow and lower blood pressure.³⁸ Since methyldopa serves as an alternate substrate to L -aromatic amino acid decarboxylase, it ultimately decreases the concentration of dopamine, NE, epinephrine, and serotonin in the CNS and periphery.

Methyldopa is used only by oral administration since its zwitterionic character limits its solubility. Absorption can range from 8 to 62% and appears to involve an amino acid transporter. Absorption is affected by food, and about 40% of that absorbed is converted to methyldopa-*O*-sulfate by the mucosal intestinal cells. Entry into the CNS also appears to involve an active transport process. The ester hydrochloride salt of methyldopa, **methyldopate** (Aldomet ester), was developed as a highly water-soluble derivative that could be used to make parenteral preparations. Methyldopate is converted to methyldopa in the body through the action of esterases (Fig. 16-6).

DUAL α - AND β -ADRENERGIC RECEPTOR AGONISTS

Dobutamine. There are synthetic direct-acting sympathomimetics whose therapeutic use relies on their ability to act at both α - and β -adrenergic receptors. One example is dobutamine (Dobutrex). Structurally, dobutamine can be viewed as an analogue of dopamine in which a 1-(methyl)-3-(4-hydroxyphenyl)propyl substituent has been placed on the amino group. This substitution gives a compound that possesses an asymmetric carbon atom. Thus, dobutamine exists as a pair of enantiomers, with each enantiomer possessing a distinct pharmacology.⁴⁹ The (+) enantiomer is a potent full agonist at both β_1 and β_2 receptors. In contrast, the (−) enantiomer is some 10 times less potent at β_1 and β_2 receptors. The (−) enantiomer is, however, a potent agonist at α_1 receptors. Dobutamine does not act as an agonist at the dopaminergic receptors that mediate renal vasodilation.

In vivo, racemic dobutamine increases the inotropic activity of the heart to a much greater extent than it increases chronotropic activity. This pharmacological profile has led to its use in treating congestive heart failure. Since β_1 receptors are involved positively in both inotropic and chronotropic effects of the heart, the selective inotropic effect seen with dobutamine cannot simply be due to its activity at β_1 receptors. Rather, this effect is the result of a combination of the inotropic effect of (+)-dobutamine on β_1 receptors and that of (−)-dobutamine mediated through α_1 receptors.⁵⁰ Thus, this is a case where a racemic mixture provides a more desirable pharmacological and therapeutic effect than would either enantiomer alone.

Dobutamine is given by intravenous infusion, since it is not effective orally. Solutions of the drug can exhibit a slight pink color as a result of oxidation of the catechol function. It has a plasma half-life of about 2 minutes. It is metabolized by COMT and conjugation but not by MAO.

Figure 16-6 ■ Metabolic conversion of methyldopate and methyldopa to α -methylnorepinephrine.

β -ADRENERGIC RECEPTOR AGONISTS

Isoproterenol. Isoproterenol (Isuprel, structure shown above under "Structure-Activity Relationships") is the prototypical β -adrenergic receptor agonist. Because of an isopropyl substitution on the nitrogen atom, it has virtually no effect on α receptors. However, it does act on both β_1 and β_2 receptors. It thus can produce an increase in cardiac output by stimulating cardiac β_1 receptors and can bring about bronchodilation through stimulation of β_2 receptors in the respiratory tract. It also produces the metabolic effects expected of a potent β agonist. Isoproterenol is available for use by inhalation and injection. Its principal clinical use is for the relief of bronchospasms associated with bronchial asthma. In fact, it is one of the most potent bronchodilators available. Cardiac stimulation is an occasionally dangerous adverse effect in its use. This effect of isoproterenol on the heart is sometimes made use of in the treatment of heart block.

After oral administration, the absorption of isoproterenol is rather erratic and undependable. The drug has a duration of action of 1 to 3 hours after inhalation. The principal reason for its poor absorption characteristics and relatively short duration of action is its facile metabolic transformation by sulfate and glucuronide conjugation of the ring hydroxyls and methylation by COMT. Unlike epinephrine and NE, isoproterenol does not appear to undergo oxidative deamination by MAO. Since it is a catechol, it is sensitive to light and air. Aqueous solutions become pink on standing.

The problems of lack of β -receptor selectivity and rapid metabolic inactivation associated with isoproterenol have been overcome at least partially by the design and development of a number of selective β_2 -adrenergic receptor agonists. These agents relax smooth muscle of the bronchi, uterus, and skeletal muscle vascular supply. They find their primary use as bronchodilators in the treatment of acute and chronic bronchial asthma and other obstructive pulmonary diseases.

Metaproterenol and Terbutaline. As pointed out in the discussion of structure-activity relationships, modification of the catechol portion of a β agonist has resulted in the development of selective β_2 -receptor agonists. For example, metaproterenol (Alupent, structure shown above under "Structure-Activity Relationships") and terbutaline (Bricanyl, Brethine) are resorcinol derivatives that are β_2 selective. Metaproterenol is less β_2 selective than either terbutaline or albuterol. Although these agents have a lower affinity for β_2 receptors than isoproterenol, they are much more effective when given orally, and they have a longer duration of action. This is because they are not metabolized by either COMT or MAO. Instead, their metabolism primarily involves glucuronide conjugation. Although both metaproterenol and terbutaline exhibit significant β_2 -receptor selectivity, the common cardiovascular effects associated with other adrenergic agents can also be seen with these drugs when high doses are used.

Albuterol, Pirbuterol, and Salmeterol. Albuterol (Proventil, Ventolin, structure shown above under "Structure-Activity Relationships"), pirbuterol (Maxair), and salmeterol (Serevent) are examples of selective β_2 -receptor agonists whose selectivity results from replacement of the *meta*-hydroxyl group of the catechol ring with a hydroxymethyl moiety. Pirbuterol is closely related structurally to albuterol; the only difference between the two is that pirbuterol contains a pyridine ring instead of a benzene ring. As in the case of metaproterenol and terbutaline, these drugs are not metabolized by either COMT or MAO. Instead, they are conjugated with sulfate. They thus are active orally, and they exhibit a longer duration of action than isoproterenol. The duration of action of terbutaline, albuterol, and pirbuterol is in the range of 3 to 6 hours.

Pirbuterol

Salmeterol

Salmeterol is a partial agonist at β_2 receptors and has a potency similar to that of isoproterenol. It is very long acting (12 hours), an effect attributed to the lipophilic phenylalkyl substituent on the nitrogen atom, which is believed to interact with a site outside but adjacent to the active site. This agent associates with the β_2 receptor slowly and dissociates from the receptor at an even slower rate.⁵¹

Formoterol and Levalbuterol. Another long-acting β_2 -receptor agonist is Formoterol (Foradil). Its long duration of action, which is comparable to that of salmeterol, has been suggested to result from its association with the membrane lipid bilayer.⁵² Formoterol has a much faster onset of action than does salmeterol. Both of these long-acting drugs are used by inhalation and are recommended for maintenance treatment of asthma, usually in conjunction with an inhaled corticosteroid.

All of the above β_2 -receptor agonists possess at least one chiral center and are used as racemic mixtures. Formoterol

possesses two chiral centers and is used as the racemic mixture of the (*R,R*) and (*S,S*) enantiomers. As mentioned above, it is the (*R*) isomer of the phenylethanamines that possesses the pharmacological activity. Concerns have been raised about the use of such racemic mixtures under the belief that the inactive (*S*) isomer may be responsible for some of the adverse effects seen with these agents. Levalbuterol (Xopenex), the (*R*) isomer of racemic albuterol, represents the first attempt to address this issue.

Isoetharine. Another sympathomimetic drug that finds use as a bronchodilator is the α -ethyl catecholamine, isoetharine. This agent is weaker than isoproterenol at stimulating β_2 receptors. In addition, its β_2 selectivity is not as great as that seen with drugs such as terbutaline or albuterol. Because of the presence of the α -ethyl group, isoetharine is not metabolized by MAO. Because it contains the catechol ring system, however, it is metabolized quite effectively by COMT. It also is *O*-sulfated quite effectively. Isoetharine has a duration of action similar to that of isoproterenol.

Bitolterol. Bitolterol (Tornalate) is a prodrug of the β_2 -selective adrenergic agonist colterol, the *N*-*tert*-butyl analogue of NE. The presence of the two *p*-toluic acid esters in bitolterol makes it considerably more lipophilic than colterol. Bitolterol is administered by inhalation for bronchial asthma and reversible bronchospasm. It is hydrolyzed by esterases in the lung and other tissues to produce the active agent, colterol. Bitolterol has a longer duration of action than isoproterenol (5 to 8 hours) and is metabolized, after hydrolysis of the esters, by COMT and conjugation.

Ritodrine. Ritodrine (Yutopar) is a selective β_2 -receptor agonist used to control premature labor and to reverse

fetal distress caused by excessive uterine activity. Its uterine inhibitory effects are more sustained than its effects on the cardiovascular system, which are minimal compared with those caused by nonselective β agonists. The cardiovascular effects usually associated with its administration are mild tachycardia and slight diastolic pressure decrease. Usually, it is administered initially by intravenous infusion to stop premature labor. Subsequently, it may be given orally.

β_3 -Adrenergic Receptor Agonists. Selective direct-acting agonists for the β_3 -adrenergic receptor have been developed, but they have not been approved for therapeutic use.⁵³ Because stimulation of the β_3 receptor promotes lipolysis, these agents may have potential as antiobesity drugs and as drugs for the treatment of non-insulin-dependent diabetes.

Indirect-Acting Sympathomimetics

Indirect-acting sympathomimetics act by releasing endogenous NE. They enter the nerve ending by way of the active-uptake process and displace NE from its storage granules. Certain structural characteristics tend to impart indirect sympathomimetic activity to phenylethanamines. As with the direct-acting agents, the presence of the catechol hydroxyls enhances the potency of indirect-acting phenylethanamines. However, the indirect-acting drugs that are used therapeutically are not catechol derivatives and, in most cases, do not even contain a hydroxyl moiety. In contrast with the direct-acting agents, the presence of a β -hydroxyl group decreases, and an α -methyl group increases, the effectiveness of indirect-acting agents. The presence of nitrogen substituents decreases indirect activity, with substituents larger than methyl rendering the compound virtually inactive. Phenylethanamines that contain a tertiary amino group are also ineffective as NE-releasing agents. Given the foregoing structure-activity considerations, it is easy to understand why amphetamine and *p*-tyramine are often cited as prototypical indirect-acting sympathomimetics. Since amphetamine-type drugs exert their primary effects on the CNS, they are discussed in more detail in Chapter 15. This chapter discusses those agents that exert their effects primarily on the periphery.

Hydroxyamphetamine. Although *p*-tyramine is not a clinically useful agent, its α -methylated derivative, hydroxyamphetamine (Paredrine), is an effective, indirect-acting sympathomimetic drug. Hydroxyamphetamine has little or

no ephedrine-like, CNS-stimulating action. It is used to dilate the pupil for diagnostic eye examinations and for surgical procedures on the eye. It is used sometimes with cholinergic blocking drugs like atropine to produce a mydriatic effect, which is more pronounced than that produced by either drug alone.

L-(+)-Pseudoephedrine. L-(+)-Pseudoephedrine (Sudafed, Afrinol, Drixoral) is the (*S,S*) diastereoisomer of ephedrine. It is a naturally occurring alkaloid from the *Ephedra* species. Whereas ephedrine has a mixed mechanism of action, pseudoephedrine acts principally by an indirect mechanism. The structural basis for this difference in mechanism is the stereochemistry of the carbon atom possessing the β -hydroxyl group. In pseudoephedrine, this carbon atom possesses the (*S*) configuration, which is the wrong stereochemistry at this center for a direct-acting effect at adrenergic receptors. This agent is found in many over-the-counter nasal decongestant and cold medications. Although it is less prone to increase blood pressure than ephedrine, it should be used with caution in hypertensive individuals, and it should not be used in combination with MAO inhibitors.

Propylhexedrine. Propylhexedrine (Benzedrex) is an analogue of amphetamine in which the aromatic ring has been replaced with a cyclohexane ring. This drug produces vasoconstriction and a decongestant effect on the nasal membranes, but it has only about one-half the pressor effect of amphetamine and produces decidedly fewer effects on the CNS. Its major use is for a local vasoconstrictive effect on nasal mucosa in the symptomatic relief of nasal congestion caused by the common cold, allergic rhinitis, or sinusitis.

Sympathomimetics With a Mixed Mechanism of Action

Those phenylethylamines considered to have a mixed mechanism of action usually have no hydroxyls on the aromatic ring but do have a β -hydroxyl group.

D-(-)-Ephedrine. D-(-)-Ephedrine is the classic example of a sympathomimetic with a mixed mechanism of action. This drug is an alkaloid that can be obtained from the

TABLE 16-1 Relative Pressor Activity of the Isomers of Ephedrine

Isomer Relative Activity	
D-(-)-Ephedrine	36
DL-(±)-Ephedrine	26
L-(+)-Ephedrine	11
L-(+)-Pseudoephedrine	7
DL-(±)-Pseudoephedrine	4
D-(-)-Pseudoephedrine	1

stems of various species of *Ephedra*. Mahuang, the plant containing ephedrine, was known to the Chinese in 2,000 BC, but the active principle, ephedrine, was not isolated until 1885.

Ephedrine has two asymmetric carbon atoms; thus, there are four optically active forms. The *erythro* racemate is called "ephedrine," and the *threo* racemate is known as "pseudoephedrine" (ψ -ephedrine). Natural ephedrine is the D-(-) isomer, and it is the most active of the four isomers as a pressor amine (Table 16-1). This is largely due to the fact that this isomer has the correct (*R*) configuration at the carbon atom bearing the hydroxyl group and the desired (*S*) configuration at the carbon bearing the methyl group for optimal direct action at adrenergic receptors.

Ephedrine decomposes gradually and darkens when exposed to light. The free alkaloid is a strong base, and at aqueous solution of the free alkaloid has a pH above 10. The salt form has a pK_a of 9.6.

The pharmacological activity of ephedrine resembles that of epinephrine. The drug acts on both α - and β -adrenergic receptors. Although it is less potent than epinephrine, its pressor and local vasoconstrictive actions are of greater duration. It also causes more pronounced stimulation of the CNS than epinephrine, and it is effective when given orally. The drug is not metabolized by either MAO or COMT. Rather, it is p-hydroxylated and N-demethylated by cytochrome P-450 mixed-function oxidases.

Ephedrine and its salts are used orally, intravenously, intramuscularly, and topically for a variety of conditions, such as allergic disorders, colds, hypotensive conditions, and narcolepsy. It is used locally to constrict the nasal mucosa and cause decongestion and to dilate the pupil or the bronchi. Systemically, it is effective for asthma, hay fever, and urticaria.

Phenylpropanolamine. Phenylpropanolamine (Propadrine) is similar in structure to ephedrine except that it is primary instead of a secondary amine. This modification gives an agent that has slightly higher vasopressor action and lower central stimulatory action than ephedrine. Its α -

tion as a nasal decongestant is more prolonged than that of ephedrine. It is effective when given orally. Phenylpropanolamine was a common active component in over-the-counter appetite suppressants and cough and cold medications until 2001, when the Food and Drug Administration (FDA) recommended its removal from such medications because studies showed an increased risk of hemorrhagic stroke in young women who took the drug.

Phenylpropanolamine

Metaraminol. Metaraminol (Aramine) is structurally similar to phenylephrine except that it is a primary instead of a secondary amine. It possesses a mixed mechanism of action, with its direct-acting effects mainly on α -adrenergic receptors. It is used parenterally as a vasopressor in the treatment and prevention of the acute hypotensive state occurring with spinal anesthesia. It also has been used to treat severe hypotension brought on by other traumas that induce shock.

Metaraminol

ADRENERGIC RECEPTOR ANTAGONISTS

α -Adrenergic Receptor Antagonists

Unlike the β -adrenergic receptor antagonists, which bear clear structural similarities to the adrenergic agonists NE, epinephrine, and isoproterenol, the α -adrenergic receptor antagonists consist of a number of compounds of diverse chemical structure that bear little obvious resemblance to the α -adrenergic receptor agonists.³⁴

NONSELECTIVE α -RECEPTOR ANTAGONISTS

Tolazoline and Phentolamine. The agents in this class are structurally similar to the imidazoline α -agonists, such as naphazoline, tetrahydrozoline, and xylometazoline. The type of group attached to the imidazoline ring dictates whether an imidazoline is an agonist or an antagonist. The two representatives of the imidazoline α antagonists that are used therapeutically are tolazoline (Priscoline) and phentolamine (Regitine). Both are competitive (reversible) blocking agents. Phentolamine is the more effective α antagonist, but neither drug is useful in treating essential hypertension. Theoretically, the vasodilatory effects of an α -antagonist should be beneficial in the management of hypertension. Tolazoline and phentolamine, however, have both α_1 - and α_2 -antagonistic activity and produce tachycardia. Presum-

ably, the antagonistic actions of these agents at presynaptic α_2 receptors contribute to their cardiac stimulant effects by enhancing the release of NE. Both agents have a direct vasodilatory action on vascular smooth muscle that may be more prominent than their α -receptor antagonistic effects.

Tolazoline

Phentolamine

The antagonistic action of tolazoline is relatively weak, but its histamine-like and acetylcholine-like agonistic actions probably contribute to its vasodilatory activity. Its histamine-like effects include stimulation of gastric acid secretion, rendering it inappropriate for administration to patients who have gastric or peptic ulcers. It has been used to treat Raynaud's syndrome and other conditions involving peripheral vasospasm. Tolazoline is available in an injectable form and is indicated for use in persistent pulmonary hypertension of the newborn when supportive measures are not successful.

Phentolamine is used to prevent or control hypertensive episodes that occur in patients with pheochromocytoma. It can be used as an aid in the diagnosis of pheochromocytoma, but measurement of catecholamine levels is a safer and more reliable method of diagnosis. It also has been used in combination with papaverine to treat impotence.

IRREVERSIBLE α -RECEPTOR BLOCKERS

Agents in this class, when given in adequate doses, produce a slowly developing, prolonged adrenergic blockade that is not overcome by epinephrine. In essence, they are irreversible blockers of the α -adrenergic receptor. Chemically, they are β -haloalkylamines. Although dibenamine is the prototypical agent in this class, it is phenoxybenzamine that is used therapeutically today.

Dibenamine

Phenoxybenzamine

Figure 16-7 ■ Mechanism of inactivation of α -adrenergic receptors by β -haloalkylamines.

The mechanism whereby β -haloalkylamines produce a long-lasting, irreversible α -adrenergic receptor blockade is depicted in Figure 16-7. The initial step involves the formation of an intermediate aziridinium ion (ethylene iminium ion), which then forms an initial reversible complex with the receptor. The positively charged aziridinium ion electrophile then reacts with a nucleophilic group on the receptor, resulting in the formation of a covalent bond between the drug and the receptor. Although the aziridinium ion intermediate has long been believed to be the active receptor-alkylating species, it was not until 1976 that it was demonstrated unequivocally that the aziridinium ions derived from dibenamine and phenoxybenzamine are capable of α -receptor alkylation.^{5,4}

Phenoxybenzamine. The action of phenoxybenzamine (Dibenzylamine) has been described as representing a "chemical sympathectomy" because of its selective blockade of the excitatory responses of smooth muscle and of the heart muscle. Although phenoxybenzamine is capable of

blocking acetylcholine, histamine, and serotonin receptors, its primary pharmacological effects, especially vasodilation, may be attributed to its α -adrenergic blocking capability. As would be expected of a drug that produces such a profound α blockade, administration is frequently associated with reflex tachycardia, increased cardiac output, and postural hypotension. There is also evidence indicating that blockade of presynaptic α_2 receptors contributes to the increased heart rate produced by phenoxybenzamine.

The onset of action of phenoxybenzamine is slow, but the effects of a single dose of drug may last 3 to 4 days, since essentially new receptors need to be made to replace those that have been inhibited irreversibly. The principal effects following its administration are an increase in peripheral blood flow, an increase in skin temperature, and a lowering of blood pressure. It has no effect on the parasympathetic system and little effect on the gastrointestinal tract. The most common side effects are miosis, tachycardia, nasal stuffiness, and postural hypotension, all of which are related to the production of adrenergic blockade.

Oral phenoxybenzamine is used for the preoperative management of patients with pheochromocytoma and in the chronic management of patients whose tumors are not amenable to surgery. Only about 20 to 30% of an oral dose is absorbed.

SELECTIVE α_1 -RECEPTOR ANTAGONISTS

Prazosin, Terazosin, Doxazosin. One group of highly selective α_1 -receptor antagonists are the quinazolines. Examples include prazosin (Minipress), terazosin (Hytrin), and doxazosin (Cardura). Structurally, these three agents consist of three components: the quinazoline ring, the piperazine ring, and the acyl moiety. The 4-amino group on the quinazoline ring is very important for α_1 -receptor affinity. Although prazosin, terazosin, and doxazosin possess a piperazine moiety attached to the quinazoline ring, this group can be replaced with other heterocyclic moieties (e.g., piperidine moiety) without loss of affinity. The nature of the acyl group has a significant effect on the pharmacokinetic properties.⁶

These drugs are used in the treatment of hypertension. They dilate both arterioles and veins. Agents in this class offer distinct advantages over the other α -blockers because they produce peripheral vasodilation without an increase in heart rate or cardiac output. This advantage, at least in part, is attributed to the fact that prazosin blocks postjunctional α_1 receptors selectively without blocking presynaptic α_2 receptors. These agents also find use in the treatment of benign prostatic hyperplasia, where they help improve urine flow rates.

Although the adverse effects of these drugs are usually minimal, the most frequent one, known as the *first-dose phenomenon*, is sometimes severe. This is a dose-dependent effect characterized by marked excessive postural hypotension and syncope. This phenomenon can be minimized by giving an initial low dose at bedtime.

The main difference between prazosin, terazosin, and doxazosin lies in their pharmacokinetic properties. As mentioned above, these differences are dictated by the nature of the acyl moiety attached to the piperazine ring. A comparison of these three agents with respect to their oral bioavailability, half-life, and duration of action is shown in Table 16-2. These drugs are metabolized extensively, with the metabolites excreted in the bile.

Tamsulosin. The aryl sulfonamide tamsulosin (Flomax) represents the first in the class of subtype selective α_{1A} -receptor antagonists. It is selective for the α_{1A} -adrenergic receptor, which seems to predominate in the prostate. It is approved for treating benign prostatic hyperplasia, for which it is administered once daily. Orthostatic hypotension may not be as great with this agent as with the nonselective quinazolinines.

Tamsulosin

SELECTIVE α_2 -RECEPTOR ANTAGONISTS

Yohimbine and Corynanthine. Isomeric indole alkaloids known as the yohimbanes exhibit different degrees of selectivity toward the α_1 - and α_2 -adrenergic receptors, depending on their stereochemistry. For example, yohimbine is a selective antagonist of the α_2 receptor, while corynan-

thine is a selective antagonist of the α_1 receptor. The only difference between these two compounds is the relative stereochemistry of the carbon containing the carbomethoxy substituent. In yohimbine, this group lies in the plane of the alkaloid ring system, while in corynanthine, it lies in an axial position and thus is out of the plane of the rings.⁵⁶

Yohimbine

Corynanthine

Yohimbine increases heart rate and blood pressure as a result of its blockade of α_2 receptors in the CNS. It has been used experimentally to treat male erectile impotence.

Mirtazapine. The tetracyclic mirtazapine (Remeron) is another example of an α -antagonist that shows selectivity for α_2 receptors versus α_1 receptors.⁵⁷ Blockade of central α_2 receptors results in an increased release of norepinephrine and serotonin. This has prompted its use as an antidepressant. This agent also has activity at nonadrenergic receptors. It is a potent blocker of 5-HT₂ and 5-HT₃ serotonin receptors and at histamine H₁ receptors.

Mirtazapine

TABLE 16-2 Pharmacokinetic Properties of Prazosin, Terazosin, and Doxazosin

Agent	Bioavailability (%)	Half-life (hours)	Duration of Action (hours)
Prazosin	50–70	2–3	4–6
Terazosin	90	9–12	18
Doxazosin	65	22	36

β -Adrenergic Receptor Antagonists

STRUCTURE-ACTIVITY RELATIONSHIPS

The first β blocker was not reported until 1958, when Powell and Slater⁵⁸ described the activity of dichloroisoproterenol (DCI). The structure of DCI is like that of isoproterenol, except that the catechol hydroxyl groups have been replaced by two chloro groups. This simple structural modification, involving the replacement of the aromatic hydroxyl groups,

has provided the basis for nearly all of the approaches used in subsequent efforts to design and synthesize therapeutically useful β -receptor antagonists.⁵⁵ Unfortunately, DCl is not a pure antagonist but a partial agonist. The substantial direct sympathomimetic action of DCl precluded its development as a clinically useful drug.

Dichloroisoproterenol

Pronethalol was the next important β antagonist to be described. Although it had much less intrinsic sympathomimetic activity than DCl, it was withdrawn from clinical testing because of reports that it caused thymic tumors in mice. Within 2 years of this report, however, Black and Stephenson⁵⁹ described the β -blocking actions of propranolol, a close structural relative of pronethalol. Propranolol has become one of the most thoroughly studied and widely used drugs in the therapeutic armamentarium. It is the standard against which all other β antagonists are compared.

Pronethalol

Propranolol

Propranolol belongs to the group of β -blocking agents known as *aryloxypropanolamines*. This term reflects the fact that an $-OCH_2-$ group has been incorporated into the molecule between the aromatic ring and the ethylamino side chain. Because this structural feature is frequently found in β antagonists, the assumption is made that the $-OCH_2-$ group is responsible for the antagonistic properties of the molecules. However, this is not true; in fact, the $-OCH_2-$ group is present in several compounds that are potent β agonists.⁶⁰ This latter fact again leads to the conclusion that it is the nature of the aromatic ring and its substituents that is the primary determinant of β -antagonistic activity. The aryl group also affects the absorption, excretion, and metabolism of the β blockers.⁶¹

The nature of the aromatic ring is also a determinant in the β_1 selectivity of the antagonists. One common structural feature of many cardioselective antagonists is the presence of a *para* substituent of sufficient size on the aromatic ring along with the absence of *meta* substituents. Practolol is the prototypical example of a β_1 antagonist of this structural

type. Although it was not released for use in the United States, it was the first cardioselective β_1 antagonist to be used extensively in humans. Because it produced several toxic effects, however, it is no longer in general use in most countries.

Practolol

As in the sympathomimetics, bulky aliphatic groups, such as the *tert*-butyl and isopropyl groups, are normally found on the amino function of the aryloxypropanolamine β -receptor antagonists. It must be a secondary amine for optimal activity.

The β -blocking agents exhibit high stereoselectivity in the production of their β -blocking effects. As with the sympathomimetic agents, the configuration of the hydroxyl-bearing carbon of the aryloxypropanolamine side chain plays a critical role in the interaction of β -antagonist drugs with β receptors. This carbon must possess the (*S*) configuration for optimal affinity to the β receptor. The enantiomer with the (*R*) configuration is typically 100 times less potent. The available data indicate that the pharmacologically more active enantiomer interacts with the receptor recognition site in a manner analogous to that of the agonists. The structural features of the aromatic portion of the antagonist, however, appear to perturb the receptor or to interact with it in a manner that inhibits activation. In spite of the fact that nearly all of the β -antagonistic activity resides in one enantiomer, propranolol and most other β blockers are used clinically as racemic mixtures. The only exceptions are levobunolol, timolol, and penbutolol, with which the (*S*) enantiomer is used.

NONSELECTIVE β BLOCKERS

Propranolol. Propranolol (Inderal) is the prototypical β -adrenergic receptor antagonist. It is nonselective in that it blocks the β_1 and β_2 receptors equally well. Propranolol, like the other β -receptor antagonists that are discussed, is a competitive antagonist whose receptor-blocking actions can be reversed with sufficient concentrations of β agonists. Currently, propranolol is approved for use in the United States for hypertension, cardiac arrhythmias, angina pectoris, post myocardial infarction, hypertrophic cardiomyopathy, pheochromocytoma, migraine prophylaxis, and essential tremor. In addition, propranolol is under investigation for the treatment of a variety of other conditions, including anxiety, schizophrenia, alcohol withdrawal syndrome, and aggressive behavior.

Some of the most prominent effects of propranolol are on the cardiovascular system. By blocking the β receptors in the heart, propranolol slows the heart, reduces the force of contraction, and reduces cardiac output. Because of reflex sympathetic activity and blockade of vascular β_2 receptors,

administration may result in increased peripheral resistance. The antihypertensive action, at least in part, may be attributed to its ability to reduce cardiac output, as well as to its suppression of renin release from the kidney. Because it exhibits no selectivity for β_1 receptors, it is contraindicated in the presence of conditions such as asthma and bronchitis.

A facet of the pharmacological action of propranolol that has received a good deal of attention is its so-called membrane-stabilizing activity. This is a nonspecific effect (i.e., not mediated by a specific receptor), which is also referred to as a *local anesthetic effect* or a *quinidine-like effect*. Both enantiomers possess membrane-stabilizing activity. Since the concentrations required to produce this effect far exceed those obtained with normal therapeutic doses of propranolol and related β -blocking drugs, it is most unlikely that the nonspecific membrane-stabilizing activity plays any role in the clinical efficacy of β -blocking agents.

The metabolism of propranolol has received intense study. Propranolol is well absorbed after oral administration, but it undergoes extensive first-pass metabolism before it reaches the systemic circulation. Lower doses are extracted more efficiently than higher doses, indicating that the extraction process may become saturated at higher doses. In addition, the active enantiomer is cleared more slowly than the inactive enantiomer.⁶²

Numerous metabolites of propranolol have been identified, but the major metabolite in people, after a single oral dose, is naphthoxylic acid, which is formed by a series of metabolic reactions involving N-dealkylation, deamination, and oxidation of the resultant aldehyde. One metabolite of particular interest is 4-hydroxypropranolol. This compound is a potent β antagonist that has some intrinsic sympathomimetic activity. It is not known what contribution, if any, 4-hydroxypropranolol makes to the pharmacological effects seen after administration of propranolol. The half-life of propranolol after a single oral dose is 3 to 4 hours, which increases to 4 to 6 hours after long-term therapy.

Naphthoxylic Acid

4-Hydroxypropranolol

Other Nonselective β Blockers. Several other nonselective β blockers are used clinically. These include **nadolol** (Corgard), **pindolol** (Visken), **penbutolol** (Levitol), **carteolol**

(Cartrol, Ocupress), **timolol** (Blocadren, Timoptic), **levobunolol** (Betagan), **sotalol** (Betapace) and **metipranolol** (OptiPranolol). Structures of these compounds are shown in Figure 16-8. The first five of these agents are used to treat hypertension. Nadolol is also used in the long-term management of angina pectoris, while timolol finds use in the prophylaxis of migraine headaches and in the therapy following myocardial infarction. Sotalol is used as an antiarrhythmic in treating ventricular arrhythmias and atrial fibrillation because in addition to its β -adrenergic blocking activity, this agent blocks the inward K^+ current that delays cardiac repolarization.

Carteolol, timolol, levobunolol, and metipranolol are used topically to treat open-angle glaucoma. These agents lower intraocular pressure with virtually no effect on pupil size or accommodation. They thus offer an advantage over many of the other drugs used in the treatment of glaucoma. Although the precise mechanism whereby β blockers lower intraocular pressure is not known with certainty, it is believed that they may reduce the production of aqueous humor. Even though these agents are administered into the eye, systemic absorption can occur, producing such adverse effects as bradycardia and acute bronchospasm in patients with bronchospastic disease.

Pindolol possesses modest membrane-stabilizing activity and significant intrinsic β -agonistic activity. Penbutolol and carteolol also have partial agonistic activity but not to the degree that pindolol does. The β antagonists with partial agonistic activity cause less slowing of the resting heart rate than do agents without this capability. The partial agonistic activity may be beneficial in patients who are likely to exhibit severe bradycardia or who have little cardiac reserve.

Timolol, pindolol, penbutolol, and carteolol have half-life values in the same range as propranolol. The half-life of nadolol, however, is about 20 hours, making it one of the longest-acting β blockers. Timolol undergoes first-pass metabolism but not to the same extent that propranolol does. Timolol and penbutolol are metabolized extensively, with little or no unchanged drug excreted in the urine. Pindolol is metabolized by the liver to the extent of 60%, with the remaining 40% being excreted in the urine unchanged. In contrast, nadolol undergoes very little hepatic metabolism. Most of this drug is excreted unchanged in the urine.

β_1 -SELECTIVE BLOCKERS

The discovery that β -blocking agents are useful in the treatment of cardiovascular disease, such as hypertension, stimulated a search for cardioselective β blockers. Cardioselective β antagonists are drugs that have a greater affinity for the β_1 receptors of the heart than for β_2 receptors in other tissues. Such cardioselective agents should provide two important therapeutic advantages. The first advantage should be the lack of an antagonistic effect on the β_2 receptors in the bronchi. Theoretically, this would make β_1 blockers safe for use in patients who have bronchitis or bronchial asthma. The second advantage should be the absence of blockade of the vascular β_2 receptors, which mediate vasodilation. This would be expected to reduce or eliminate the increase in peripheral resistance that sometimes occurs after the administration of nonselective β antagonists. Unfortunately, cardi-

Figure 16-8 ■ Nonselective β blockers.

oselectivity is usually observed with β_1 antagonists at only relatively low doses. At normal therapeutic doses, much of the selectivity is lost.

At present, the following β_1 -selective agents are used therapeutically: **acebutolol** (Sectral), **atenolol** (Tenormin), **betaxolol** (Kerlone, Betoptic), **bisoprolol** (Zebeta), **esmolol** (Brevibloc), and **metoprolol** (Lopressor). Structures of these agents are depicted in Figure 16-9. All of these agents except esmolol are indicated for the treatment of hypertension. Atenolol and metoprolol are also approved for use in treating angina pectoris and in therapy following myocardial infarction. Betaxolol is the only β_1 -selective blocker indicated for the treatment of glaucoma.

Acebutolol and esmolol are indicated for treating certain cardiac arrhythmias. Esmolol was designed specifically to possess a very short duration of action; it has an elimination half-life of 9 minutes. This agent is administered by continuous intravenous infusion for control of ventricular rate in

patients with atrial flutter, atrial fibrillation, or sinus tachycardia. Its rapid onset and short duration of action render it useful during surgery, after an operation, or during emergency situations for short-term control of heart rates. Its effects disappear within 20 to 30 minutes after the infusion is discontinued. Esmolol must be diluted with an injectable solution before administration; it is incompatible with sodium bicarbonate.

The short duration of action of esmolol is the result of rapid hydrolysis of its ester functionality by esterases present in erythrocytes (Fig. 16-10). The resultant carboxylic acid is an extremely weak β antagonist that does not appear to exhibit clinically significant effects. The acid metabolite has an elimination half-life of 3 to 4 hours and is excreted primarily by the kidneys.

In the class of β_1 -selective blockers, only acebutolol possesses intrinsic sympathomimetic activity. This activity is very weak, however. Acebutolol and betaxolol possess

Figure 16-9 ■ β_1 -Selective blockers.

membrane-stabilizing activity, but the activity is much weaker than that seen with propranolol.

The half-life values of acebutolol and metoprolol are comparable to that seen with propranolol, and those of atenolol and bisoprolol are about twice that of propranolol. Betaxolol,

with a half-life ranging between 14 and 22 hours, has the longest duration of action of the β_1 -selective blockers. Like propranolol, metoprolol has low bioavailability because of significant first-pass metabolism. Although the bioavailability of betaxolol is very high, it is metabolized extensively by the liver, with very little unchanged drug excreted in the urine. Atenolol, like nadolol, has low lipid solubility and does not readily cross the blood-brain barrier. It is absorbed incompletely from the gastrointestinal tract, the oral bioavailability being approximately 50%. Little of the absorbed portion of the dose is metabolized; most of it is excreted unchanged in the urine. In the case of bisoprolol, about 50% of a dose undergoes hepatic metabolism, while the remaining 50% is excreted in the urine unchanged.

Acebutolol is one of the very few β blockers whose metabolite plays a significant role in its pharmacological actions. This drug is absorbed well from the gastrointestinal tract, but it undergoes extensive first-pass metabolic conversion to diacetolol. Diacetolol is formed by hydrolytic conversion of the amide group to the amine, followed by acetylation of the amine (Fig. 16-11). After oral administration, plasma levels of diacetolol are higher than those of acebutolol. Diacetolol is also a selective β_1 -receptor antagonist with partial

Figure 16-10 ■ Metabolism of esmolol.

Figure 16-11 ■ Metabolism of acebutolol.

agonistic activity; it has little membrane-stabilizing activity. It has a longer half-life (8 to 12 hours) than the parent drug and is excreted by the kidneys.

β BLOCKERS WITH α_1 -RECEPTOR ANTAGONIST ACTIVITY

Several drugs have been developed that possess both β - and α -receptor-blocking activities within the same molecule. Two examples of such molecules are labetalol (Normodyne) and carvedilol (Coreg).

Labetalol. Labetalol (Normodyne) is a phenylethanolamine derivative that is a competitive inhibitor at both β_1 - and β_2 -adrenergic receptors and at the α_1 -adrenergic receptor. It is a more potent β antagonist than α antagonist. Since it has two asymmetric carbon atoms (1 and 1'), it exists as a mixture of four isomers. It is this mixture that is used clinically in treating hypertension. The different isomers, however, possess different α - and β -antagonistic activities. The β -blocking activity resides solely in the (1*R*, 1'*R*) isomer, while the α_1 -antagonistic activity is seen in the (1*S*, 1'*R*) and (1*S*, 1'*S*) isomers, with the (1*S*, 1'*R*) isomer possessing the greater activity.⁶³ Labetalol is a clinically useful antihypertensive agent. The rationale for its use in the management of hypertension is that its α -receptor-blocking effects produce vasodilation and its β -receptor-blocking effects prevent the reflex tachycardia usually associated with vasodilation. Although labetalol is very well absorbed, it undergoes extensive first-pass metabolism.

Carvedilol. Carvedilol (Coreg), like labetalol, is a β blocker that possesses α_1 -adrenergic receptor-blocking activity. Only the (*S*) enantiomer possesses the β -blocking activity, while both enantiomers are antagonists of the α_1 -adrenergic receptor.⁶⁴ This drug is also unique in that it possesses antioxidant activity and an antiproliferative effect on vascular smooth muscle cells. It thus has a neuroprotective effect and the ability to provide major cardiovascular organ protection.⁶⁵ It is used in treating hypertension and congestive heart failure.

Cholinergic Drugs and Related Agents

GEORGE H. COCOLAS AND STEPHEN J. CUTLER

Few systems, if any, have been studied as extensively as those innervated by neurons that release acetylcholine (ACh) at their endings. Since the classic studies of Dale,¹ who described the actions of the esters and ethers of choline on isolated organs and their relationship to muscarine, pharmacologists, physiologists, chemists, and biochemists have applied their knowledge to understand the actions of the cholinergic nerve and its neurotransmitter. Advances in the applications of biotechnology and chemistry have developed probes that have uncovered the complexity of the action of ACh on cholinergic neurons and receptors, unknown when ACh was first demonstrated in the frog heart in 1921 by Loewi as the substance released by vagus nerve stimulation.²

This chapter includes the drugs and chemicals that act on cholinergic nerves or the tissues they innervate to either mimic or block the action of ACh. Drugs that mimic the action of ACh do so either by acting directly on the cholinergic receptors in the tissue or by inhibiting acetylcholinesterase (AChE), the enzyme that inactivates ACh at the nerve terminal. Chemicals that bind or compete with ACh for binding to the receptor may block cholinergic neurotransmission.

Cholinergic nerves are found in the peripheral nervous system and central nervous system (CNS) of humans. Its presence in the CNS is currently receiving the most attention, as researchers are beginning to unlock the mysteries surrounding cognitive impairment and, most particularly, Alzheimer's disease. Synaptic terminals in the cerebral cortex, corpus striatum, hippocampus, and several other regions in the CNS are rich in ACh and in the enzymes that synthesize and hydrolyze this neurotransmitter. Many experiments show that agonists and antagonists of cholinergic receptors can modify the output of neurotransmitters, including ACh, from brain preparations. Although the function of ACh in the brain and brainstem is not clear, it has been implicated in memory and behavioral activity in humans.³ The *peripheral nervous system* consists of those nerves outside the cerebrospinal axis and includes the somatic nerves and the autonomic nervous system. The *somatic nerves* are made up of a sensory (afferent) nerve and a motor (efferent) nerve. The *motor nerves* arise from the spinal cord and project uninterrupted throughout the body to all skeletal muscle. ACh me-

diates transmission of impulses from the motor nerve to skeletal muscle (i.e., neuromuscular junction).

The *autonomic nervous system* is composed of two divisions: *sympathetic* and *parasympathetic*. ACh serves as a neurotransmitter at both sympathetic and parasympathetic preganglionic nerve endings, postganglionic nerve fibers in the parasympathetic division, and some postganglionic fibers (e.g., salivary and sweat glands) in the sympathetic division of the autonomic nervous system. The autonomic nervous system regulates the activities of smooth muscle and glandular secretions. These, as a rule, function below the level of consciousness (e.g., respiration, circulation, digestion, body temperature, metabolism). The two divisions have contrasting effects on the internal environment of the body. The sympathetic division frequently discharges as a unit, especially during conditions of rage or fright, and expends energy. The parasympathetic division is organized for discrete and localized discharge and stores and conserves energy.

Drugs and chemicals that cause the parasympathetic division to react are termed *parasympathomimetic*, whereas those blocking the actions are called *parasympatholytic*. Agents that mimic the sympathetic division are *sympathomimetic*, and those that block the actions are *sympatholytic*. Another classification used to describe drugs and chemicals acting on the nervous system or the structures that the fibers innervate is based on the neurotransmitter released at the nerve ending. Drugs acting on the autonomic nervous system are divided into *adrenergic*, for those postganglionic sympathetic fibers that release norepinephrine and epinephrine, and *cholinergic*, for the remaining fibers in the autonomic nervous system and the motor fibers of the somatic nerves that release ACh.

CHOLINERGIC RECEPTORS

There are two distinct receptor types for ACh that differ in composition, location, and pharmacological function and have specific agonists and antagonists. Cholinergic receptors have been characterized as *nicotinic* and *muscarinic* on the basis of their ability to be bound by the naturally occurring alkaloids nicotine and muscarine, respectively. Receptor subtypes that differ in location and specificity to agonist and antagonists have been identified for both the nicotinic and muscarinic receptors.

Nicotinic Receptors

Nicotinic receptors are coupled directly to ion channels and, when activated by ACh, mediate very rapid responses to

Figure 17-1 ■ Hydrated cation showing a highly structured shell of water around the cation (A), a less structured layer surrounding the inner water shell (B), and water in a "normal" state (C). (With permission from the author and the Royal Society of Chemistry.)

channels are responsible for the electrical excitability of nerve and muscle cells and for the sensitivity of sensory cells. The channels are pores that open or close in an all-or-nothing fashion on time scales ranging from 0.1 to 10 milliseconds to provide aqueous pathways through the plasma membrane that ions can transverse. Factors affecting selectivity of ion pores include both the charge and size of the ion. Ions in aqueous solution are hydrated. The water around the ion is characterized by the presence of two distinct water structures: a tightly bound, highly ordered layer immediately surrounding the ion and a second, less structured layer⁴ (Fig. 17-1). Ion transport through a channel requires some denuding of the surrounding water shell. The degree of organization of the water structure determines the energy required to remove the hydration shell and is a factor

TABLE 17-1 Radii of Alkali and Alkali Earth Cations

Ion	Ionic Radius (Å)	Effective Hydrated Radius (Å)
Li	0.60	4.5

in the selectivity of that ion channel.⁵ Table 17-1 lists the effective radii of alkali and alkaline earth cations.

The nicotinic ACh receptor was the first neurotransmitter isolated and purified in an active form.⁶ It is a glycoprotein embedded into the polysynaptic membrane that can be obtained from the electric organs of the marine ray *Torpedo californica* and the electric eel *Electrophorus electricus*. The receptor is pictured as a cylindrical protein of about 250,000 Da and consists of five-subunit polypeptide chains, of which two appear to be identical.^{7, 8} The subunit stoichiometry of the polypeptide units from the *Torpedo* receptor is $\alpha_2\beta\gamma\delta$.⁹ The peptide chains of the receptor are arranged to form an opening in the center, which is the ion channel. Each α chain contains a negatively charged binding site for the quaternary ammonium group of ACh. The receptor appears to exist as a dimer of the two five-subunit polypeptide chain monomers linked through a disulfide bond between δ chains. A structural protein of molecular weight 43,000 binds the nicotinic receptor to the membrane (Fig. 17-2). With so many variables in the subunits, many combinations of nicotinic subtype receptors are available.

When the neurotransmitter ACh binds to the nicotinic receptor, it causes a change in the permeability of the membrane to allow passage of small cations Ca^{2+} , Na^{+} , and

Figure 17-2 ■ Model of the nicotinic receptor consisting of five protein subunits embedded in a cell membrane, based on electron microscopy and neutron scattering data. Jagged lines represent oligosaccharide chains on the upper part of the receptor. A 43K protein is bound to the receptor on the cytosolic side of the cell membrane. The ACh-binding sites are shown on the two-subunit proteins. (Reprinted with permission from Lindstrom, J. M., et al.: Cold Spring Harbor Symp. Quant. Biol. 48:93, 1983.)

K⁺. The physiological effect is to temporarily depolarize the end plate. This depolarization results in muscular contraction at a neuromuscular junction or, as occurs in autonomic ganglia, continuation of the nerve impulse. Neuromuscular nicotinic ACh receptors are of interest as targets for autoimmune antibodies in myasthenia gravis and for muscle relaxants used during the course of surgical procedures. Nicotinic receptors in autonomic ganglia, when blocked by drugs, can play a role in the control of hypertension.

NICOTINIC RECEPTOR SUBTYPES

Nicotinic receptors located in the neuromuscular junction differ from those on neurons, such as those in the CNS and autonomic ganglia, in that they have different ligand specificities. Nicotinic receptors at the neuromuscular junction (N₁) are blocked by succinylcholine, *d*-tubocurarine, and decamethonium and stimulated by phenyltrimethylammonium. N₂ nicotinic receptors are found in autonomic ganglia. They are blocked by hexamethonium and trimethaphan but stimulated by tetramethylammonium and dimethyl-4-phenylpiperazinium (DMPP). Nicotinic receptor subtypes have also been identified in many regions of the CNS; however, their pharmacological function is not yet fully understood.¹⁰ Even so, great attempts are being made to understand the role of so many receptor subtypes, particularly those found in the CNS.^{11, 12}

Decamethonium

Phenyltrimethylammonium

Muscarinic Receptors

Muscarinic receptors play an essential role in regulating the functions of organs innervated by the autonomic nervous system to maintain homeostasis of the organism. The action of ACh on muscarinic receptors can result in stimulation or inhibition of the organ system affected. ACh stimulates secretions from salivary and sweat glands, secretions and contraction of the gut, and constriction of the airways of the respiratory tract. It inhibits contraction of the heart and relaxes smooth muscle of blood vessels.

As early as 1980, it became apparent that a single muscar-

inic receptor type could not mediate the actions of ACh. Research on cholinergic receptors has increased since the 1980s, as these receptors represent potential targets for useful drugs for disease states that are becoming more prevalent because of our increasing population of aged persons. The outcome of these studies has been the discovery of several muscarinic receptor subtypes.

Hexamethonium

Tetramethylammonium

DMPP

Muscarinic receptors mediate their effects by activating guanosine triphosphate (GTP)-binding proteins (G proteins). These receptors have seven protein helices that transcend the plasma membrane, creating four extracellular domains and four intracellular domains (Fig. 17-3). The extracellular domain of the receptor contains the binding site for ACh. The intracellular domain couples with G proteins to initiate biochemical changes that result in pharmacological action from receptor activation.

MUSCARINIC RECEPTOR SUBTYPES

Evidence from both pharmacological and biochemical studies shows that subtypes of muscarinic receptors are located in the CNS and peripheral nervous system.^{13, 14} Molecular cloning studies have revealed the existence of five different molecular mammalian muscarinic receptor proteins. The cloned receptors have been identified as m₁ to m₅. In another method of identification, muscarinic receptor subtypes have been defined on the basis of their affinity for selective agonists and antagonists and the pharmacological effects they cause. These receptors are designated with capital letters and subscript numbers as M₁ to M₅. The nomenclature convention adopted for these receptors is that the pharmacologically defined subtypes M₁, M₂, and M₃ correspond to the gene-

Figure 17-3 ■ Hypothetical model of a muscarinic receptor showing the location of the transmembrane helical protein domains and the extracellular and intracellular domains connecting the seven α -helical proteins in the membrane. (Reprinted from Goyal, R. K.: *N. Engl. J. Med.* 321:1024, 1989, with permission from the author and the Massachusetts Medical Society.)

cally defined subtypes m_1 , m_2 , and m_3 . The m_4 gene-derived protein is referred to as the M_4 subtype and has many pharmacological properties similar to those of the M_2 subtype. The m_5 receptor gene product does not have an equivalent pharmacological profile.

M_1 Receptors. Even though molecules do not have exclusive selectivity on muscarinic receptor subtypes, M_1 receptors have been defined as those with high affinity for pirenzepine and low affinity for compounds such as AF-DX 116. They have been termed *neural* because of their distribution within particular brain structures. In addition to the CNS, M_1 receptors are located in exocrine glands and autonomic ganglia. In humans, these receptors seem to affect arousal, attention, rapid eye movement (REM) sleep, emotional responses, affective disorders including depression, and modulation of stress. They are believed to participate in higher brain functions, such as memory and learning. Alzheimer's disease research has implicated cholinergic neurons and receptors, but evidence does not show conclusively that these are the primary causes of the disease. M_1 receptors have been identified in submucosal glands and some smooth muscle. They are located in parietal cells in the gastrointestinal (GI) tract and in peripheral autonomic ganglia, such as the intramural ganglia of the stomach wall. When stimulated, M_1 receptors cause gastric secretion.¹⁵ Although McN-A-43 is a selective agonist, pirenzepine HCl acts as an antago-

nist and has been used outside the United States for the treatment of peptic ulcer disease.

M_2 Receptors. M_2 receptors are identified by their high affinity for methoctramine, a polyamine, and by their low affinity for pirenzepine. M_2 receptors are also called *cardiac* muscarinic receptors because they are located in the atria and conducting tissue of the heart. Their stimulation causes a decrease in the strength and rate of cardiac muscle contraction. These effects may be produced by affecting intracellular K^+ and Ca^{2+} levels in heart tissue. M_2 receptors activate K^+ channels to cause hyperpolarization of cardiac cells, resulting in bradycardia. These receptors may also act through an inhibitory G protein (G_i) to reduce adenylate cyclase activity and lower cyclic 3',5'-adenosine monophosphate (cAMP) levels in cardiac cells. Lower cAMP levels decrease the amount of free Ca^{2+} in cardiac cells and slow down the heart rate.¹⁶ M_2 receptors can also serve as autoreceptors on presynaptic terminals of postganglionic cholinergic nerves to inhibit ACh release. The balance of the effects of multiple muscarinic receptor subtypes determines the size of the airway of the smooth muscle in the bronchioles. Contraction is primarily the result of the action of ACh on M_3 receptors (see below) following stimulation of the vagus. At the same time, ACh stimulates inhibitor M_2 autoreceptors located on nerve endings to limit release of ACh. In asthmatics, neuronal M_2 receptors in the lungs do not function normally.¹⁷

M₃ Receptors. M₃ receptors, referred to as *glandular* muscarinic receptors, are located in exocrine glands and smooth muscle. Their effect on these organ systems is mostly stimulatory. Glandular secretions from lacrimal, salivary, bronchial, pancreatic, and mucosal cells in the GI tract are characteristic of M₃ receptor activation. Contraction of visceral smooth muscle is also a result of M₃ receptor stimulation. These stimulant effects are mediated through G protein activation of phospholipase C (PLC) to form the second messengers inositol triphosphate (IP₃) and diacylglycerol (DAG). Discoveries in the past decade have revealed that the endothelium can control the tone of vascular smooth muscle by the synthesis of a potent relaxant, endothelium-derived relaxing factor (EDRF), now identified as nitric oxide (NO), and a vasoconstrictor substance, endothelium-derived contracting factor (EDCF). The synthesis and release of these substances contribute to the tone of the vascular epithelium. M₃ receptors, when activated in endothelial cells, cause the release of EDRF and contribute to vasodilation.¹⁸

M₄ Receptors. M₄ receptors, like M₂ receptors, act through G_i protein to inhibit adenylate cyclase. They also function by a direct regulatory action on K⁺ and Ca²⁺ ion channels. M₄ receptors in tracheal smooth muscle, when stimulated, inhibit the release of ACh¹⁹ in the same manner that M₂ receptors do.

M₅ Receptors. A great deal of research remains to be performed on the M₅ subclass of receptors. Since the M₅ receptor messenger RNA (mRNA) is found in the substantia nigra, it has been suggested that M₅ receptors may regulate dopamine release at terminals within the striatum.

BIOCHEMICAL EFFECTS OF MUSCARINIC RECEPTOR STIMULATION

Transmission at the synapse involving second messengers is much slower, about 100 milliseconds, compared with the few milliseconds at synapses where ion channels are activated directly. The delayed reaction to receptor stimulation is due to a cascade of biochemical events that must occur to cause the pharmacological response (Fig. 17-4). The sequence of events in these second-messenger systems begins with activation of the receptors by an agonist and involves the activation of G proteins that are bound to a portion of the intracellular domain of the muscarinic receptor.²⁰ G proteins are so called because of their interaction with the guanine nucleotides GTP and guanosine diphosphate (GDP). They translate drug-receptor interactions at the surface of the cell to components inside the cell to create the biological response. G proteins consist of three subunits, α , β , and γ . When the receptor is occupied, the α subunit, which has enzymatic activity, catalyzes the conversion of GTP to GDP. The α subunit bound with GTP is the active form of the G protein that can associate with various enzymes (i.e., PLC and adenylate cyclase) and ion channels (K⁺ and Ca²⁺). G proteins are varied, and the α subunit may cause activation (G_s) or inactivation (G_i) of the enzymes or channels. Recent studies suggest that β and γ subunits also contribute to pharmacological effects.²¹

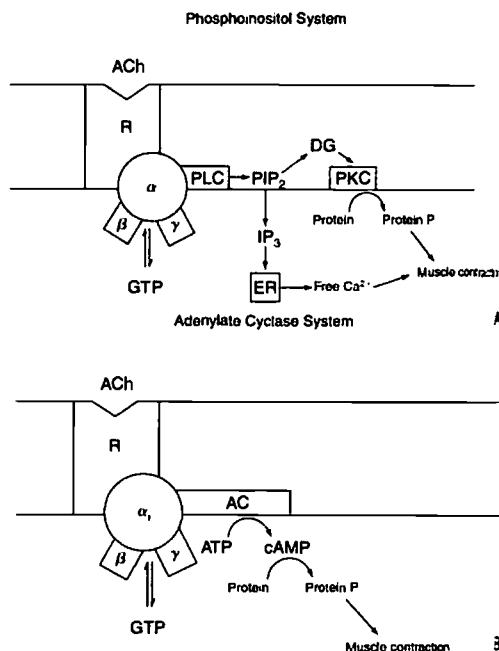

Figure 17-4 ■ Proposed biochemical mechanisms of cholinergic receptor action. **A.** ACh activates a G protein (α , β , γ) to activate the phosphoinositol system to activate the membrane enzyme phospholipase C (PLC), enhancing muscle contraction. **B.** Inhibition of adenylate cyclase system through an inhibitory G protein (α_i) to cause muscle relaxation.

A single drug-receptor complex can activate several G protein molecules, and each in turn can remain associated with a target molecule, e.g., an enzyme, and cause the production of many molecules, amplifying the result of the initial drug-receptor combination. M₁, M₃, and M₅ receptors activate PLC, causing the release of IP₃ and DAG, which in turn release intracellular Ca²⁺ and activate protein kinases respectively. M₂ and M₄ receptors produce inhibition of adenylate cyclase.

Phosphoinositol System. The phosphoinositol system requires the breakdown of membrane-bound phosphatidylinositol 4,5-diphosphate (PIP₂) by PLC to IP₃ and DAG which serve as second messengers in the cell. IP₃ mobilizes Ca²⁺ from intracellular stores in the endoplasmic reticulum to elevate cytosolic free Ca²⁺. The Ca²⁺ activates Ca²⁺-dependent kinases (e.g., troponin C in muscle) directly or binds to the Ca²⁺-binding protein calmodulin, which activates calmodulin-dependent kinases. These kinases phosphorylate cell-specific enzymes to cause muscle contraction. DAG is lipid-like and acts in the plane of the membrane through activation of protein kinase C to cause the phosphorylation of cellular proteins, also leading to muscle contraction (Fig. 17-4).^{22, 23}

Adenylate Cyclase. Adenylate cyclase, a membrane enzyme, is another target of muscarinic receptor activation. The second messenger cAMP is synthesized within the cell from adenosine triphosphate (ATP) by the action of adenylate cyclase. The regulatory effects of cAMP are many, as it can activate a variety of protein kinases. Protein kinases catalyze the phosphorylation of enzymes and ion channels, altering the amount of calcium entering the cell and thus affecting muscle contraction. Muscarinic receptor activation causes lower levels of cAMP, reducing cAMP protein-dependent kinase activity, and a relaxation of muscle contraction. Some have suggested that a GTP-inhibitory protein (G_i) reduces the activity of adenylate cyclase, causing smooth muscle relaxation (Fig. 17-4).^{20, 24}

Ion Channels. In addition to the action of protein kinases that phosphorylate ion channels and modify ion conductance, G proteins are coupled directly to ion channels to regulate their action.²⁴ The Ca^{2+} channel on the cell membrane is activated by G proteins without the need of a second messenger to allow Ca^{2+} to enter the cell. The α subunit of

the G protein in heart tissue acts directly to open the K^+ channel, producing hyperpolarization of the membrane and slowing the heart rate.

CHOLINERGIC NEUROCHEMISTRY

Cholinergic neurons synthesize, store, and release ACh (Fig. 17-5). The neurons also form choline acetyltransferase (ChAT) and AChE. These enzymes are synthesized in the soma of the neuron and distributed throughout the neuron by axoplasmic flow. AChE is also located outside the neuron and is associated with the neuroglial cells in the synaptic cleft. ACh is prepared in the nerve ending by the transfer of an acetyl group from acetyl-coenzyme A (CoA) to choline. The reaction is catalyzed by ChAT. Cell fractionation studies show that much of the ACh is contained in synaptic vesicles in the nerve ending but that some is also free in the cytosol. Choline is the limiting substrate for the synthesis

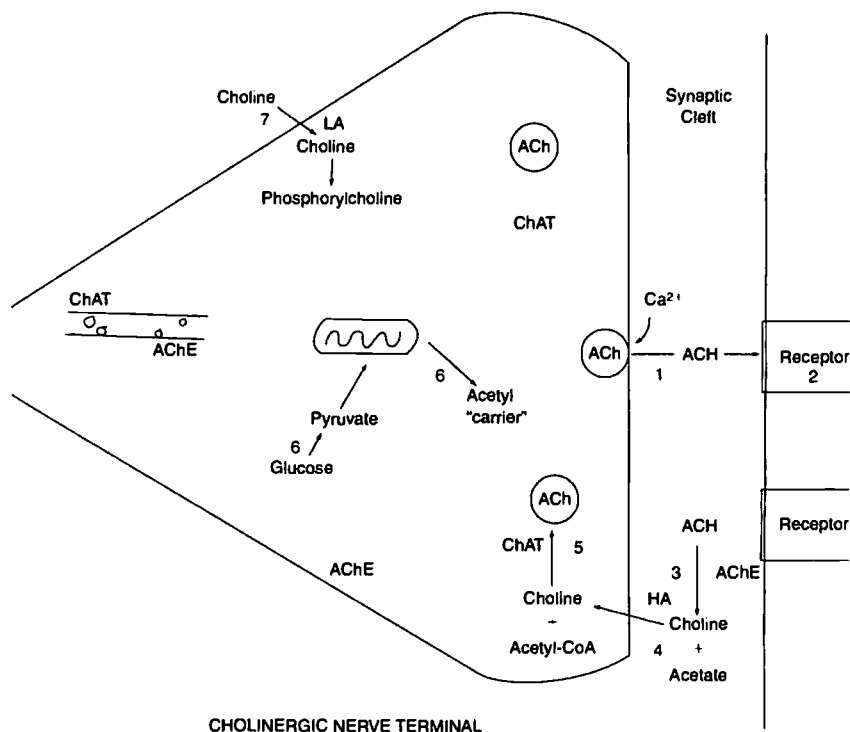

Figure 17-5 ■ Hypothetical model of synthesis, storage, and release of ACh. (1) ACh is released from storage granules under the influence of the nerve action potential and Ca^{2+} . (2) ACh acts on postsynaptic cholinergic receptors. (3) Hydrolysis of ACh by AChE occurs in the synaptic cleft. (4) A high-affinity uptake system returns choline to the cytosol. (5) ChAT synthesizes ACh in the cytosol, and the ACh is stored in granules. (6) Glucose is converted to pyruvate, which is converted to acetyl-CoA in the mitochondria. Acetyl-CoA is released from the mitochondria by an acetyl carrier. (7) Choline is also taken up into the neuron by a low-affinity uptake system and converted partly to phosphorylcholine.

of ACh. Most choline for ACh synthesis comes from the hydrolysis of ACh in the synapse. Choline is recaptured by the presynaptic terminal as part of a high-affinity uptake system under the influence of sodium ions²⁵ to synthesize ACh.

Several quaternary ammonium bases act as competitive inhibitors of choline uptake. Hemicholinium (HC-3), a bis-quaternary cyclic hemiacetal, and the triethyl analogue of choline, 2-hydroxyethyltriethylammonium, act at the presynaptic membrane to inhibit the high-affinity uptake of choline into the neuron. These compounds cause a delayed paralysis at repetitively activated cholinergic synapses and can produce respiratory paralysis in test animals. The delayed block is due to the depletion of stored ACh, which may be reversed by choline. The acetyl group used for the synthesis of ACh is obtained by conversion of glucose to pyruvate in the cytosol of the neuron and eventual formation of acetyl-CoA. Because of the impermeability of the mitochondrial membrane to acetyl-CoA, this substrate is brought into the cytosol by the aid of an acetyl "carrier."

The synthesis of ACh from choline and acetyl-CoA is catalyzed by ChAT. Transfer of the acetyl group from acetyl-CoA to choline may be by a random or an ordered reaction of the Theorell-Chance type. In the ordered sequence, acetyl-CoA first binds to the enzyme, forming a complex (EA) that then binds to choline. The acetyl group is transferred, and the ACh formed dissociates from the enzyme active site. The CoA is then released from the enzyme complex, EQ.

Figure 17-6 ■ Ordered synthesis of acetylcholine (ACh) by choline acetyltransferase (ChAT).

to regenerate the free enzyme. The scheme is diagrammed in Figure 17-6. ChAT is inhibited *in vitro* by *trans*-*N*-methyl-4-(1-naphthylvinyl)pyridinium iodide²⁶; however, its inhibitory activity in whole animals is unreliable.²⁷

trans-*N*-Methyl-4-(1-naphthylvinyl)pyridinium iodide

Newly formed ACh is released from the presynaptic membrane when a nerve action potential invades a presynaptic nerve terminal.²⁸ The release of ACh results from depolarization of the nerve terminal by the action potential, which alters membrane permeability to Ca^{2+} . Calcium enters the nerve terminal and causes release of the contents of several synaptic vesicles containing ACh into the synaptic cleft. This burst, or quantal release, of ACh causes depolarization of the postsynaptic membrane. The number of quanta of ACh released may be as high as several hundred at a neuromuscular junction, with each quantum containing between 12,000 and 60,000 molecules. ACh is also released spontaneously in small amounts from presynaptic membranes. This small amount of neurotransmitter maintains muscle tone by acting on the cholinergic receptors on the postsynaptic membrane.

After ACh has been released into the synaptic cleft, its concentration decreases rapidly. It is generally accepted that there is enough AChE at nerve endings to hydrolyze into choline and acetate any ACh that has been liberated. For example, there is sufficient AChE in the nerve junction of rat intercostal muscle to hydrolyze about 2.7×10^8 ACh molecules in 1 millisecond; this far exceeds the 3×10^7 molecules released by one nerve impulse.²⁹

Figure 17-7 ■ Spatial orientation of O1-C5-C4-N atoms in ACh.

CHOLINERGIC AGONISTS

Cholinergic Stereochemistry

Three techniques have been used to study the conformational properties of ACh and other cholinergic chemicals: x-ray crystallography, nuclear magnetic resonance (NMR), and molecular modeling by computation. Each of these methods may report the spatial distribution of atoms in a molecule in terms of torsion angles. A *torsion angle* is defined as the angle formed between two planes, for example, by the O1-C5-C4-N atoms in ACh. The angle between the oxygen and nitrogen atoms is best depicted by means of Newman projections (Fig. 17-7). A torsion angle has a positive sign when the bond of the front atom is rotated to the right to eclipse the bond of the rear atom. The spatial orientation of ACh is described by four torsion angles (Fig. 17-8).

The conformation of the choline moiety of ACh has drawn the most attention in studies relating structure and pharmacological activity. The torsion angle (τ_2) determines the spatial orientation of the cationic head of ACh to the ester group. X-ray diffraction studies have shown that the torsion angle (τ_2) on ACh has a value of $+77^\circ$. Many compounds that are muscarinic receptor agonists containing a choline component—e.g., O-C-C-N⁺(CH₃)₃—have a preferred synclinal (gauche) conformation, with τ_2 values ranging from 68° to 89° (Table 17-2). Intermolecular packing forces in the crystal as well as electrostatic interactions between the charged nitrogen group and the ether oxygen of the ester group are probably the two dominant factors that lead to a preference for the synclinal conformation in the crystal state. Some choline esters display an antiperiplanar (*trans*) conformation between the onium and ester groups. For example, carbamoyl choline chloride (τ_2 , $+178^\circ$) is stabilized in this *trans* conformation by several hydrogen bonds. Acetylthiocholine iodide (τ_2 , $+171^\circ$) is in this conformation because of the presence of the bulkier and less electronegative sulfur

Figure 17-8 ■ ACh torsion angles.

From Shefter, L.: Structural variations in cholinergic legends. In Triggle, D. J., Moran, J. F., and Barnard, E. A. (eds.) *Cholinergic Ligand Interactions*. New York, Academic Press, 1971, pp. 87-89.

atom, and (+) *trans*-(1*S*,2*S*)-acetoxycyclopropyltrimethylammonium iodide (τ_2 , $+137^\circ$) is fixed in this conformation by the rigidity of the cyclopropyl ring.

NMR spectroscopy of cholinergic molecules in solution is more limited than crystallography in delineating the conformation of compounds and is restricted to determining the torsion angle O1-C5-C4-N. Most NMR data are in agreement with the results of x-ray diffraction studies. NMR studies indicate that ACh and methacholine apparently are not in their most stable *trans* conformation but exist in one of two gauche conformers³⁰ (Fig. 17-9). This may result from strong intramolecular interactions that stabilize the conformation of these molecules in solution.³¹

Molecular orbital calculations based on the principles of quantum mechanics may be used to determine energy minima of rotating bonds and to predict preferred conformations for the molecule. By means of molecular mechanics, theoretical conformational analysis has found that ACh has an energy minimum for the τ_2 torsion angle at about 84° and that the preferred conformation of ACh corresponds closely in aqueous solution to that found in the crystal state.

The study of interactions between bimolecules and small

Figure 17-9 ■ Gauche conformers of methacholine.

Figure 17-10 ■ Geometric isomers of muscarine.

molecules is of great interest and importance toward the understanding of drug action. These studies are challenging because of the large size of at least one molecule. For the first time, the conformation of a neurotransmitter has been determined for a molecule in the bound state. ACh is transformed from the gauche conformation in the free state to a nearly *trans* conformation when bound to the nicotinic receptor.³² The active conformation of muscarinic agonists on their receptor has a dihedral angle of τ_3 between 110 and 117°.³³

The parasympathomimetic effects of muscarine were first reported in 1869,³⁴ but its structure was not elucidated until 1957.³⁵ Muscarine has four geometric isomers: muscarine, epimuscarine, allomuscarine, and epiallomuscarine (Fig. 17-10). None has a center or plane of symmetry. Each geometric isomer can exist as an enantiomeric pair. The activity of muscarine, a nonselective muscarinic receptor agonist, resides primarily in the naturally occurring (+)-muscarine enantiomer. It is essentially free of nicotinic activity and apparently has the optimal stereochemistry to act on the muscarinic receptor subtypes. Synthetic molecules with a substituent on the carbon atom that corresponds to the β carbon of ACh also show great differences in muscarinic activity between their isomers. Acetyl-(+)-(*S*)- β -methylcholine, (+)-*cis*-(2*S*)-methyl-(4*R*)-trimethylammonium-

1,3-dioxolane, (+)-*trans*-(1*S*,2*S*)-acetoxycyclopropyltrimethylammonium, and naturally occurring (+)-(*S*,3*R*,5*S*)-muscarine are more potent than their enantiomers and have very high ratios of activity between the (*S*) and (*R*) isomers (Table 17-3). A similar observation may be made of (-)-acetyl-(*S*)- β -methylcholine, (+)-*cis*-(2*S*)-methyl-(4*R*)-trimethylammonium-1,3-dioxolane, and (+)-*trans*-(1*S*,2*S*)-acetoxycyclopropyltrimethylammonium, all of which have an (*S*) configuration at the carbon atom that corresponds to the β carbon of ACh. Each of these active muscarinic molecules may be deployed on the receptor in the same manner as ACh and (+)-muscarine. Their (*S*)/(*R*) ratios (Table 17-3) show the greatest stereoselectivity of the muscarinic receptor in guinea pig ileum for the configuration at the carbon adjacent to the ester group. In contrast, the nicotinic receptors are not considered as highly stereoselective as their muscarinic counterparts.

Figure 17-11 ■ Hypothetical structure of the muscarinic receptor.

Structure-Activity Relationships

Although muscarinic receptors have been cloned and the amino acid sequences are known, their three-dimensional structures remain unresolved. Thus, it is not possible to use this information alone to design specific drug molecules. Scientists still use pharmacological and biochemical tests to determine optimal structural requirements for activity. ACh is a relatively simple molecule. The chemistry and ease of testing for ACh biological activity have allowed numerous chemical derivatives to be made and studied. Alterations on the molecule may be divided into three categories: the onium group, the ester function, and the choline moiety.

The onium group is essential for intrinsic activity and contributes to the affinity of the molecule for the receptors, partially through the binding energy and partially because of its action as a detecting and directing group. Molecular modeling data show the binding site to be a negatively charged aspartic acid residue in the third of the seven trans-

membrane helices of the muscarinic receptor.³⁶ Hydrophobic pockets are located in helices 4, 5, 6, and 7 of the muscarinic receptor (Fig. 17-11).³⁷ The trimethylammonium group is the optimal functional moiety for activity, though some significant exceptions are known (e.g., pilocarpine, arcoline, nicotine, and oxotremorine). Phosphonium, sulfonium, arsonium isosteres, or substituents larger than methyl on the nitrogen increase the size of the onium moiety, produce diffusion of the positive charge, and interfere sterically with proper drug-receptor interaction, resulting in decreased activity (Table 17-4).

The ester group in ACh contributes to the binding of the compound to the muscarinic receptor because of hydrogen bond formation with threonine and asparagine residues at the receptor site. A comparison of the cholinergic activity of a series of alkyltrimethylammonium compounds [R-N⁺(CH₃)₃, R = C₁-C₆] shows *n*-amyltrimethylammonium,³⁸ which may be considered to have a size and mass similar to those of ACh and to be one magnitude weaker as a muscarinic agonist. The presence of the acetyl group in ACh is not as critical as the size of the molecule. Studying a series of *n*-alkyltrimethylammonium salts revealed³⁹ that for maximal muscarinic activity, the quaternary ammonium group should be followed by a chain of five atoms; this has been referred to as the *five-atom rule*.

Shortening or lengthening the chain of atoms that separates the ester group from the onium moiety reduces muscarinic activity. An α substitution on the choline moiety decreases both nicotinic and muscarinic activity, but muscarinic activity is decreased to a greater extent. Nicotinic activity is decreased to a greater degree by substitution on the β carbon. Therefore, acetyl α -methylcholine, although less potent than ACh, has more nicotinic than muscarinic activity, while acetyl β -methylcholine (methacholine) exhibits

Pharmacol. 7:103, 1952.

^a Reduces effect of acetylcholine

Figure 17-12 ■ Comparison of the geometries of oxotremorine and muscarine.

more muscarinic than nicotinic activity. Hydrolysis by AChE is more affected by substitutions on the β than the α carbon. The hydrolysis rate of racemic acetyl β -methylacetylcholine is about 50% of that of ACh; racemic acetyl α -ACh is hydrolyzed about 90% as fast.

Oxotremorine. Oxotremorine [1-(pyrrolidono)-4-pyrrolidino-2-butyne] has been regarded as a CNS muscarinic stimulant. Its action on the brain produces tremors in experimental animals. It increases ACh brain levels in rats up to 40% and has been studied as a drug in the treatment of Alzheimer's disease. Although earlier studies suggested that this approach of elevating levels of ACh to treat Alzheimer's disease is useful, this belief was highly disputed by many researchers. Nevertheless, oxotremorine, as a cholinergic agonist, facilitates memory storage.⁴⁰ These findings have served as important leads in the development of agents useful in treating Alzheimer's disease. Although it possesses groups that do not occur in other highly active muscarinic agents, oxotremorine's *trans* conformation shows that distances between possible active centers correspond with (+)-muscarine (Fig. 17-12).⁴¹

Arecoline. Arecoline is an alkaloid obtained from the seeds of the betel nut (*Areca catechu*). For many years, natives of the East Indies have consumed the betel nut as a source of a euphoria-creating substance.

CHOLINERGIC RECEPTOR ANTAGONISTS

Characterization of muscarinic receptors can now be extended beyond the pharmacological observations on organ systems (e.g., smooth muscle, heart) to determine structure-activity relationships. Dissociation constants of antagonists from radioligand-binding experiments on the various muscarinic receptors have played a major role in identifying these receptors and the selectivity of antagonists to the five muscarinic receptor subtypes. Antagonists with high affinity for one receptor and a low affinity for the other four receptor types are very few, however, and many antagonists bind to several subtypes with equal affinity. M_1 receptors have been identified as those with high affinity for pirenzepine and low affinity for a compound such as AF-DX 116. Pirenzepine can distinguish between M_1 and M_2 , M_3 , or M_5 but has significant affinity for M_4 receptors. Himbacine can distinguish between M_1 and M_3 receptors. Methoctramine, a polymethylenetetramine, not only discriminates between

M_1 and M_2 receptors but also has good selectivity for M_3 muscarinic receptors. M_2 receptors bind to AF-DX 116 and gallamine, a neuromuscular blocking agent. M_3 receptors have a high affinity for 4-diphenylacetoxy-*N*-methylpiperidine (4-DAMP) and hexahydrostiladifenidol (HHSiD) but also exhibit affinity for M_1 and M_2 receptors.²¹ Tropicamide has been reported to be a putative M_4 receptor antagonist. Figure 17-13 includes structures of some receptor subtype antagonists.

Products

Acetylcholine Chloride. ACh chloride exerts a powerful stimulant effect on the parasympathetic nervous system. Attempts have been made to use it as a cholinergic agent, but its duration of action is too short for sustained effects, because of rapid hydrolysis by esterases and lack of specificity when administered for systemic effects. It is a cardiac depressant and an effective vasodilator. Stimulation of the vagus and the parasympathetic nervous system produces a tonic action on smooth muscle and induces a flow from the salivary and lacrimal glands. Its cardiac-depressant effect results from (a) a negative chronotropic effect that causes a decrease in heart rate and (b) a negative inotropic action on heart muscle that produces a decrease in the force of myocardial contractions. The vasodilatory action of ACh is primarily on the arteries and the arterioles, with distinct effect on the peripheral vascular system. Bronchial constriction is a characteristic side effect when the drug is given systemically.

Acetylcholine Chloride

One of the most effective antagonists to the action of ACh is atropine, a nonselective muscarinic antagonist. Atropine blocks the depressant effect of ACh on cardiac muscle and its production of peripheral vasodilation (i.e., muscarinic effects) but does not affect the skeletal muscle contraction (i.e., nicotinic effect) produced.

ACh chloride is a hygroscopic powder that is available in an admixture with mannitol to be dissolved in sterile water for injection shortly before use. It is a short-acting miotic when introduced into the anterior chamber of the eye and is especially useful after cataract surgery during the placement of sutures. When applied topically to the eye, it has little therapeutic value because of poor corneal penetration and rapid hydrolysis by AChE.

Methacholine Chloride, USP. Methacholine chloride acetyl- β -methylcholine chloride or (2-hydroxypropyl)dimethylammonium chloride acetate, is the acetyl ester of β -methylcholine. Unlike ACh, methacholine has sufficient stability in the body to give sustained parasympathetic stimu-

Figure 17-13 ■ Chemical structures of partially selective muscarinic antagonists.

tion. This action is accompanied by little (1/1000 that of ACh) or no nicotinic effect.

Methacholine Chloride

Methacholine can exist as (*S*) and (*R*) enantiomers. Although the chemical is used as the racemic mixture, its muscarinic activity resides principally in the (*S*) isomer. The (*S*)/(*R*) ratio of muscarinic potency for these enantiomers is 240:1.

(+)-Acetyl-(*S*)- β -methylcholine is hydrolyzed by AChE, whereas the (*R*)(-) isomer is not. (-)-Acetyl-(*R*)- β -methylcholine is a weak competitive inhibitor (K_i , 4×10^{-4} M) of AChE obtained from the electric organ of the eel (*Electrophorus electricus*). The hydrolysis rate of the (*S*)(+) isomer is about 54% that of ACh. This rate probably compensates for any decreased association (affinity) owing to the β -

methyl group with the muscarinic receptor site and may account for the fact that ACh and (+)-acetyl- β -methylcholine have equimolar muscarinic potencies in vivo. (-)-Acetyl-(*R*)- β -methylcholine weakly inhibits AChE and slightly reinforces the muscarinic activity of the (*S*)(+) isomer in the racemic mixture of acetyl- β -methylcholine.

In the hydrolysis of the acetyl α - and β -methylcholines, the greatest stereochemical inhibitory effects occur when the choline is substituted in the β position. This also appears to be true of organophosphorous inhibitors. The (*R*)(-) and (*S*)(+) isomers of acetyl- α -methylcholine are hydrolyzed at 78 and 97% of the rate of ACh, respectively.

Methacholine chloride occurs as colorless or white crystals or as a white crystalline powder. It is odorless or has a slight odor and is very deliquescent. It is freely soluble in water, alcohol, or chloroform, and its aqueous solution is neutral to litmus and bitter. It is hydrolyzed rapidly in alkaline solutions. Solutions are relatively stable to heat and will keep for at least 2 or 3 weeks when refrigerated to delay growth of molds.

Carbachol. Choline chloride carbamate is nonspecific in its action on muscarinic receptor subtypes. The pharmaco-

logical activity of carbachol is similar to that of ACh. It is an ester of choline and thus possesses both muscarinic and nicotinic properties by cholinergic receptor stimulation. It can also act indirectly by promoting release of ACh and by its weak anticholinesterase activity. Carbachol forms a carbamyl ester in the active site of AChE, which is hydrolyzed more slowly than an acetyl ester. This slower hydrolysis rate reduces the amount of free enzyme and prolongs the duration of ACh in the synapse. Carbachol also stimulates the autonomic ganglia and causes contraction of skeletal muscle but differs from a true muscarinic agent in that it does not have cardiovascular activity despite the fact that it seems to affect M_2 receptors.⁴²

Carbachol is a mitotic and has been used to reduce the intraocular tension of glaucoma when a response cannot be obtained with pilocarpine or neostigmine. Penetration of the cornea is poor but can be enhanced by the use of a wetting agent in the ophthalmic solution. In addition to its topical use for glaucoma, carbachol is used during ocular surgery, when a more prolonged miosis is required than can be obtained with ACh chloride.

Carbachol Chloride

Carbachol differs chemically from ACh in its stability to hydrolysis. The carbamyl group of carbachol decreases the electrophilicity of the carbonyl and, thus, can form resonance structures more easily than ACh can. The result is that carbachol is less susceptible to hydrolysis and, therefore, more stable in aqueous solutions.

Bethanechol Chloride, USP. Bethanechol, β -methylcholine chloride carbamate, (2-hydroxypropyl)trimethylammonium chloride carbamate, carbamylmethylcholine chloride (Urecholine), is nonspecific in its action on muscarinic receptor subtypes but appears to be more effective at eliciting pharmacological action of M_3 receptors.⁴³ It has pharmacological properties similar to those of methacholine. Both are esters of β -methylcholine and have feeble nicotinic activity. Bethanechol is inactivated more slowly by AChE in vivo than is methacholine. It is a carbamyl ester and is expected to have stability in aqueous solutions similar to that of carbachol.

The main use of bethanechol chloride is in the relief of urinary retention and abdominal distention after surgery. The drug is used orally and by subcutaneous injection. It must never be administered by intramuscular or intravenous injection because of the danger from cholinergic overstimulation and loss of selective action. Proper administration of the drug is associated with low toxicity and no serious side effects. Bethanechol chloride should be used with caution in asthmatic patients; when used for glaucoma, it produces frontal headaches from the constriction of the sphincter muscle in the eye and from ciliary muscle spasms. Its duration of action is 1 hour.

Bethanechol Chloride

Pilocarpine Hydrochloride, USP. Pilocarpine monohydrochloride is the hydrochloride of an alkaloid obtained from the dried leaflets of *Pilocarpus jaborandi* or *P. microphyllus*, in which it occurs to the extent of about 0.5% together with other alkaloids.

Pilocarpine Hydrochloride

It occurs as colorless, translucent, odorless, faintly bitter crystals that are soluble in water (1:0.3), alcohol (1:3), and chloroform (1:360). (In this chapter, a solubility expressed as 1:360 indicates that 1 g is soluble in 360 mL of the solvent at 25°C. Solubilities at other temperatures are so indicated.) It is hygroscopic and affected by light; its solutions are acid to litmus and may be sterilized by autoclaving. Alkalies saponify the lactone group to give the pharmacologically inactive hydroxy acid (pilocarpic acid). Base-catalyzed epimerization at the ethyl group position occurs to an appreciable extent and is another major pathway of degradation.⁴⁴ Both routes result in loss of pharmacological activity.

Pilocarpine is a nonselective agonist on the muscarinic receptors. Despite this, it reportedly acts on M_3 receptors in smooth muscle to cause contractions in the gut, trachea, and eye.^{45, 46} In the eye, it produces pupillary constriction (miosis) and a spasm of accommodation. These effects are valuable in the treatment of glaucoma. The pupil constriction and spasm of the ciliary muscle reduce intraocular tension by establishing better drainage of ocular fluid through the canal of Schlemm, located near the corner of the iris and cornea. Pilocarpine is used as a 0.5 to 0.6% solution (i.e., of the salts) in treating glaucoma. Systemic effects include copious sweating, salivation, and gastric secretion.

Pilocarpine Nitrate, USP. Pilocarpine mononitrate occurs as shining white crystals that are not hygroscopic but are light sensitive. It is soluble in water (1:4) and alcohol (1:75) but insoluble in chloroform and ether. Aqueous solutions are slightly acid to litmus and may be sterilized by the autoclave. The alkaloid is incompatible with alkaline iodides, silver nitrate, and reagents that precipitate alkaloids.

Cholinesterase Inhibitors

There are two types of cholinesterases in humans, AChE and butyrylcholinesterase (BuChE). The cholinesterases differ in their location in the body and their substrate specificity.

TABLE 17-5 Hydrolysis of Various Substrates by AChE and BuChE

Enzyme Substrate	AChE		BuChE	
	Source	Relative Rate*	Source	Relative Rate*

*Relative rates at approximately optimal substrate concentration; rate with acetylcholine = 100.

AChE is associated with the outside surface of glial cells in the synapse and catalyzes the hydrolysis of ACh to choline and acetic acid. Inhibition of AChE prolongs the duration of the neurotransmitter in the junction and produces pharmacological effects similar to those observed when ACh is administered. These inhibitors are indirect-acting cholinergic agonists. AChE inhibitors have been used in the treatment of myasthenia gravis, atony in the GI tract, and glaucoma. They have also been used as agricultural insecticides and nerve gases. More recently, they have received attention as symptomatic drug treatments in patients suffering from Alzheimer's disease.⁴⁷

BuChE (pseudocholinesterase) is located in human plasma. Although its biological function is not clear, it has catalytic properties similar to those of AChE. The substrate specificity is broader (Table 17-5), and it may hydrolyze dietary esters and drug molecules in the blood.

Three different chemical groupings, acetyl, carhamyl, and phosphoryl, may react with the esteratic site of AChE. Although the chemical reactions are similar, the kinetic parameters for each type of substrate differ and result in differences between toxicity and usefulness.

The initial step in the hydrolysis of ACh by AChE is a reversible enzyme-substrate complex formation. The association rate (k_{+1}) and dissociation rate (k_{-1}) are relatively large. The enzyme-substrate complex, E_A -ACh, may also form an acetyl-enzyme intermediate at a rate (k_2) that is slower than either the association or dissociation rates. Choline is released from this complex with the formation of the acetyl-enzyme intermediate, EA. This intermediate is then hydrolyzed to regenerate the free enzyme and acetic acid. The acetylation rate, k_2 , is the slowest step in this sequence and is rate-limiting (see discussion below).

Kinetic studies with different substrates and inhibitors suggest that the active center of AChE consists of several major domains: an anionic site, to which the trimethylammonium group binds; an esteratic site, which causes hydrolysis of the ester portion of ACh; and hydrophobic sites, which bind aryl substrates, other uncharged ligands, and the alkyl portion of the acyl moiety of ACh. There is also a peripheral anionic site, removed by at least 20 Å from this active center, which allosterically regulates activity at the esteratic site.⁴⁸ The anionic site was believed to have been formed by the γ -carboxylate group of a glutamic acid residue,⁴⁹ but more

Figure 17-14 ■ Mechanism of hydrolysis of ACh by AChE. **A.** ACh-AChE reversible complex. **B.** Acetylation of esteratic site. **C.** General base-catalyzed hydrolysis of acetylated enzyme. **D.** Free enzyme.

recent studies suggest that the aromatic moieties of tryptophan and phenylalanine residues bind the quaternary ammonium group of ACh in the anionic site through cation- π interactions.⁵⁰ The location and spatial organization in the esteratic site by serine, histidine, and glutamic acid residues constitute the esteratic site. The triad of these amino acid residues contributes to the high catalytic efficiency of AChE (Fig. 17-14).⁵¹

AChE attacks the ester substrate through a serine hydroxyl, forming a covalent acyl-enzyme complex. The serine is activated as a nucleophile by the glutamic acid and histidine residues that serve as the proton sink to attack the carbonyl carbon of ACh. Choline is released, leaving the acetylated serine residue on the enzyme. The acetyl-enzyme intermedi-

ate is cleaved by a general base catalysis mechanism to regenerate the free enzyme. The rate of the deacetylation step is indicated by k_3 .

Carbamates such as carbachol are also able to serve as substrates for AChE, forming a carbamylated enzyme intermediate (E-C). The rate of carbamylation (k_2) is slower than the rate of acetylation. Hydrolysis (k_3 , decarbamylation) of the carbamyl-enzyme intermediate is 10^7 times slower than that of its acetyl counterpart. The slower hydrolysis rate limits the optimal functional capacity of AChE, allowing carbamate substrates to be semireversible inhibitors of AChE.

In the mechanism above, k_3 is rate-limiting. The rate depends not only on the nature of the alcohol moiety of the

where CX = carbamylating substrate

ester but also on the type of carbamyl ester. Esters of carbamic acid

are better carbamylating agents of AChE than the methylcarbamyl

and dimethylcarbamyl analogues.⁵²

Organophosphate esters of selected compounds can also esterify the serine residue in the active site of AChE. The hydrolysis rate (k_3) of the phosphorylated serine is extremely slow, and hydrolysis to the free enzyme and phosphoric acid derivative is so limited that the inhibition is considered irreversible. These organophosphorous compounds are used in the treatment of glaucoma, as agricultural insecticides, and, at times, as nerve gases in warfare and bioterrorism. Finally, some have either been or are currently being evaluated for use against Alzheimer's disease. Table 17-6 shows the relative potencies of several AChE inhibitors.

Reversible Inhibitors

Physostigmine, USP. Physostigmine is an alkaloid obtained from the dried ripe seed of *Physostigma venenosum*. It occurs as a white, odorless, microcrystalline powder that is slightly soluble in water and freely soluble in alcohol, chloroform, and the fixed oils. The alkaloid, as the free base, is quite sensitive to heat, light, moisture, and bases, undergoing rapid decomposition. In solution it is hydrolyzed to methylcarbamic acid and eseroline, neither of which inhibits AChE. Eseroline is oxidized to a red compound, rubreserine,⁵³ and then further decomposed to eserine blue and eserine brown. Addition of sulfite or ascorbic acid prevents oxidation of the phenol, eseroline, to rubreserine. Hydrolysis does take place, however, and the physostigmine is inactivated. Solutions are most stable at pH 6 and should never be sterilized by heat.

TABLE 17-6 Inhibition Constants for Anticholinesterase Potency of Acetylcholinesterase Inhibitors

Reversible and Semireversible Inhibitors	K_1 (M)
Ambenonium	4.0×10^{-8}
Carbachol	1.0×10^{-4}
Demecarium	1.0×10^{-10}
Edrophonium	3.0×10^{-7}
Neostigmine	1.0×10^{-7}
Physostigmine	1.0×10^{-8}
Pyridostigmine	4.0×10^{-7}
Irreversible Inhibitors	K_2 (mol/min)
Isoflurophate	1.9×10^4
Echothiophate	1.2×10^5
Paraoxon	1.1×10^6
Sarin	6.3×10^7
Tetraethylpyrophosphate	2.1×10^8

Physostigmine is a relatively poor carbamylating agent of AChE and is often considered a reversible inhibitor of the enzyme. Its cholinesterase-inhibiting properties vary with the pH of the medium (Fig. 17-15). The conjugate acid of physostigmine has a pK_a of about 8, and as the pH of the solution is lowered, more is present in the protonated form. Inhibition of cholinesterase is greater in acid media, suggesting that the protonated form makes a contribution to the inhibitory activity well as its carbamylation of the enzyme.

Physostigmine was used first as a topical application in the treatment of glaucoma. Its lipid solubility properties permit adequate absorption from ointment bases. It is used systemically as an antidote for atropine poisoning and other anticholinergic drugs by increasing the duration of action of ACh at cholinergic sites through inhibition of AChE. Physostigmine, along with other cholinomimetic drugs acting in the CNS, has been studied for use in the treatment of Alzheimer's disease.⁵⁴ Cholinomimetics that are currently used or which have been recently evaluated in the treatment of Alzheimer's disease include donepezil, galantamine, metriflo-

where PX = phosphorylating substrate

nate, rivastigmine, and tacrine.⁴⁷ It is anticipated that this list will continue to grow as the etiology of this disease becomes better understood.

Physostigmine Salicylate, USP. The salicylate of physostigmine (eserine salicylate) may be prepared by neutralizing an ethereal solution of the alkaloid with an ethereal solution of salicylic acid. Excess salicylic acid is removed from the precipitated product by washing it with ether. The salicylate is less deliquescent than the sulfate.

Physostigmine salicylate occurs as a white, shining, odorless crystal or white powder that is soluble in water (1:75), alcohol (1:16), or chloroform (1:6) but much less soluble in ether (1:250). On prolonged exposure to air and light, the

crystals turn red. The red may be removed by washing the crystals with alcohol, although this causes loss of the compound as well. Aqueous solutions are neutral or slightly acidic and take on a red coloration after a period. The coloration may be taken as an index of the loss of activity of physostigmine solutions.

Solutions of physostigmine salicylate are incompatible with the usual reagents that precipitate alkaloids (alkalies) and with iron salts. Incompatibility also occurs with benzalkonium chloride and related wetting agents because of the salicylate ion.

Physostigmine Sulfate, USP. Physostigmine sulfate occurs as a white, odorless, microcrystalline powder that is deliquescent in moist air. It is soluble in water (1:4), alcohol (1:0.4), and ether (1:200). It has the advantage over the salicylate salt of being compatible in solution with benzalkonium chloride and related compounds.

Neostigmine Bromide. Neostigmine bromide, (*m*-hydroxyphenyl)trimethylammonium bromide dimethylcarbamate,

Figure 17-15 ■ Effect of pH on inhibition of cholinesterase by physostigmine and neostigmine.

mate or the dimethylcarbamate ester of 3-hydroxyphenyltrimethylammonium bromide (Prostigmin bromide), is used as an antidote to nondepolarizing neuromuscular blocking drugs and in the treatment of myasthenia gravis. It occurs as a bitter, odorless, white, crystalline powder. It is soluble in water and alcohol. The crystals are much less hygroscopic than those of neostigmine methylsulfate and thus may be used in tablets. Solutions are stable and may be sterilized by boiling. Aqueous solutions are neutral to litmus.

Neostigmine Bromide

Use of physostigmine, as a prototype of an indirect-acting parasympathomimetic drug, facilitated the development of stigmine, in which a trimethylamine group was placed *para* to a dimethylcarbamate group in benzene. Better inhibition of cholinesterase was observed when these groups were placed *meta* to each other as in neostigmine, a more active and useful agent. Although physostigmine contains a methylcarbamate functional group, greater chemical stability toward hydrolysis was obtained with the dimethylcarbamyl group in neostigmine.⁵⁵

Neostigmine has a half-life of about 50 minutes after oral or intravenous administration. About 80% of a single intramuscular dose is excreted in the urine within 24 hours; approximately 40% is excreted unchanged, and the remainder is excreted as metabolites. Of the neostigmine that reaches the liver, 98% is metabolized in 10 minutes to 3-hydroxyphenyltrimethyl ammonium, which has activity similar to, but weaker than, neostigmine. Its transfer from plasma to liver cells and then to bile is probably passive. Because cellular membranes permit the passage of plasma proteins synthesized in the liver into the bloodstream through capillary walls or lymphatic vessels, they may not present a barrier to the diffusion of quaternary amines such as neostigmine. The rapid hepatic metabolism of neostigmine may provide a downhill gradient for the continual diffusion of this compound.⁵⁶ A certain amount is hydrolyzed slowly by plasma cholinesterase.

Neostigmine has a mechanism of action quite similar to that of physostigmine. It effectively inhibits cholinesterase at about 10^{-6} M concentration. Its activity does not vary with pH, and at all ranges it exhibits similar cationic properties (Fig. 17-15). Skeletal muscle is also stimulated by neostigmine, a property that physostigmine does not have.

The uses of neostigmine are similar to those of physostigmine but differ in exhibiting greater miotic activity, fewer and less unpleasant local and systemic manifestations, and greater chemical stability. The most frequent application of neostigmine is to prevent atony of the intestinal, skeletal, and bladder musculature. An important use is in the treatment of

myasthenia gravis, a condition caused by an autoimmune mechanism that requires an increase in ACh concentration in the neuromuscular junction to sustain normal muscular activity.

Neostigmine Methylsulfate. Neostigmine methylsulfate, (*m*-hydroxyphenyl)trimethylammonium methylsulfate dimethylcarbamate or the dimethylcarbamate ester of 3-hydroxyphenyltrimethylammonium methylsulfate (Prostigmin methylsulfate), is a bitter, odorless, white, crystalline powder. It is very soluble in water and soluble in alcohol. Solutions are stable and can be sterilized by boiling. The compound is too hygroscopic for use in a solid form and thus is always used as an injection. Aqueous solutions are neutral to litmus.

Neostigmine Methylsulfate

The methylsulfate salt is used postoperatively as a urinary stimulant and in the diagnosis and treatment of myasthenia gravis.

Pyridostigmine Bromide, USP. Pyridostigmine bromide, 3-hydroxy-1-methylpyridinium bromide dimethylcarbamate or pyridostigmine bromide (Mestinon), occurs as a white, hygroscopic, crystalline powder with an agreeable, characteristic odor. It is freely soluble in water, alcohol, and chloroform.

Pyridostigmine Bromide

Pyridostigmine bromide is about one-fifth as toxic as neostigmine. It appears to function in a manner similar to that of neostigmine and is the most widely used anticholinesterase agent for treating myasthenia gravis. The liver enzymes and plasma cholinesterase metabolize the drug. The principal metabolite is 3-hydroxy-*N*-methylpyridinium. Orally administered pyridostigmine has a half-life of 90 minutes and a duration of action of between 3 and 6 hours.

Ambenonium Chloride. Ambenonium chloride, [oxalylbis(iminoethylene)]bis[(*o*-chlorobenzyl)diethylammon-

Ambenonium Chloride

ium] dichloride (Mytelase chloride), is a white, odorless powder, soluble in water and alcohol, slightly soluble in chloroform, and practically insoluble in ether and acetone. Ambenonium chloride is used for the treatment of myasthenia gravis in patients who do not respond satisfactorily to neostigmine or pyridostigmine.

This drug acts by suppressing the activity of AChE. It possesses a relatively prolonged duration of action and causes fewer side effects in the GI tract than the other anticholinesterase agents. The dosage requirements vary considerably, and the dosage must be individualized according to the response and tolerance of the patient. Because of its quaternary ammonium structure, ambenonium chloride is absorbed poorly from the GI tract. In moderate doses, the drug does not cross the blood-brain barrier. Ambenonium chloride is not hydrolyzed by cholinesterases.

Demecarium Bromide, USP. Demecarium bromide, (*m*-hydroxyphenyl)trimethylammonium bromide, decamethylenebis[methylcarbamate] (Humorsol), is the diester of (*m*-hydroxyphenyl)trimethylammonium bromide with de-

camethylene bis(methylcarbamic acid) and thus is comparable to a his-prostigmine molecule.

It occurs as a slightly hygroscopic powder that is freely soluble in water or alcohol. Ophthalmic solutions of the drug have a pH of 5 to 7.5. Aqueous solutions are stable and may be sterilized by heat. Its efficacy and toxicity are comparable to those of other potent anticholinesterase inhibitor drugs. It is a long-acting miotic used to treat wide-angle glaucoma and accommodative esotropia. Maximal effect occurs hours after administration, and the effect may persist for days.

Donepezil. Donepezil, (\pm)-2,3-dihydro-5,6-dimethoxy-2-[[1-(phenylmethyl)-4-piperidinyl]methyl]-1*H*-inden-1-one (Aricept), commonly referred to in the literature as E2020, is a reversible inhibitor of AChE. It is indicated for the treatment of symptoms of mild-to-moderate Alzheimer's disease. Donepezil is approximately 96% bound to plasma proteins, with an elimination half-life of 70 hours. It is metabolized principally by the 2D6 and 3A4 isozymes of the P-450 system.

Demecarium Bromide

Donepezil

Edrophonium Chloride, USP. Edrophonium chloride, ethyl(*m*-hydroxyphenyl)dimethylammonium chloride (Tensilon), is a reversible anticholinesterase agent. It is bitter and very soluble in water and alcohol. Edrophonium chloride injection has a pH of 5.2 to 5.5. On parenteral administration, edrophonium has a more rapid onset and shorter duration of action than neostigmine, pyridostigmine, or ambenonium. It is a specific anticholinesterase agent and acts within 1 minute to alleviate overdose of *d*-tubocurarine, dimethyl *d*-tubocurarine, or gallamine triethiodide. The drug is also used to terminate the action of any one of these drugs when the physician so desires. It is of no value, however, in terminating the action of the depolarizing (i.e., noncompetitive) blocking agents, such as decamethonium and succinylcholine. In addition to inhibiting AChE, edrophonium chloride has a direct cholinomimetic effect on skeletal muscle, which is greater than that of most other anticholinesterase drugs.

Edrophonium Chloride

Edrophonium chloride is structurally related to neostigmine methylsulfate and has been used as a potential diagnostic agent for myasthenia gravis. This is the only degenerative neuromuscular disease that can be temporarily improved by administration of an anticholinesterase agent. Edrophonium chloride brings about a rapid increase in muscle strength without significant side effects.

Galantamine. Galantamine, 4a,5,9,10,11,12-hexahydro-3-methoxy-11-methyl-6*H*-benzofuro-[3a,3,2,ef][2]-benzazepin-6-ol (Nivalin, Reminyl), is an alkaloid extracted from the tuberous plant *Leucojum aestivum* (L.) belonging to the Amaryllidaceae family and from the bulbs of the daffodil, *Narcissus pseudonarcissus*. It is a reversible cholinesterase inhibitor that appears to have no effect on butyrylcholinesterase. In addition, it acts at allosteric nicotinic sites, further enhancing its cholinergic activity. Galantamine undergoes slow and minor biotransformation with approximately 5 to 6% undergoing demethylation. It is primarily excreted in the urine.

Galantamine

Metrifonate. Metrifonate is an organophosphate that was originally developed to treat schistosomiasis under the trade name Bilarcil. It is an irreversible cholinesterase inhibitor with some selectivity for BuChE over AChE. It achieves sustained cholinesterase inhibition by its nonenzymatic metabolite dichlorvos (DDVP), a long-acting organophosphate. Its use in mild- to moderate Alzheimer's disease was suspended recently because of adverse effects experienced by several patients during the clinical evaluation of this product. Toxicity at the neuromuscular junction is probably attributable to the inhibition by the drug of neurotoxic esterase, a common feature of organophosphates.

Rivastigmine. Rivastigmine (Exelon, EA 713) is a pseudoirreversible noncompetitive carbamate inhibitor of AChE. Although the half-life is approximately 2 hours, the inhibitory properties of this agent last for 10 hours because of the slow dissociation of the drug from the enzyme. The FDA approved its use in mild-to-moderate Alzheimer's disease in April 2000.

Rivastigmine

Tacrine Hydrochloride. Tacrine hydrochloride, 1,2,3,4-tetrahydro-9-aminoacridine hydrochloride (THA, Cognex), is a reversible cholinesterase inhibitor that has been used in the treatment of Alzheimer's disease for several years. The drug has been used to increase the levels of ACh in these patients on the basis of observations from autopsies that concentrations of ChAT and AChE are markedly reduced in the brain, while the number of muscarinic receptors is almost normal. The use of the drug is not without controversy, as conflicting results on efficacy have been reported.^{57, 58} The drug has been used in mild-to-moderate Alzheimer's dementia.

Tacrine Hydrochloride

Irreversible Inhibitors

Both AChE and BuChE are inhibited irreversibly by a group of phosphate esters that are highly toxic (LD₅₀ for humans is 0.1 to 0.001 mg/kg). These chemicals are nerve poisons and have been used in warfare, in bioterrorism, and as agricultural insecticides. They permit ACh to accumulate at nerve endings and exacerbate ACh-like actions. The compounds belong to a class of organophosphorous esters. A general formula for such compounds follows:

A is usually oxygen or sulfur but may also be selenium. When A is other than oxygen, biological activation is required before the compound becomes effective as an inhibitor of cholinesterases. Phosphorothionates $[\text{R}_1\text{R}_2\text{P}(\text{S})\text{X}]$ have much poorer electrophilic character than their oxygen analogues and are much weaker hydrogen bond-forming molecules because of the sulfur atom.⁵⁹ Their anticholinesterase activity is 10^5 -fold weaker than their oxygen analogues. X is the leaving group when the molecule reacts with the enzyme. Typical leaving groups include fluoride, nitrile, and *p*-nitrophenoxy. The R groups may be alkyl, alkoxy, aryl, aryloxy, or amino. The R moiety imparts lipophilicity to the molecule and contributes to its absorption through the skin.

Inhibition of AChE by organophosphorous compound takes place in two steps, association of enzyme and inhibitor and the phosphorylation step, completely analogous to acylation by the substrate (Fig. 17-16). Stereospecificity is mainly due to interactions of enzyme and inhibitor at the esteric site.

The serine residue at the esteric site forms a stable phosphoryl ester with the organophosphorous inhibitors. This stability permits labeling studies⁶⁰ to be carried out on this and other enzymes (e.g., trypsin, chymotrypsin) that have the serine hydroxyl as part of their active site.

Although insecticides and nerve gases are irreversible inhibitors of cholinesterases by forming a phosphorylated ser-

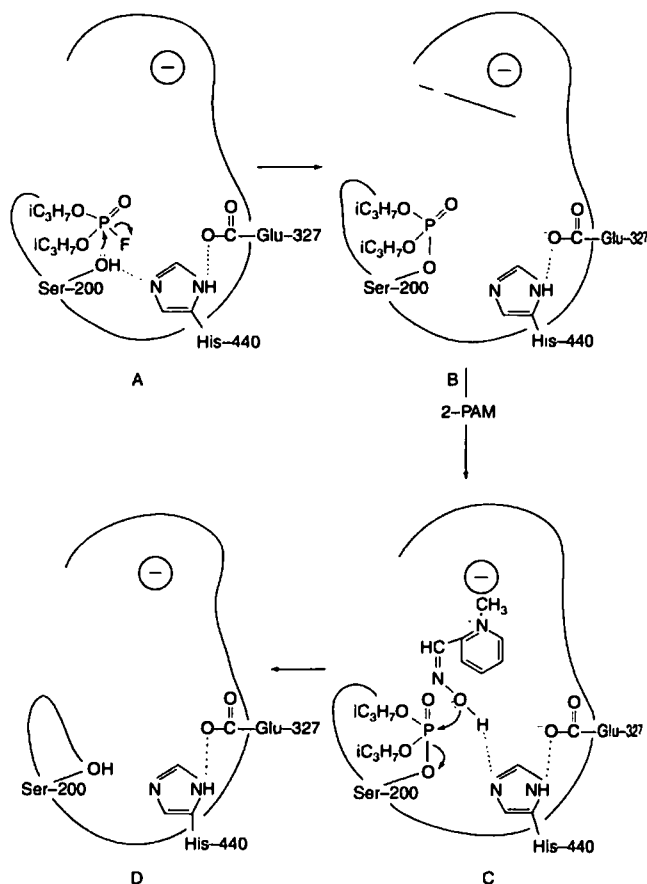

Figure 17-16 ■ Phosphorylation and reactivation of cholinesterase. **A.** Phosphorylation of serine by isofluorophate. **B.** Phosphorylated serine at the esteric site. **C.** Nucleophilic attack on phosphorylated residue by 2-PAM. **D.** Free enzyme.

Figure 17-17 ■ Aging of phosphorylated enzyme.

ine at the esteratic site of the enzyme, it is possible to reactivate the enzyme if action is taken soon after exposure to these poisons. Several compounds can provide a nucleophilic attack on the phosphorylated enzyme and cause regeneration of the free enzyme. Substances such as choline, hydroxylamine, and hydroxamic acid have led to the development of more effective cholinesterase reactivators, such as nicotinic hydroxamic acid and pyridine-2-aldoxime methiodide (2-PAM). A proposed mode of action for the reactivation of cholinesterase that has been inactivated by isofluorophate by 2-PAM is shown in Figure 17-16.

Cholinesterases that have been exposed to phosphorylating agents (e.g., sarin) become refractory to reactivation by cholinesterase reactivators. The process is called *aging* and occurs both in vivo and in vitro with AChE and BuChE. Aging occurs by partial hydrolysis of the phosphorylated moiety that is attached to the serine residue at the esteratic site of the enzyme (Fig. 17-17).

Phosphate esters used as insecticidal agents are toxic and must be handled with extreme caution. Symptoms of toxicity are nausea, vomiting, excessive sweating, salivation, miosis, bradycardia, low blood pressure, and respiratory difficulty, which is the usual cause of death.

The organophosphate insecticides of low toxicity, such as malathion, generally cause poisoning only by ingestion of relatively large doses. Parathion or methylparathion, however, cause poisoning by inhalation or dermal absorption. Because these compounds are so long acting, cumulative and serious toxic manifestations may result after several small exposures.

Sarin

Products

Isofluorophate, USP. Isofluorophate, diisopropylphosphorofluoridate (Floropryl), is a colorless liquid soluble in water to the extent of 1.54% at 25°C, which decomposes to give a pH of 2.5. It is soluble in alcohol and to some extent in peanut oil. It is stable in peanut oil for a period of 1 year but decomposes in water in a few days. Solutions in peanut oil can be sterilized by autoclaving. The compound should be stored in hard glass containers. Continued contact with soft glass is said to hasten decomposition, as evidenced by discoloration.

Isofluorophate

Isofluorophate must be handled with extreme caution. Contact with eyes, nose, mouth, and even skin should be avoided because it can be absorbed readily through intact epidermis and more so through mucous tissues.

Since isofluorophate irreversibly⁶¹ inhibits cholinesterase, its activity lasts for days or even weeks. During this period, new cholinesterase may be synthesized in plasma, erythrocytes, and other cells.

A combination of atropine sulfate and magnesium sulfate protects rabbits against the toxic effects of isofluorophate. Atropine sulfate counteracts the muscarinic effect, and magnesium sulfate counteracts the nicotinic effect of the drug.⁶² Isofluorophate has been used in the treatment of glaucoma.

Echothiophate iodide, USP. Echothiophate iodide, (2-mercaptoethyl)trimethylammonium iodide, S-ester with O,O-diethylphosphorothioate (Phospholine iodide), occurs as a white, crystalline, hygroscopic solid that has a slight mercaptan-like odor. It is soluble in water (1:1) and dehydrated alcohol (1:25); aqueous solutions have a pH of about 4 and are stable at room temperature for about 1 month.

Echothiophate iodide

Echothiophate iodide is a long-lasting cholinesterase inhibitor of the irreversible type, as is isofluorophate. Unlike the latter, however, it is a quaternary salt, and when applied locally, its distribution in tissues is limited, which can be very desirable. It is used as a long-acting anticholinesterase agent in the treatment of glaucoma.

Hexaethyltetraphosphate (HETP) and Tetraethylpyrophosphate (TEPP). HETP and TEPP are compounds that also show anticholinesterase activity. HETP was developed by the Germans during World War II and is used as an insecticide against aphids. When used as insecticides, these compounds have the advantage of being hydrolyzed rapidly to the relatively nontoxic, water-soluble compounds phosphoric acid and ethyl alcohol. Fruit trees or vegetables sprayed with this type of compound retain no harmful residue after a period of a few days or weeks, depending on the weather conditions. Workers spraying with these agents should use extreme caution so that the vapors are not

breathed and none of the vapor or liquid comes in contact with the eyes or skin.

Tetraethylpyrophosphate

Malathion. Malathion, 2-[(dimethoxyphosphinothioyl)thio]butanedioic acid diethyl ester, is a water-insoluble phosphodithioate ester that has been used as an agricultural insecticide. Malathion is a poor inhibitor of cholinesterases. Its effectiveness as a safe insecticide is due to the different rates at which humans and insects metabolize the chemical. Microsomal oxidation, which causes desulfuration, occurs slowly to form the phosphothioate (malaoxon), which is 10,000 times more active than the phosphodithioate (malathion) as a cholinesterase inhibitor. Insects detoxify the phosphothioate by a phosphatase, forming dimethyl phosphorothioate, which is inactive as an inhibitor. Humans, however, can rapidly hydrolyze malathion by a carboxyesterase en-

zyme, yielding malathion acid, a still poorer inhibitor of AChE. Phosphatases and carboxyesterases further metabolize malathion acid to dimethylphosphorothioate. The metabolic reactions are shown in Figure 17-18.

Parathion. Parathion, *O,O*-diethyl *O-p*-nitrophenyl phosphorothioate (Thiophos), is a yellow liquid that is freely soluble in aromatic hydrocarbons, ethers, ketones, esters, and alcohols but practically insoluble in water, petroleum ether, kerosene, and the usual spray oils. It is decomposed at a pH above 7.5. Parathion is used as an agricultural insecticide. It is a relatively weak inhibitor of cholinesterase; however, enzymes present in liver microsomes and insect tissues convert parathion ($pI_{50} < 4$) to paraoxon, a more potent inhibitor of cholinesterase ($pI_{50} > 8$).^{6,1} Parathion is also metabolized by liver microsomes to yield *p*-nitrophenol and diethylphosphate; the latter is inactive as an irreversible cholinesterase inhibitor.^{6,4}

Schradan. Schradan, octamethyl pyrophosphoramidate, OMPA, *bis*[*bis*(dimethylaminophosphonous)] anhydride (Pestox III), is a viscous liquid that is miscible with water and soluble in most organic solvents. It is not hydrolyzed by alkalies or water but is hydrolyzed by acids. Schradan is used as a systemic insecticide for plants, being absorbed by

Figure 17-18 ■ Comparison of metabolism of malathion by mammals and insects.

the plants without appreciable injury. Insects feeding on the plant are incapacitated.

Schradan is a weak inhibitor of cholinesterases in vitro. In vivo, it is metabolized to the very strong inhibitor hydroxymethyl OMPA. Hydroxymethyl OMPA is not stable and is metabolized further to the *N*-methoxide, which is a weak inhibitor of cholinesterase.⁶⁵

Pralidoxime Chloride, USP. Pralidoxime chloride, 2-formyl-1-methylpyridinium chloride oxime, 2-PAM chloride, or 2-pyridine aldoxime methyl chloride (Protopam chloride), is a white, nonhygroscopic, crystalline powder that is soluble in water, 1 g in less than 1 mL.

Pralidoxime chloride is used as an antidote for poisoning by parathion and related pesticides. It may be effective against some phosphates that have a quaternary nitrogen. It is also an effective antagonist for some carbamates, such as neostigmine methylsulfate and pyridostigmine bromide. The mode of action of pralidoxime chloride is described in Figure 17-16.

Pralidoxime chloride is used as an antidote for poisoning by parathion and related pesticides. It may be effective against some phosphates that have a quaternary nitrogen. It is also an effective antagonist for some carbamates, such as neostigmine methylsulfate and pyridostigmine bromide. The mode of action of pralidoxime chloride is described in Figure 17-16.

Pralidoxime Chloride

The biological half-life of pralidoxime chloride in humans is about 2 hours, and its effectiveness is a function of its concentration in plasma, which reaches a maximum 2 to 3 hours after oral administration.

Pralidoxime chloride, a quaternary ammonium compound, is most effective by intramuscular, subcutaneous, or intravenous administration. Treatment of poisoning by an anticholinesterase will be most effective if given within a few hours. Little will be accomplished if the drug is used more than 36 hours after parathion poisoning has occurred.

CHOLINERGIC BLOCKING AGENTS

A wide variety of tissues respond to ACh released by the neuron or exogenously administered chemicals to mimic this neurotransmitter's action. Peripheral cholinergic receptors are located at parasympathetic postganglionic nerve endings in smooth muscle, sympathetic and parasympathetic ganglia, and neuromuscular junctions in skeletal muscle. Although ACh activates these receptors, there are antagonists that are selective for each. Atropine is an effective blocking agent at parasympathetic postganglionic terminals. Like most classic blocking agents, it acts on all muscarinic receptor subtypes. *d*-Tubocurarine blocks the effect of ACh on skeletal muscle, which is activated by N_1 nicotinic receptors. Hexamethonium blocks transition at N_2 nicotinic receptors located in autonomic ganglia.

Anticholinergic action by drugs and chemicals apparently depends on their ability to reduce the number of free receptors that can interact with ACh. The theories of Stephenson⁶⁶ and Ariens⁶⁷ have explained the relationship between drug-receptor interactions and the observed biological response (see Chapter 2). These theories indicate that the amount of drug-receptor complex formed at a given time depends on the affinity of the drug for the receptor and that a drug that acts as an agonist must also possess another property, called *efficacy* or *intrinsic activity*. Another explanation of drug-receptor interactions, the Paton rate theory,⁶⁸ defines a biological stimulus as proportional to the rate of drug-receptor interactions (see Chapter 2). Both of these theories are compatible with the concept that a blocking agent that has high affinity for the receptor may decrease the number of available free receptors and the efficiency of the endogenous neurotransmitter.

Structure-Activity Relationships

A wide variety of compounds possess anticholinergic activity. The development of such compounds has been largely empiric and based principally on atropine as the prototype.

Nevertheless, structural permutations have resulted in compounds that do not have obvious relationships to the parent molecule. The following classification delineates the major chemical types encountered:

- Solanaceous alkaloids and synthetic analogues
- Synthetic aminoalcohol esters
- Aminoalcohol ethers
- Aminoalcohols
- Aminoamides
- Miscellaneous
- Papaveraceous

The chemical classification of anticholinergics acting on parasympathetic postganglionic nerve endings is complicated somewhat because some agents, especially the quaternary ammonium derivatives, act on the ganglia that have a muscarinic component to their stimulation pattern and, at high doses, at the neuromuscular junction in skeletal muscle.

There are several ways in which the structure-activity relationship could be considered, but in this discussion we follow, in general, the considerations of Long et al.,⁶⁹ who based their postulations on the 1-hyoscyamine molecule being one of the most active anticholinergics and, therefore, having an optimal arrangement of groups.

Anticholinergic compounds may be considered chemicals that have some similarity to ACh but contain additional substituents that enhance their binding to the cholinergic receptor.

As depicted above, an anticholinergic agent may contain a quaternary ammonium function or a tertiary amine that is protonated in the biophase to form a cationic species. The nitrogen is separated from a pivotal carbon atom by a chain that may include an ester, ether, or hydrocarbon moiety. The substituent groups *A* and *B* contain at least one aromatic moiety capable of van der Waals' interactions to the receptor surface and one cycloaliphatic or other hydrocarbon moiety for hydrophobic bonding interactions. *C* may be hydroxyl or carboxamide to undergo hydrogen bonding with the receptor.

THE CATIONIC HEAD

It is generally considered that the anticholinergic molecules have a primary point of attachment to cholinergic sites through the *cationic head* (i.e., the positively charged nitrogen). For quaternary ammonium compounds, there is no question of what is implied, but for tertiary amines, one assumes, with good reason, that the cationic head is achieved by protonation of the amine at physiological pH. The nature of the substituents on this cationic head is critical insofar as a parasympathomimetic response is concerned. Steric factors that cause diffusion of the onium charge or produce a less-than-optimal drug-receptor interaction result in a decrease

of parasympathomimetic properties and allow the drug to act as an antagonist because of other bonding interactions. Ariens⁶⁷ has shown that carboccholines (e.g., benzilylcarboccholine) engage in a typical competitive action with ACh, though they are less effective than the corresponding compounds possessing a cationic head, suggesting that hydrophobic bonding may play an important role in these drug–receptor interactions.

Benzilylcarboccholine

THE HYDROXYL GROUP

Although not requisite for activity, a suitably placed alcoholic hydroxyl group enhances antimuscarinic activity over that of a similar compound without the hydroxyl group. The position of the hydroxyl group relative to the nitrogen appears to be fairly critical, with the diameter of the receptive area estimated to be about 2 to 3 Å. It is assumed that the hydroxyl group contributes to the strength of binding, probably by hydrogen bonding to an electron-rich portion of the receptor surface.

THE ESTERATIC GROUP

Many of the highly potent antimuscarinic compounds possess an ester grouping, and this may be a contributing feature for effective binding. This is reasonable because the agonist (i.e., ACh) possesses a similar function for binding to the same site. An esteratic function is not necessary for activity, since several types of compounds do not possess such a group (e.g., ethers, aminoalcohols).

CYCLIC SUBSTITUTION

Examination of the active compounds discussed in the following sections reveals that at least one cyclic substituent (phenyl, thienyl, or other) is a common feature in almost all anticholinergic molecules. Aromatic substitution is often used in connection with the acidic moiety of the ester function. Virtually all acids used, however, are of the aryl-substituted acetic acid variety. Use of aromatic acids leads to low activity of these compounds as anticholinergics but potential activity as local anesthetics.

In connection with the apparent need for a cyclic group, Ariens⁶⁷ points out that the “mimetic” molecules, richly endowed with polar groups, undoubtedly require a complementary polar receptor area for effective binding. As a consequence, it is implied that a relatively nonpolar area surrounds such sites. Thus, increasing the binding of the molecule in this peripheral area by introducing flat, nonpolar groups (e.g., aromatic rings) should achieve compounds with

excellent affinity but without intrinsic activity. This postulate is consistent with most antimuscarinic drugs, whether they possess an ester group or not.

PARASYMPATHETIC POSTGANGLIONIC BLOCKING AGENTS

Parasympathetic postganglionic blocking agents are also known as antimuscarinic, anticholinergic, parasympatholytic, or cholinolytic drugs. Antimuscarinic drugs act by competitive antagonism of ACh binding to muscarinic receptors. Endogenous neurotransmitters, including ACh, are relatively small molecules. Ariens⁶⁷ noted that competitive reversible antagonists generally are larger molecules capable of additional binding to the receptor surface. The most potent anticholinergic drugs are derived from muscarinic agonists that contain one or sometimes two large or bulky groups. Ariens⁶⁷ suggested that molecules that act as competitive reversible antagonists generally are capable of binding to the active site of the receptor but have an additional binding interaction that increases receptor affinity but does not contribute to the intrinsic activity (efficacy) of the drug. Several three-dimensional models of G-protein–coupled receptors, including the muscarinic receptor, have been reported. Despite knowledge of their amino acid sequences, it is not yet possible to provide an unambiguous description of the docking of molecules to these receptors. The concepts of Ariens⁶⁷ and others, however, appear consistent with the binding site models proposed. Bebbington and Brimblecombe⁴¹ proposed in 1965 that there is a relatively large area lying outside the agonist–receptor binding site, where van der Waals’ interactions can take place between the agonist and the receptor area. This, too, is not inconsistent with contemporary theories on cholinergic receptor interaction with small molecules.

Therapeutic Actions

Organs controlled by the autonomic nervous system usually are innervated by both the sympathetic and the parasympathetic systems. There is a continual state of dynamic balance between the two systems. Theoretically, one should achieve the same end result by either stimulation of one of the systems or blockade of the other. Unfortunately, there is usually a limitation to this type of generalization. There are, however, three predictable and clinically useful results from blocking the muscarinic effects of ACh.

1. *Mydriatic effect*: dilation of the pupil of the eye; and *cycloplegia*, a paralysis of the ciliary structure of the eye, resulting in a paralysis of accommodation for near vision
2. *Antispasmodic effect*: lowered tone and motility of the GI tract and the genitourinary tract
3. *Antisecretory effect*: reduced salivation (*antisialagogue*), reduced perspiration (*anhidrotic*), and reduced acid and gastric secretion

These three general effects of parasympatholytics can be expected in some degree from any of the known drugs, though occasionally one must administer rather heroic doses to demonstrate the effect. The mydriatic and cycloplegic

effects, when produced by topical application, are not subject to any greatly undesirable side effects because of limited systemic absorption. This is not true for the systemic antispasmodic effects obtained by oral or parenteral administration. Drugs with effective blocking action on the GI tract are seldom free of adverse effects on the other organs. The same is probably true of drugs used for their antisecretory effects. Perhaps the most common side effects experienced from the oral use of these drugs, under ordinary conditions, are dryness of the mouth, mydriasis, and urinary retention.

Mydriatic and cycloplegic drugs are generally prescribed or used in the office by ophthalmologists. Their principal use is for refractive studies in the process of fitting lenses. This permits the physician to examine the eye retina for possible abnormalities and diseases and provides controlled conditions for the proper fitting of glasses. Because of the inability of the iris to contract under the influence of these drugs, there is a definite danger to the patient's eyes during the period of drug activity unless they are protected from strong light by the use of dark glasses. These drugs also are used to treat inflammation of the cornea (keratitis), inflammation of the iris and the ciliary organs (iritis and iridocyclitis), and inflammation of the choroid (choroiditis). A dark-colored iris appears to be more difficult to dilate than a light-colored one and may require more concentrated solutions. Caution in the use of mydriatics is advisable because of their demonstrated effect in raising the intraocular pressure. Pupil dilation tends to cause the iris to restrict drainage of fluid through the canal of Schlemm by crowding the angular space, thereby leading to increased intraocular pressure. This is particularly true for patients with glaucomatous conditions.

Atropine is used widely as an antispasmodic because of its marked depressant effect on parasympathetically innervated smooth muscle. It appears to block all muscarinic receptor subtypes. Atropine is, however, the standard by which other similar drugs are measured. Also, atropine has a blocking action on the transmission of the nerve impulse, rather than a depressant effect directly on the musculature. This action is termed *neurotropic*, in contrast with the action of an antispasmodic such as papaverine, which appears to act by depressing the muscle cells and is termed *musculotropic*.

Papaverine is the standard for comparison of musculotropic antispasmodics and, although not strictly a parasympatholytic, is treated together with its synthetic analogues below in this chapter. The synthetic antispasmodics appear to combine neurotropic and musculotropic effects in greater or lesser measure, together with a certain amount of ganglion-blocking activity for the quaternary derivatives.

Anticholinergic drugs have a minor role in the management of peptic ulcer disease.⁷⁰ For the present, the most rational therapy involving anticholinergic drugs seems to be a combination of a nonirritating diet to reduce acid secretion, antacid therapy, and reduction of emotional stress. Most of the anticholinergic drugs are offered either as the chemical alone, or in combination with a CNS depressant such as phenobarbital, or with a neuroleptic drug to reduce the CNS contribution to parasympathetic hyperactivity. In addition to the antisecretory effects of anticholinergics on hydrochloric acid and gastric acid secretion, there have been some efforts to use them as antisialagogues and anhidrotics.

Paralysis agitans or parkinsonism (Parkinson's disease),

first described by the English physician James Parkinson in 1817, is another condition that is often treated with anticholinergic drugs. It is characterized by tremor, "pill rolling," cogwheel rigidity, festinating gait, sialorrhea, and mask-like facies. Fundamentally, it represents a malfunction of the extrapyramidal system. Parkinsonism is characterized by progressive and selective degeneration of dopaminergic neurons, which originate in the substantia nigra of the midbrain and terminate in the basal ganglia (i.e., caudate nucleus, putamen, and pallidum). Skeletal muscle movement is controlled to a great degree by patterns of excitation and inhibition resulting from the feedback of information in the cortex and mediated through the pyramidal and extrapyramidal pathways. The basal ganglia structures, such as the pallidum, corpus striatum, and substantia nigra, serve as processors for the pyramidal pathways and the structures through which the extrapyramidal pathways pass on their way from the spinal cord to the cortex. Lesions of the pyramidal pathways lead to a persistent increase in muscle tone, resulting in an excess of spontaneous involuntary movements, along with changes in the reflexes. Thus the basal ganglia are functional in maintaining normal motor control. In parkinsonism, there is degeneration of the substantia nigra and corpus striatum, which are involved with controlled integration of muscle movement. The neurons in the substantia nigra and basal ganglia use the neurotransmitter dopamine and interact with short cholinergic interneurons. When dopamine neurons degenerate, the balance between them is altered. The inhibitory influence of dopamine is reduced, and the activity of cholinergic neurons is increased. The principal goal of anticholinergic drugs in the treatment of parkinsonism is to decrease the activity of cholinergic neurons in the basal ganglia.

The usefulness of the belladonna group of alkaloids for the treatment of parkinsonism was an empiric discovery. Since then, chemists have prepared many synthetic analogues of atropine in an effort to retain the useful antitremor and antirigidity effects of the belladonna alkaloid while reducing the adverse effects. In this process, it was discovered that antihistamine drugs (e.g., diphenhydramine) reduced tremor and rigidity. The antiparkinsonian-like activity of antihistamines has been attributed to their anticholinergic properties. The activity of these drugs is confined to those that can pass through the blood-brain barrier.

SOLANACEOUS ALKALOIDS AND ANALOGUES

The solanaceous alkaloids, represented by (–)-hyoscyamine, atropine [(–)-hyoscyamine], and scopolamine (hyoscinol), are the forerunners of the class of antimuscarinic drugs. These alkaloids are found principally in henbane (*Hyoscyamus niger*), deadly nightshade (*Atropa belladonna*), and jimson weed (*Datura stramonium*). There are other alkaloids that are members of the solanaceous group (e.g., apocarpine, noratropine, belladonnine, tigloidine, meteloidine) but lack sufficient therapeutic value to be considered in this text.

Crude drugs containing these alkaloids have been used since early times for their marked medicinal properties, which depend largely on inhibition of the parasympathetic nervous system and stimulation of the higher nervous cen-

ters. Belladonna, probably as a consequence of the weak local anesthetic activity of atropine, has been used topically for its analgesic effect on hemorrhoids, certain skin infections, and various itching dermatoses. Application of sufficient amounts of belladonna or its alkaloids results in mydriasis. Internally, the drug causes diminution of secretions, increases the heart rate (by depression of the vagus nerve), depresses the motility of the GI tract, and acts as an antispasmodic on various smooth muscles (ureter, bladder, and biliary tract). In addition, it directly stimulates the respiratory center. The multiplicity of actions exerted by the drug is looked on with some disfavor, because the physician seeking one type of response unavoidably also obtains the others. The action of scopolamine-containing drugs differs from those containing hyoscyamine and atropine in having no CNS stimulation; rather, a narcotic or sedative effect predominates. The use of this group of drugs is accompanied by a fairly high incidence of reactions because of individual idiosyncrasies; death from overdosage usually results from respiratory failure. A complete treatment of the pharmacology and uses of these drugs is not within the scope of this text. The introductory pages of this chapter briefly review some of the more pertinent points in connection with the major activities of these drug types.

Structural Considerations

All of the solanaceous alkaloids are esters of the bicyclic aminoalcohol 3-hydroxytropane or of related aminoalcohols. The structural formulas that follow show the piperidine ring system in the commonly accepted chair conformation because this form has the lowest energy requirement. The alternate boat form can exist under certain conditions, however, because the energy barrier is not great. Inspection of the 3-hydroxytropane formula also indicates that even though there is no optical activity because of the plane of symmetry, two stereoisomeric forms (tropine and pseudotropine) can exist because of the rigidity imparted to the molecule through the ethylene chain across the 1,5 positions.

In tropine, the axially oriented hydroxyl group, *trans* to the nitrogen bridge, is designated α , and the alternate *cis* equatorially oriented hydroxyl group is designated β . The aminoalcohol derived from scopolamine, namely scopine, has the axial orientation of the 3-hydroxyl group but, in addition, a β -oriented epoxy group bridged across the 6,7 positions, as shown. Of the several different solanaceous alkaloids known, it has been indicated that (–)-hyoscyamine, atropine, and scopolamine are the most important. Their structures are shown, but antimuscarinic activity is associated with all of the solanaceous alkaloids that possess the tropine-like axial orientation of the esterified hydroxyl group. Studying the formulas reveals that in each case tropic acid is the esterifying acid. Tropic acid contains an easily racemized asymmetric carbon atom, the moiety accounting for optical activity in these compounds in the absence of racemization. The proper enantiomorph is necessary for high antimuscarinic activity, as illustrated by the potent (–)-hyoscyamine in comparison with the weakly active (+)-hyoscyamine. The racemate, atropine, has intermediate activity. The marked difference in antimuscarinic potency of the optical enantiomorphs apparently does not extend to the action

on the CNS, inasmuch as both seem to have the same degree of activity.⁷¹

The solanaceous alkaloids have been modified by preparing other esters of 3- α -tropanol or making a quaternary of the nitrogen in tropanol or scopine with a methyl halide. These compounds represent some of the initial attempts to separate the varied actions of atropine and scopolamine. Few aminoalcohols have been found that impart the same degree of neurotropic activity as that exhibited by the ester formed by combination of tropine with tropic acid. Similarly, the tropic acid portion is highly specific for the anticholinergic action, and substitution by other acids decreases neurotropic potency, though the musculotropic action may increase. The earliest attempts to modify the atropine molecule retained the tropine portion and substituted various acids for tropic acid.

Besides changing the acid residue, other changes have been directed toward the quaternization of the nitrogen. Examples of this type of compound are methscopolamine bromide, homatropine methylbromide, and anisotropine methylbromide. Quaternization of the tertiary amine produces variable effects in terms of increasing potency. Decreases in activity are apparent in comparing atropine with methylatropine (no longer used) and scopolamine with methscopolamine. Ariens et al.⁷² ascribed decreased activity, especially when the groups attached to nitrogen are larger than methyl, to a possible decrease in affinity for the anionic site on the cholinergic receptor. They attributed this decreased affinity to a combination of greater electron repulsion by such groups and greater steric interference to the approach of the cationic head to the anionic site. In general, quaternization reduces parasympathomimetic action much more than parasympatholytic action. This may be partially due to the additional blocking at the parasympathetic ganglion induced by quaternization, which could offset the decreased affinity at the postganglionic site. However, quaternization increases the curariform activity of these alkaloids and aminoesters, a usual consequence of quaternizing alkaloids. Another disadvantage in converting an alkaloidal base to the quaternary form is that the quaternized base is absorbed more poorly through the intestinal wall, so that the activity becomes erratic and, in some instances, unpredictable. Bases (such as alkaloids) are absorbed through the lipoidal gut wall only in the dissociated form, which can be expected to exist for a tertiary base, in the small intestine. Quaternary nitrogen bases cannot revert to an undissociated form, even in basic media and, presumably, may have difficulty passing through the gut wall. Since quaternary compounds can be absorbed, other less efficient mechanisms for absorption probably prevail. Quaternary ammonium compounds combine reversibly with endogenous substances in the gut, such as mucin, to form neutral ion-pair complexes. These complexes penetrate the lipid membrane by passive diffusion.

Products

Atropine, USP. Atropine is the tropine ester of racemic tropic acid and is optically inactive. It possibly occurs naturally in various Solanaceae, though some claim, with justification, that whatever atropine is isolated from natural sources results from racemization of (–)-hyoscyamine during the isolation process. Conventional methods of alkaloid

isolation are used to obtain a crude mixture of atropine and hyoscyamine from the plant material. This crude mixture is racemized to atropine by refluxing in chloroform or by treatment with cold dilute alkali. Because the racemization process makes atropine, an official limit is set on the hyoscyamine content by restricting atropine to a maximum levorotation under specified conditions.

Atropine occurs in the form of optically inactive, white, odorless crystals possessing a bitter taste. It is not very soluble in water (1:460, 1:90 at 80°C) but is more soluble in alcohol (1:2, 1:1.2 at 60°C). It is soluble in glycerin (1:27),

in chloroform (1:1), and in ether (1:25). Saturated aqueous solutions are alkaline in reaction (pH \sim 9.5). The free base is useful when nonaqueous solutions are to be made, such as in oily vehicles and ointment bases. Atropine has a plasma half-life of about 2 to 3 hours. It is metabolized in the liver to several products, including tropic acid and tropine.

Atropine Sulfate, USP. Atropine sulfate (Atropisol) is prepared by neutralizing atropine in acetone or ether solution with an alcoholic solution of sulfuric acid, with care used to prevent hydrolysis. The salt occurs as colorless crystals

or as a white, crystalline powder. It is efflorescent in dry air and should be protected from light to prevent decomposition.

Atropine sulfate is freely soluble in water (1:0.5), in alcohol (1:5, 1:2.5 at boiling point), and in glycerin (1:2.5). Aqueous solutions are not very stable, though solutions may be sterilized at 120°C (15 lb pressure) in an autoclave if the pH is kept below 6. Sterilization probably is best effected by the use of aseptic techniques and a bacteriological filter. It has been suggested that no more than a 30-day supply of an aqueous solution should be made and that for small quantities the best procedure is to use hypodermic tablets and sterile distilled water.⁷² Kondritzer and Zvirblis⁷³ have studied the kinetics of alkaline and proton-catalyzed hydrolyses of atropine in aqueous solution. The region of maximal stability lies between pH 3 and approximately 5. They have also proposed an equation to predict the half-life of atropine undergoing hydrolysis at constant pH and temperature.

The action of atropine or its salts is the same. It produces a mydriatic effect by paralyzing the iris and the ciliary muscles and, for this reason, is used by the oculist in iritis and corneal inflammations and lesions. Its use is rational in these conditions because one of the first rules in the treatment of inflammation is rest, which, of course, is accomplished by the paralysis of muscular motion. Its use in the eye (0.5 to 1% solutions or gelatin disks) for fitting glasses is widespread. Atropine is administered in small doses before general anesthesia to lessen oral and air passage secretions and, when administered with morphine, to lessen the respiratory depression induced by morphine.

Atropine causes restlessness, prolonged pupillary dilation, and loss of visual accommodation and, furthermore, gives rise to arrhythmias such as atrioventricular dissociation, ventricular extrasystoles, and even ventricular fibrillation. Even though ether has been gradually replaced by other anesthetics, thereby eliminating problems with respiratory secretions caused by ether and thus requiring atropine, surgeons and anesthesiologists today continue to use it as an anesthetic premedicant to reduce excessive salivary and airway secretions and to prevent vagal reflexes.

Its ability to dry secretions has also been used in the so-called rhinitis tablets for symptomatic relief in colds. In cathartic preparations, atropine or belladonna has been used as an antispasmodic to lessen the smooth muscle spasm (gripping) often associated with catharsis.

Atropine may be used to treat some types of arrhythmias. It increases the heart rate by blocking the effects of ACh on the vagus. In this context, it is used to treat certain reversible bradyarrhythmias that may accompany acute myocardial infarction. It is also used as an adjunct to anesthesia to protect against bradycardia, hypotension, and even cardiac arrest induced by the skeletal muscle relaxant succinylcholine chloride.

Another use for atropine sulfate emerged following the development of the organophosphates, which are potent inhibitors of AChE. Atropine is a specific antidote to prevent the muscarinic effects of ACh accumulation, such as vomiting, abdominal cramps, diarrhea, salivation, sweating, bronchoconstriction, and excessive bronchial secretions. It is used intravenously but does not protect against respiratory failure caused by depression of the respiratory center and the muscles of respiration.

Hyoscyamine, USP. Hyoscyamine is a levorotatory alkaloid obtained from various solanaceous species. One of the commercial sources is Egyptian henbane (*Hyoscyamus muticus*), in which it occurs to the extent of about 0.5%. Usually, it is prepared from the crude drug in a manner similar to that used for atropine and is purified as the oxalate. The free base is obtained easily from this salt.

It occurs as white needles that are sparingly soluble in water (1:281), more soluble in ether (1:69) or benzene (1:150), very soluble in chloroform (1:1), and freely soluble in alcohol. It is used as the sulfate and hydrobromide. The principal reason for the popularity of the hydrobromide has been its nondeliquescent nature. The salts have the advantage over the free base in being quite water soluble.

Hyoscyamine is the *levo* form of the racemic mixture known as atropine. The *dextro* form does not exist naturally but has been synthesized. Cushny⁷⁴ compared the activities of (–)-hyoscyamine, (+)-hyoscyamine, and the racemate (atropine) in 1904 and found greater peripheral potency for the (–) isomer and twice the potency of the racemate. All later studies have essentially confirmed that the (+) isomer is only weakly active and that the (–) isomer is, in effect, the active portion of atropine. Inspection of the relative doses of atropine sulfate and hyoscyamine sulfate illustrates the differences very nicely. The principal criticism offered against the use of hyoscyamine sulfate exclusively is that it tends to racemize to atropine sulfate rather easily in solution, so that atropine sulfate then becomes the more stable of the two. All of the isomers behave very much the same in the CNS.

Hyoscyamine is used to treat disorders of the urinary tract more so than any other antispasmodic, though there is no evidence that it has any advantages over the other belladonna preparations and the synthetic anticholinergics. It is used to treat spasms of the bladder and, in this manner, serves as a urinary stimulant. It is used together with a narcotic to counteract the spasm produced by the narcotic when the latter is used to relieve the pain of urethral colic. Hyoscyamine preparations are also used as antispasmodics in the therapy of peptic ulcers.

Hyoscyamine Sulfate, USP. Hyoscyamine sulfate (Levsin sulfate) is a white, odorless, crystalline compound of a deliquescent nature that also is affected by light. It is soluble in water (1:0.5) and alcohol (1:5) but almost insoluble in ether. Solutions of hyoscyamine sulfate are acidic to litmus.

This drug is used as an anticholinergic in the same manner and for the same indications as atropine and hyoscyamine, but it possesses the disadvantage of being deliquescent.

Scopolamine. Scopolamine (hyoscine) is found in various members of the Solanaceae (e.g., *H. niger*, *Duboisia myoporoides*, *Scopolia* spp., and *Datura metel*). Scopolamine usually is isolated from the mother liquor remaining from the isolation of hyoscyamine.

Hyoscine is the older name for this alkaloid, though *scopolamine* is the accepted name in the United States. Scopolamine is the *levo* component of the racemic mixture that is known as *atrosine*. The alkaloid is racemized readily in the presence of dilute alkali.

The alkaloid occurs in the form of a levorotatory, viscous liquid that is only slightly soluble in water but very soluble in alcohol, chloroform, or ether. It forms crystalline salts with most acids, with the hydrobromide being the most stable and the most popularly accepted. An aqueous solution of the hydrobromide containing 10% mannitol is said to be less prone to decomposition than unprotected solutions. The commercially available transdermal system of scopolamine comprises an outer layer of polymer film and a drug reservoir containing scopolamine, polyisobutylene, and mineral oil, which is interfaced with a microporous membrane to control diffusion of the drug. In this dosage form, scopolamine is effective in preventing motion sickness. The action is believed to be on the cortex or the vestibular apparatus. Whereas atropine stimulates the CNS, causing restlessness and talkativeness, scopolamine usually acts as a CNS depressant.

Scopolamine Hydrobromide, USP. Scopolamine hydrobromide (hyoscyne hydrobromide) occurs as white or colorless crystals or as a white, granular powder. It is odorless and tends to effloresce in dry air. It is freely soluble in water (1:1.5), soluble in alcohol (1:20), only slightly soluble in chloroform, and insoluble in ether.

Scopolamine is a competitive blocking agent of the parasympathetic nervous system as is atropine, but it differs markedly from atropine in its action on the higher nerve centers. Both drugs readily cross the blood-brain barrier and, even in therapeutic doses, cause confusion, particularly in the elderly.

A sufficiently large dose of scopolamine will cause an individual to sink into a restful, dreamless sleep for about 8 hours, followed by a period of approximately the same length in which the patient is in a semiconscious state. During this time, the patient does not remember events that take place. When scopolamine is administered with morphine, this temporary amnesia is termed *twilight sleep*.

Homatropine Hydrobromide, USP. Homatropine hydrobromide, 1*αH,5αH*-tropan-3*α*-ol mandelate (ester) hydrobromide (Homatroccl), occurs as white crystals or as a white, crystalline powder that is affected by light. It is soluble in water (1:6) and alcohol (1:40), less soluble in chloroform (1:420), and insoluble in ether.

Solutions are incompatible with alkaline substances, which precipitate the free base, and with the common reagents that precipitate alkaloids. As with atropine, solutions are sterilized best by filtration through a bacteriological filter.

Homatropine hydrobromide is used topically to paralyze the ciliary structure of the eye (cycloplegia) and to effect mydriasis. It behaves very much like atropine but is weaker and less toxic. In the eye, it acts more rapidly but less persistently than atropine. Dilatation of the pupil takes place in about 15 to 20 minutes, and the action subsides in about 24 hours. By using a miotic, such as physostigmine, it is possible to restore the pupil to normality in a few hours.

Homatropine Hydrobromide

Homatropine Methylbromide, USP. Homatropine methylbromide, 3*α*-hydroxy-8-methyl-1*αH,5αH*-tropanium bromide mandelate (Novatropine, Mesopin), occurs as a bitter, white, odorless powder and is affected by light. The compound is readily soluble in water and alcohol but insoluble in ether. The pH of a 1% solution is 5.9 and that of a 10% solution is 4.5. Although a solution of the compound yields a precipitate with alkaloidal reagents, such as mercuric potassium iodide test solution, addition of alkali hydroxides or carbonates does not cause the precipitate that occurs with nonquaternary nitrogen salts (e.g., atropine, homatropine).

Homatropine Methylbromide

Homatropine methylbromide is transported poorly across the blood-brain barrier because of its quaternary ammonium group and, therefore, has far fewer stimulant properties than atropine. It does have all the characteristic peripheral parasympathetic depressant properties of atropine and is used to reduce oversecretion and to relieve GI spasms.

Ipratropium Bromide. Ipratropium bromide, 3-(3-hydroxy-1-oxo-2-phenylpropoxy)-8-methyl-8-(1-methylethyl)-8-azoniabicyclo[3.2.1]octane bromide (Atrovent), is a quaternary ammonium derivative of atropine. It is freely soluble in water and ethanol but insoluble in chloroform and ether. The salt is stable in neutral and acidic solutions but rapidly hydrolyzed in alkaline solutions.

Ipratropium Bromide

Ipratropium bromide is used in inhalation therapy to produce dilation of bronchial smooth muscle for acute asthmatic attacks. The drug produces bronchodilation by competitive inhibition of cholinergic receptors bound to smooth muscle of the bronchioles. Ipratropium may also act on the surface of mast cells to inhibit ACh-enhanced release of chemical mediators. The drug has a slow onset of action, within 5 to 15 minutes after being administered by inhalation, and should not be used alone for acute asthmatic attacks. The peak therapeutic effect from one dose is observed between 1 and 2 hours. The effects of the drug last for about 6 hours. It has a half-life of 3.5 hours.

SYNTHETIC CHOLINERGIC BLOCKING AGENTS

Aminoalcohol Esters

The solanaceous alkaloids are generally agreed to be potent parasymphatholytics, but they have the undesirable property of producing a wide range of effects through their nonspecific blockade of autonomic functions. Efforts to use the antispasmodic effect of the alkaloids most often result in side effects such as dryness of the mouth and fluctuations in pulse rate. Therefore, synthesis of compounds possessing specific cholinolytic actions has been a very desirable field of study. Few prototypical drugs were as avidly dissected in the minds of researchers as atropine in attempts to modify its structure to separate the numerous useful activities (i.e., antispasmodic, antisecretory, mydriatic, and cycloplegic). Most early research was carried out in the pre- and post-World War II era before muscarinic receptor subtypes were known.

Efforts at synthesis started with rather minor deviations from the atropine molecule, but a review of the commonly used drugs today indicates a marked departure from the rigid tropane aminoalcohols and tropic acid residues. Examination of the structures of antispasmodics shows that the acid portion has been designed to provide a large hydrophobic moiety rather than the stereospecific requirement of (S)-tropic acid in (–)-hyoscyamine that was once considered important. One of the major developments in the field of aminoalcohol esters was the successful introduction of the

quaternary ammonium derivatives as contrasted with the tertiary amine-type esters synthesized originally. Although some effective tertiary amine esters are in use today, the quaternaries, as a group, represent the more popular type and appear to be slightly more potent than their tertiary amine counterparts.

The accompanying formula shows the portion of the atropine molecule (enclosed in the curved dotted line) believed to be responsible for its major activity. This is sometimes called the *spasmophoric* group and compares with the *anesthesiophoric* group obtained by similar dissection of the cocaine molecule. The validity of this conclusion has been amply borne out by the many active compounds having only a simple diethylaminoethyl residue replacing the tropine portion.

The aminoalcohol portion of eucatropine may be considered a simplification of the atropine molecule. In eucatropine, the bicyclic tropine has been replaced by a monocyclic aminoalcohol and mandelic acid replaces tropic acid (see under "Products").

Although simplification of the aminoalcohol portion of the atropine prototype has been a guiding principle in most research, many of the anticholinergics now used still include a cyclic aminoalcohol moiety. The aminoalcohol ester anticholinergics are used primarily as antispasmodics or mydriatics, and cholinolytic compounds classed as aminoalcohol or aminoalcohol ether analogues of atropine are, with few exceptions, used as antiparkinsonian drugs.

Another important feature in many of the synthetic anticholinergics used as antispasmodics is that they contain a quaternary nitrogen, presumably to enhance activity. The initial synthetic quaternary compound methantheline bromide has served as a forerunner for many others. These compounds combine anticholinergic activity of the antimuscarinic type with some ganglionic blockade to reinforce the parasympathetic blockade. Formation of a quaternary ammonium moiety, however, introduces the possibility of blockade of voluntary synapses (curariform activity); this can become evident with sufficiently high doses.

Products

The antimuscarinic compounds now in use are described in the following monographs.

Clidinium Bromide, USP. Clidinium bromide, 3-hydroxy-1-methylquinclidinium bromide benzilate (Quar-

zan), is a white or nearly white, almost odorless, crystalline powder that is optically inactive. It is soluble in water and alcohol but only very slightly soluble in ether and benzene.

Clidinium Bromide

This anticholinergic agent is marketed alone and in combination with the minor tranquilizer chlordiazepoxide (Librium) in a product known as Librax. The rationale of the combination for the treatment of GI complaints is the use of an anxiety-reducing agent together with an anticholinergic agent, based on the recognized contribution of anxiety to the development of the diseased condition. It is suggested for peptic ulcer, hyperchlorhydria, ulcerative or spastic colon, anxiety states with GI manifestations, nervous stomach, irritable or spastic colon, and others. Clidinium bromide is contraindicated in glaucoma and other conditions that may be aggravated by the parasympatholytic action, such as prostatic hypertrophy in elderly men, which could lead to urinary retention.

Cyclopentolate Hydrochloride, USP. Cyclopentolate hydrochloride, 2-dimethylaminoethyl 1-hydroxy- α -phenylcyclopentaneacetate hydrochloride (Cyclogyl), is a crystalline, white, odorless solid that is very soluble in water, easily soluble in alcohol, and only slightly soluble in ether. A 1% solution has a pH of 5.0 to 5.4.

Cyclopentolate Hydrochloride

It is used only for its effects on the eye, where it acts as a parasympatholytic. When placed in the eye, it quickly produces cycloplegia and mydriasis. Its primary field of usefulness is in refraction studies. Cyclopentolate hydrochloride can be used, however, as a mydriatic in the management of iritis, iridocyclitis, keratitis, and choroiditis. Although it does not seem to affect intraocular tension significantly, it is best to be very cautious with patients with high intraocular pressure and with elderly patients with possible unrecognized glaucomatous changes.

Cyclopentolate hydrochloride has one half of the antispas-

modic activity of atropine and is nonirritating when instilled repeatedly into the eye. If not neutralized after the refraction studies, its effect dissipates within 24 hours. Neutralization with a few drops of pilocarpine nitrate solution, 1 to 2%, often results in complete recovery in 6 hours. It is supplied as a ready-made ophthalmic solution in concentrations of either 0.5 or 2%.

Dicyclomine Hydrochloride, USP. Dicyclomine hydrochloride, 2-(diethylamino)ethyl bicyclohexyl-1-carboxylate hydrochloride (Bentyl), has some muscarinic receptor subtype selectivity. It binds more firmly to M_1 and M_3 than to M_2 and M_4 receptors.⁷⁵

Dicyclomine Hydrochloride

Dicyclomine hydrochloride has one eighth of the neurotropic activity of atropine and approximately twice the musculotropic activity of papaverine. This preparation, first introduced in 1950, has minimized the adverse effects associated with the atropine-type compounds. It is used for its spasmolytic effect on various smooth muscle spasms, particularly those associated with the GI tract. It is also useful in dysmenorrhea, pylorospasm, and biliary dysfunction.

Eucatropine Hydrochloride, USP. Eucatropine hydrochloride, euphthalmine hydrochloride or 1,2,2,6-tetramethyl-4-piperidyl mandelate hydrochloride, possesses the aminoalcohol moiety characteristic of one of the early local anesthetics (e.g., β -eucaine) but differs in the acidic portion of the ester by being a mandelate instead of a benzoate. The salt is an odorless, white, granular powder, providing solutions that are neutral to litmus. It is very soluble in water, freely soluble in alcohol and chloroform, but almost insoluble in ether.

Eucatropine Hydrochloride

The action of eucatropine hydrochloride closely parallels that of atropine, though it is much less potent than the latter. It is used topically in a 0.1 mL dose as a mydriatic in 2% solution or in the form of small tablets. Use of concentrations from 5 to 10% is, however, not uncommon. Dilution, with

little impairment of accommodation, takes place in about 30 minutes, and the eye returns to normal in 2 to 3 hours.

Glycopyrrolate, USP. Glycopyrrolate, 3-hydroxy-1,1-dimethylpyrrolidinium bromide α -cyclopentylmandelate (Robinul), occurs as a white, crystalline powder that is soluble in water or alcohol but practically insoluble in chloroform or ether.

Glycopyrrolate

Glycopyrrolate is a typical anticholinergic and possesses, at adequate dosage levels, the atropine-like effects characteristic of this class of drugs. It has a spasmolytic effect on the musculature of the GI tract as well as the genitourinary tract. It diminishes gastric and pancreatic secretions and the quantity of perspiration and saliva. Its side effects are typically atropine-like also (i.e., dryness of the mouth, urinary retention, blurred vision, constipation). Glycopyrrolate is a more potent antagonist on M_1 than on M_2 and M_3 receptors. The low affinity of M_2 receptors may, in part, explain the low incidence of tachycardia during use of this drug as an antispasmodic.⁷⁶ Because of its quaternary ammonium character, glycopyrrolate rarely causes CNS disturbances, though in sufficiently high dosage it can bring about ganglionic and myoneural junction block.

The drug is used as an adjunct in the management of peptic ulcer and other GI ailments associated with hyperacidity, hypermotility, and spasm. In common with other anticholinergics, its use does not preclude dietary restrictions or use of antacids and sedatives if these are indicated.

Mepenzolate Bromide. Mepenzolate bromide, 3-hydroxy-1,1-dimethylpiperidinium bromide benzoate (Cantil), has an activity about one-half that of atropine in reducing ACh-induced spasms of the guinea pig ileum. The selective action on colonic hypermotility is said to relieve pain, cramps, and bloating and to help curb diarrhea.

Mepenzolate Bromide

Methantheline Bromide, USP. Methantheline bromide, diethyl(2-hydroxyethyl)methylammonium bromide xanthene-9-carboxylate (Banthine Bromide), is a white, slightly hygroscopic, crystalline salt that is soluble in water to produce solutions with a pH of about 5. Aqueous solutions are not stable and hydrolyze in a few days. The bromide form is preferable to the very hygroscopic chloride.

Methantheline Bromide

This drug, introduced in 1950, is a potent anticholinergic agent and acts at the nicotinic cholinergic receptors of the sympathetic and parasympathetic systems, as well as at the myoneural junction of the postganglionic cholinergic fibers. Like other quaternary ammonium drugs, methantheline bromide is absorbed incompletely from the GI tract.

Among the conditions for which methantheline bromide is indicated are gastritis, intestinal hypermotility, bladder irritability, cholinergic spasm, pancreatitis, hyperhidrosis, and peptic ulcer, all of which are manifestations of parasympathotonia.

Side reactions are atropine-like (mydriasis, cycloplegia, dryness of mouth). The drug is contraindicated in glaucoma. Toxic doses may bring about a curare-like action, a not too surprising fact when it is considered that ACh is the mediating factor for neural transmission at the somatic myoneural junction. This side effect can be counteracted with neostigmine methylsulfate.

Oxyphencyclimine Hydrochloride. Oxyphencyclimine hydrochloride, 1,4,5,6-tetrahydro-1-methyl-2-pyrimidinylmethyl α -phenylcyclohexanecarboxylate monohydrochloride (Daricon, Vistrax), was introduced in 1958 and promoted as a peripheral anticholinergic-antisecretory agent, with little or no curare-like activity and little or no ganglionic blocking activity. These activities are probably absent because of the tertiary character of the molecule. This activity is in contrast with that of compounds that couple antimuscarinic action with ganglionic blocking action. The tertiary character of the nitrogen promotes intestinal absorption of the molecule. Perhaps the most significant activity of this compound is its marked ability to reduce both the volume and the acid content of the gastric juices, a desirable action in view of the more recent hypotheses pertaining to peptic ulcer therapy. Another important feature of this compound is its low toxicity in comparison with many of the other available anticholinergics. Oxyphencyclimine hydrochloride is hydrolyzed in the presence of excessive moisture and heat. It is absorbed from the GI tract and has a duration of action of up to 12 hours.

Oxyphencyclimine Hydrochloride

Oxyphencyclimine hydrochloride is suggested for use in peptic ulcer, pylorospasm, and functional bowel syndrome. It is contraindicated, as are other anticholinergics, in patients with prostatic hypertrophy and glaucoma.

Propantheline Bromide, USP. Propantheline bromide, 2-hydroxy-ethyl)diisopropylmethylammonium bromide xanthen-9-carboxylate (Pro-Banthine), is prepared in a manner exactly analogous to that used for methantheline bromide. It is a white, water-soluble, crystalline substance, with properties quite similar to those of methantheline bromide. Its chief difference from methantheline bromide is in its potency, which has been estimated variously to be 2 to 5 times as great.

Propantheline Bromide

Aminoalcohol Ethers

The aminoalcohol ethers thus far introduced have been used as antiparkinsonian drugs rather than as conventional anticholinergics (i.e., as spasmolytics or mydriatics). In general, they may be considered closely related to the antihistaminics and, indeed, do possess substantial antihistaminic properties. In turn, the antihistamines possess anticholinergic activity and have been used as antiparkinsonian agents. Comparison of chlorphenoxamine and orphenadrine with the antihistaminic diphenhydramine illustrates the close similarity of structure. The use of diphenhydramine in parkinsonism has been cited above. Benztropine may also be considered a structural relative of diphenhydramine, though the aminoalcohol portion is tropine and, therefore, more distantly related than chlorphenoxamine and orphenadrine. In the structure of benztropine, a three-carbon chain intervenes between the nitrogen and oxygen functions, whereas the others evince a two-carbon chain. However, the rigid ring structure possibly orients the nitrogen and oxygen functions into more nearly

the two-carbon chain interprosthetic distance than is apparent at first glance. This, combined with the flexibility of the alicyclic chain, would help to minimize the distance discrepancy.

Diphenhydramine

Benztropine Mesylate, USP. Benztropine mesylate, 3α-(diphenylmethoxy)-1αH,5αH-tropane methanesulfonate (Cogentin), has anticholinergic, antihistaminic, and local anesthetic properties. Its anticholinergic effect makes it applicable as an antiparkinsonian agent. It is about as potent an anticholinergic as atropine and shares some of the side effects of this drug, such as mydriasis and dryness of mouth. Importantly, however, it does not produce central stimulation but instead exerts the characteristic sedative effect of the antihistamines.

Benztropine Mesylate

The tremor and rigidity characteristic of parkinsonism are relieved by benztropine mesylate, and it is particularly valuable for those patients who cannot tolerate central excitation (e.g., aged patients). It may also have a useful effect in minimizing drooling, sialorrhea, mask-like facies, oculogyric crises, and muscular cramps.

The usual caution exercised with any anticholinergic in glaucoma and prostatic hypertrophy is observed with this drug.

Orphenadrine Citrate. Orphenadrine citrate, *N,N*-dimethyl-2-(*o*-methyl- α -phenylbenzyl)oxyethylamine citrate (1:1) (Norflex), introduced in 1957, is closely related to diphenhydramine structurally but has much lower antihistaminic activity and much higher anticholinergic action. Likewise, it lacks the sedative effects characteristic of diphenhydramine. Pharmacological testing indicates that it is not primarily a peripherally acting anticholinergic because it has only weak effects on smooth muscle, on the eye, and on secretory glands. It does reduce voluntary muscle spasm, however, by a central inhibitory action on cerebral motor areas, a central effect similar to that of atropine.

Orphenadrine Citrate

This drug is used for the symptomatic treatment of Parkinson's disease. It relieves rigidity better than it does tremor, and in certain cases, it may accentuate the latter. The drug combats mental sluggishness, akinesia, adynamia, and lack of mobility, but this effect seems to diminish rather rapidly with prolonged use. It is best used as an adjunct to the other agents, such as bethtropine, procyclidine, cycrimine, and trihexyphenidyl, in the treatment of paralysis agitans. Orphenadrine citrate is also used as an adjunct to rest, physiotherapy, and other measures to relieve pain of local muscle spasm (e.g., nocturnal leg cramps).

The drug has a low incidence of the usual side effects for this group, namely, dryness of mouth, nausea, and mild excitation.

Aminoalcohols

The development of aminoalcohols as parasympatholytics took place in the 1940s. It was soon established, however, that these antispasmodics were equally efficacious in parkinsonism.

Several of the drugs in this class of antimuscarinic agents possess bulky groups in the vicinity of hydroxyl and cyclic amino functional groups. These compounds are similar to the classic aminoester anticholinergic compounds derived from atropine. The presence of the alcohol group seems to substitute adequately as a prosthetic group for the carboxyl function in creating an effective parasympathetic blocking agent. The aminoester group, per se, is not a necessary adjunct to cholinolytic activity, provided that other polar groupings, such as the hydroxyl, can substitute as a prosthetic group for the carboxyl function. Another structural feature common to all aminoalcohol anticholinergics is the γ -aminopropanol arrangement, with three carbons intervening between the hydroxyl and amino functions. All of the aminoalcohols used for paralysis agitans are tertiary amines. Because the desired locus of action is central, formation of a quaternary ammonium moiety destroys the antiparkinsonian properties. These aminoalcohols have been quaternized, however, to enhance the anticholinergic activity to produce an antispasmodic and antisecretory compound, such as tridihexethyl chloride.

Biperiden, USP. Biperiden, α -5-norbornen-2-yl- α -phenyl-1-piperidinepropanol (Akineton), introduced in

1959, has a relatively weak visceral anticholinergic, but a strong nicotinic, action in terms of its ability to block nicotine-induced convulsions. Therefore, its neurotropic action is rather low on intestinal musculature and blood vessels. It has a relatively strong musculotropic action, which is about equal to that of papaverine, in comparison with most synthetic anticholinergic drugs. Its action on the eye, although mydriatic, is much lower than that of atropine. These weak anticholinergic effects add to its usefulness in Parkinson's syndrome by minimizing side effects.

Biperiden

The drug is used in all types of Parkinson's disease (postencephalitic, idiopathic, arteriosclerotic) and helps to eliminate akinesia, rigidity, and tremor. It is also used in drug-induced extrapyramidal disorders to eliminate symptoms and permit continued use of tranquilizers. Biperiden is also of value in spastic disorders not related to parkinsonism, such as multiple sclerosis, spinal cord injury, and cerebral palsy. It is contraindicated in all forms of epilepsy.

Biperiden Hydrochloride, USP. Biperiden hydrochloride, α -5-norbornen-2-yl- α -phenyl-1-piperidinepropanol hydrochloride (Akineton hydrochloride), is a white, optically inactive, crystalline, odorless powder that is slightly soluble in water, ether, alcohol, and chloroform and sparingly soluble in methanol.

Biperiden hydrochloride has all of the actions described for biperiden. The hydrochloride is used for tablets because it is better suited to this dosage form than is the lactate salt. As with the free base and the lactate salt, xerostomia (dryness of the mouth) and blurred vision may occur.

Procyclidine Hydrochloride, USP. Procyclidine hydrochloride, α -cyclohexyl- α -phenyl-1-pyrrolidinepropanol hydrochloride (Kemadrin), was introduced in 1956. Although it is an effective peripheral anticholinergic and, indeed, has been used for peripheral effects similar to its methochloride (i.e., tricyclamul chloride), its clinical usefulness lies in its ability to relieve voluntary muscle spasticity by its central action. Therefore, it has been used with success in the treatment of Parkinson's syndrome. It is said to be as effective as trihexyphenidyl and is used to reduce muscle rigidity in postencephalitic, arteriosclerotic, and idiopathic types of the disease. Its effect on tremor is not predictable and probably should be supplemented by combination with other similar drugs.

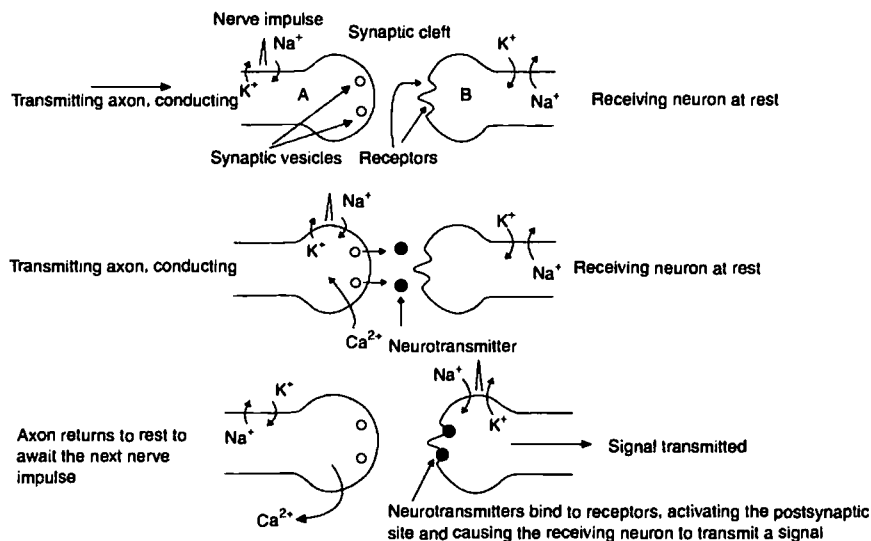

Figure 20-11 ■ Representation of the action of a neurotransmitter.

tic neuron may result in either vesicle formation or the neurotransmitter being transported to, and metabolized in, the mitochondria of the cell.

Many drugs act by interfering with either the synthesis and/or action and/or metabolism of the neurotransmitter. For example, the enkephalins are believed to act as endogenous painkillers by inhibiting substance P, a neurotransmitter that transmits pain signals across the synaptic cleft. It is thought that the activation of a pain-transmitting neuron causes both the presynaptic and postsynaptic neurons to release enkephalins. The enkephalins produced at the presynaptic site inhibit the release of substance P, while those produced at the postsynaptic site hypopolarize the postsynaptic membrane, which makes it more difficult to generate the postsynaptic action potential in the receiving neuron. Other drugs act by replacing the neurotransmitter.

Some neurotransmitters, such as glycine and γ -aminobutyric acid (GABA), act as inhibitors by opening Cl^- ion channels and allowing Cl^- ions to flow into the neuron causing hyperpolarization. This makes the internal face of the membrane relatively more electronegative, and so the neuron requires more intense depolarization if it is to transmit a signal. Ethanol is believed to act by inducing GABA receptors to open their Cl^- channels in the brain. This inhibits the excitability of the affected neurons and so reduces their ability to transmit nerve impulses. However, the ability of a neurotransmitter to either excite or inhibit a neuron appears to depend on the nature of its receptor rather than its structure.

Transmitter-gated channels are ion selective, and their receptor sites are highly selective for a particular neurotransmitter.⁵ The first to be characterized was the acetylcholine

TABLE 20-1 Examples of Neurotransmitters

Amino Acids	Small Peptides	Miscellaneous Amines and Their Derivatives
$\text{H}_3\text{N}^+\text{CH}_2\text{COO}^-$ Glycine	$\text{H-Try-Gly-Gly-Phe-Met(OH)}$ Met-enkephalin	$\text{HO-C}_6\text{H}_4\text{-CH}_2\text{CH}_2\text{NH}_2$ Dopamine
$\text{H}_3\text{N}^+\text{CH}_2\text{CH}_2\text{CH}_2\text{COO}^-$ γ -Aminobutyric acid (GABA)	$\text{H-Try-Gly-Gly-Phe-Leu(OH)}$ Leu-enkephalin	$\text{HO-C}_6\text{H}_3(\text{OH})\text{-CH(OH)CH}_2\text{NH}_2$ Noradrenaline
$\text{H}_3\text{N}^+\text{CH}(\text{COO}^-)\text{CH}_2\text{CH}_2\text{COOH}$ Glutamic acid		$(\text{CH}_3)_3\text{N}^+\text{CH}_2\text{CH}_2\text{OCOCH}_3$ Acetylcholine

This drug, introduced in 1957, is a potent anticholinergic, producing atropine-like effects peripherally. Even with its quaternary nature, it does not cause sympathetic blockade at the ganglionic level except at high dosages. Its principal distinguishing feature is its long duration of action. A single dose can provide antispasmodic and antisecretory effects for as long as 12 hours.

It is used as adjunctive therapy in the treatment of peptic ulcer and other conditions of the GI tract associated with hypermotility and hyperacidity. It has the usual side effects of anticholinergics (dryness of mouth, mydriasis, difficult urination) and is contraindicated in glaucoma, prostatic hypertrophy, etc.

Tropicamide, USP. Tropicamide, *N*-ethyl-2-phenyl-*N*-(4-pyridylmethyl)hydraerylamide (Mydrinyl), is an effective anticholinergic for ophthalmic use when mydriasis is produced by relaxation of the sphincter muscle of the iris, allowing adrenergic innervation of the radial muscle to dilate the pupil. Its maximum effect is achieved in about 20 to 25 minutes and lasts for about 20 minutes, with complete recovery in about 6 hours. Its action is more rapid in onset and wears off more rapidly than that of most other mydriatics. To achieve mydriasis, either 0.5 or 1.0% concentration may be used, though cycloplegia is achieved only with the stinger solution. Its uses are much the same as those described above for mydriatics in general, but opinions differ on whether the drug is as effective as homatropine, for example, in achieving cycloplegia. For mydriatic use, however, in examination of the fundus and treatment of acute iritis, indocyclitis, and keratitis, it is quite adequate; and because of its shorter duration of action, it is less prone to initiate a rise in intraocular pressure than the more potent, longer-lasting drugs. As with other mydriatics, however, pupil dilation can lead to increased intraocular pressure. In common with other mydriatics, it is contraindicated in patients with glaucoma, either known or suspected, and should not be used in the presence of a shallow anterior chamber. Thus far, no allergic reactions or ocular damage has been observed with this drug. The ability to clone the various muscarinic receptor subtypes has allowed the observation that tropicamide has modest selectivity for the M_3 receptor.⁷⁷

Miscellaneous

Further structural modification of classic antimuscarinic agents can be found in the drugs described below. Each of them has the typical bulky group characteristic of the usual anticholinergic molecule. One modification is represented by the diphenylmethylene moiety (e.g., diphemanil); a sec-

ond, by a phenothiazine (e.g., ethopropazine); and a third, by a thioxanthene structure (e.g., methixene).

Diphemanil Methylsulfate, USP. Diphemanil methylsulfate, 4-(diphenylmethylene)-1,1-dimethylpiperidinium methylsulfate (Prantal), or diphemanil methylsulfate is a potent cholinergic blocking agent. In the usual dosage range, it acts as an effective parasympatholytic by blocking nerve impulses at the parasympathetic ganglia, but it does not invoke a sympathetic ganglionic blockade. It is claimed to be highly specific in its action on those innervations that activate gastric secretion and GI motility. Although this drug can produce atropine-like side effects, they rarely occur at recommended doses. The highly specific nature of its action on gastric functions makes the drug useful in the treatment of peptic ulcer, and its lack of atropine-like effects makes its use much less distressing than other antispasmodic drugs. In addition to its action in decreasing gastric hypermotility, diphemanil methylsulfate is valuable in hyperhidrosis in low doses (50 mg twice daily) or topically. The drug is not well absorbed from the GI tract, particularly in the presence of food, and should be administered between meals. The methylsulfate salt was chosen as the best because the chloride is hygroscopic and the bromide and iodide ions have exhibited toxic manifestations in clinical use.

Ethopropazine Hydrochloride, USP. Ethopropazine hydrochloride, 10-[2-(diethylamino)propyl]phenothiazine monohydrochloride (Parsidol), introduced to therapy in 1954, has antimuscarinic activity and is especially useful in the symptomatic treatment of parkinsonism. In this capacity, it has value in controlling rigidity, and it also has a favorable effect on tremor, sialorrhea, and oculogyric crises. It is used often in conjunction with other antiparkinsonian drugs for complementary activity.

Side effects are common with this drug but are usually not severe. Drowsiness and dizziness are the most common side effects at ordinary dosage levels, and as the dose increases, xerostomia, mydriasis, and others become evident. It is contraindicated in conditions such as glaucoma because of its mydriatic effect.

Papaverine Hydrochloride, USP. Papaverine hydrochloride, 6,7-dimethoxy-1-veratrylisoquinoline hydrochloride, was isolated by Merck in 1848 from opium, in which it occurs to the extent of about 1%. Although its natural origin is closely related to morphine, the pharmacological actions of papaverine hydrochloride are unlike those of morphine. Its main effect is as a spasmolytic on smooth muscle, acting as a direct, nonspecific relaxant on vascular, cardiac, and other smooth muscle. Because of its broad antispasmodic action on ACh muscarinic receptors, it is often called a nonspecific antagonist. Papaverine hydrochloride has been used in the treatment of peripheral vascular disorders, but its use is limited by lack of potency.

Papaverine hydrochloride interferes with the mechanism of muscle contraction by inhibiting the cyclic nucleotide phosphodiesterases in smooth muscle cells responsible for converting cAMP and cyclic guanosine monophosphate (cGMP) to 5'-AMP and 5'-GMP, respectively. The increased levels of cAMP and cGMP are associated with muscle relaxation through their phosphorylation of myosin light-chain kinase.

Papaverine Hydrochloride

are located near the organ they innervate and have preganglionic fibers that stem from the cervical and thoracic regions of the spinal cord. *Sympathetic* ganglia consist of 22 pairs that lie on either side of the vertebral column to form lateral chains. These ganglia are connected both to each other by nerve trunks and to the lumbar or sacral regions of the spinal cord.

Nicotine

Using the sympathetic cervical ganglion as a model revealed that transmission in the autonomic ganglion is more complex than formerly believed. Traditionally, stimulation of autonomic ganglia by ACh was considered to be the nicotinic action of the neurotransmitter. It is now understood that stimulation by ACh produces a triphasic response in sympathetic ganglia. Impulse transmission through the ganglion occurs when ACh is released from preganglionic fibers and activates the N_2 nicotinic receptors of the neuronal membrane. This triggers an increase in sodium and potassium conductances of a subsynaptic membrane, resulting in an initial excitatory postsynaptic potential (EPSP) with a latency of 1 millisecond, followed by an inhibitory postsynaptic potential (IPSP) with a latency of 35 milliseconds, and, finally, a slowly generating EPSP with a latency of several hundred milliseconds. The ACh released by preganglionic fibers also activates M_1 muscarinic receptors of the ganglion and probably of the small-intensity fluorescent (SIF) cell. This results in the appearance of a slow IPSP and a slow EPSP in the neurons of the ganglion.⁷⁹ The initial EPSP is blocked by conventional competitive nondepolarizing ganglionic blocking agents, such as hexamethonium, and is considered the primary pathway for ganglionic transmission.⁸⁰ The slowly generating or late EPSP is blocked by atropine but not by the traditional ganglionic blocking agents. This receptor has muscarinic properties because methacholine causes generation of the late EPSP without causing the initial spike characteristic of ACh. Atropine also blocks the late EPSP produced by methacholine. There may be more than one type of muscarinic receptor in sympathetic ganglia. Atropine blocks both high-affinity (M_1) and low-affinity (M_2) muscarinic receptors in the ganglion.⁸¹ In addition to the cholinergic pathways, the cervical sympathetic ganglion has a neuron that contains a catecholamine.⁸² These neuronal cells, identified initially by fluorescence histochemical studies and shown to be smaller than the postganglionic neurons, are now referred to as SIF cells. Dopamine has been identified as the fluorescent catecholamine in the SIF cells that are common to many other sympathetic ganglia. Dopamine apparently mediates an increase in cAMP, which causes hyperpolarization of postganglionic neurons (Fig. 17-19). The IPSP phase of the transmission of sympathetic ganglia following ACh administration can be blocked by both atropine and α -adrenergic blocking agents.⁷⁹

GANGLIONIC BLOCKING AGENTS

Autonomic ganglia have been the subject of interest for many years in the study of interactions between drugs and nervous tissues. The first important account⁷⁸ was given by Langley and described the stimulating and blocking actions of nicotine on sympathetic ganglia. It was found that small amounts of nicotine stimulated ganglia and then produced a blockade of ganglionic transmission because of persistent depolarization. From these experiments, Langley was able to outline the general pattern of innervation of organs by the autonomic nervous system. *Parasympathetic* ganglia usually

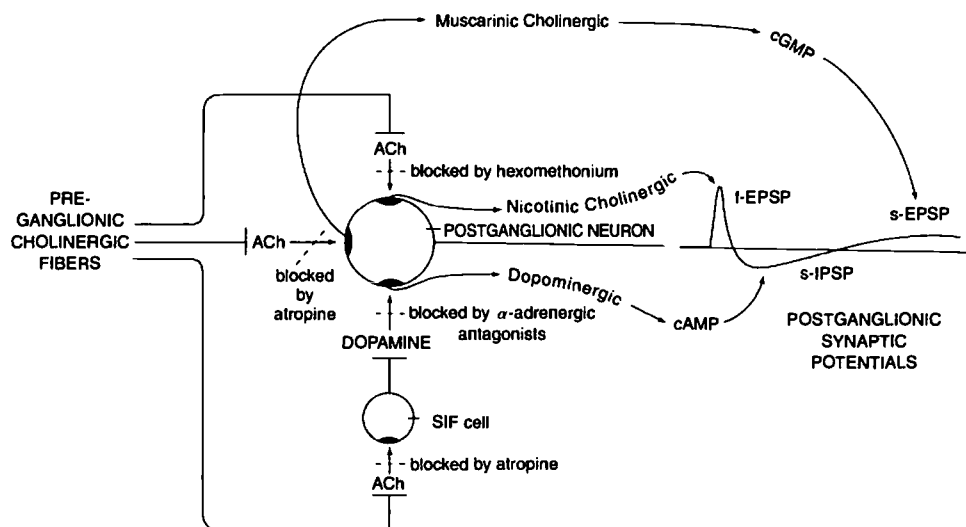

Figure 17-19 ■ Neurotransmission at the sympathetic cervical ganglion.

If a similar nontraditional type of ganglionic transmission occurs in the parasympathetic ganglia, it has not yet become evident. With the anatomical and physiological differences between sympathetic and parasympathetic ganglia, it should be no surprise that ganglionic agents may show some selectivity between the two types of ganglia. Although we do not have drug classifications such as "parasympathetic ganglionic blockers" and "sympathetic ganglionic blockers," we do find that certain ganglia have a predominant effect over certain organs and tissues and that a nondiscriminant blockade of autonomic ganglia results in a change in the effect of the autonomic nervous system on that organ (Table 17-7). None of the commonly known ganglionic blockers has yet

been identified as a selective blocker of parasympathetic ganglia.

Van Rossum^{83,84} has reviewed the mechanisms of ganglionic synaptic transmission, the mode of action of ganglionic stimulants, and the mode of action of ganglionic blocking agents. They have been classified as blocking agents in the following manner.

Depolarizing Ganglionic Blocking Agents

Depolarizing blocking agents are actually ganglionic stimulants. Thus, for nicotine, small doses give an action similar to that of the natural neuroeffector ACh, an action known as

TABLE 17-7 Results of Ganglionic Blockers on Organs

Organ	Predominant System	Results of Ganglionic Blockade
Cardiovascular system		
Heart	Parasympathetic	Tachycardia
Arterioles	Sympathetic	Vasodilation
Veins	Sympathetic	Dilation
Eye		
Iris	Parasympathetic	Mydriasis
Ciliary muscle	Parasympathetic	Cycloplegia
GI tract	Parasympathetic	Relaxation
Urinary bladder	Parasympathetic	Urinary retention

^a Neurotransmitter is ACh

the "nicotinic effect of ACh." Larger amounts of nicotine, however, bring about a ganglionic block characterized initially by depolarization, followed by a typical competitive antagonism. To conduct nerve impulses, the cell must be able to carry out a polarization and depolarization process, and if the depolarized condition is maintained without repolarization, obviously no conduction occurs. ACh itself, in high concentration, will bring about an autoinhibition. Chemicals that cause this type of ganglionic block are not of therapeutic significance. The classes of ganglionic blocking agents that are described are therapeutically useful.

Nondepolarizing Competitive Ganglionic Blocking Agents

Compounds in the class of nondepolarizing competitive ganglionic blocking agents possess the necessary affinity to attach to the nicotinic receptor sites that are specific for ACh, but they lack the intrinsic activity necessary for impulse transmission (i.e., they cannot effect depolarization of the cell). Under experimental conditions, in the presence of a fixed concentration of blocking agent of this type, a large enough concentration of ACh can offset the blocking action by competing successfully for the specific receptors. When such a concentration of ACh is administered to a ganglion preparation, it appears that the intrinsic activity of the ACh is as great as it was when no antagonist was present, the only difference being in the larger concentration of ACh required. It is evident, then, that such blocking agents are "competitive" with ACh for the specific receptors involved and that either the agonist or the antagonist, if present in sufficient concentration, can displace the other. Drugs falling into this class are tetraethylammonium salts, hexamethonium, and trimethaphan. Mecamylamine possesses a competitive component in its action but is also noncompetitive, a so-called dual antagonist.

Nondepolarizing Noncompetitive Ganglionic Blocking Agents

Nondepolarizing noncompetitive ganglionic blocking agents produce their effect not at the specific ACh receptor site but at some point farther along the chain of events that is necessary for transmission of the nerve impulse. When the block has been imposed, increasing the concentration of ACh has no effect; thus, apparently, ACh does not act competitively with the blocking agent at the same receptors. Theoretically, a pure noncompetitive blocker should have a high specific affinity for the noncompetitive receptors in the ganglia and a very low affinity for other cholinergic synapses, together with no intrinsic activity. Mecamylamine, as mentioned above, has a noncompetitive component but is also a competitive blocking agent.

The first ganglionic blocking agents used in therapy were tetraethylammonium chloride and bromide. Although one might assume that curariform activity would be a deterrent to their use, the curariform activity of the tetraethyl compound is less than 1% of that of the corresponding tetramethylammonium compound. A few years after the introduction of the tetraethylammonium compounds, Paton and Zaimis⁴⁵ investigated the usefulness of the bis-trimethylammonium polymethylene salts:

As shown, their findings indicate that there is a critical distance of about five to six carbon atoms between the onium centers for good ganglionic blocking action. Interestingly, the pentamethylene and hexamethylene compounds are effective antidotes against the curare effect of the decamethylene compound. Hexamethonium bromide and hexamethonium chloride emerged from this research as clinically useful products.

Trimethaphan camphorsulfonate, a monosulfonium compound, bears some similarity to the quaternary ammonium types because it, too, is a completely ionic compound. Although it produces a prompt ganglion-blocking action on parenteral injection, its action is short, and it is used only for controlled hypotension during surgery. Almost simultaneously with the introduction of chlorisondamine (now long removed from the market), announcement was made of the powerful ganglionic blocking action of mecamylamine, a secondary amine *without* quaternary ammonium character. As expected, the latter compound showed uniform and predictable absorption from the GI tract as well as a longer duration of action. Its action was similar to that of hexamethonium.

Drugs of this class have limited usefulness as diagnostic and therapeutic agents in the management of peripheral vascular diseases (e.g., thromboangiitis obliterans, Raynaud's disease, diabetic gangrene). The principal therapeutic application has been in the treatment of hypertension through blockade of the sympathetic pathways. Unfortunately, the action is nonspecific, and the parasympathetic ganglia, unavoidably, are blocked simultaneously to a greater or lesser extent, causing visual disturbances, dryness of the mouth, impotence, urinary retention, and constipation. Constipation, in particular, probably caused by unabsorbed drug in the intestine (poor absorption), has been a drawback because the condition can proceed to a paralytic ileus if extreme care is not exercised. For this reason, cathartics or a parasympathomimetic (e.g., pilocarpine nitrate) is frequently administered simultaneously. Another adverse effect is the production of orthostatic (postural) hypotension (i.e., dizziness when the patient stands up in an erect position). Prolonged administration of the ganglionic blocking agents results in diminished effectiveness because of a buildup of tolerance, though some are more prone to this than others. Because of the many serious side effects, more effective hypotensive agents have replaced this group of drugs.

In addition to these adverse effects, there are several limitations to the use of these drugs. For instance, they are contraindicated in disorders characterized by severe reduction of blood flow to a vital organ (e.g., severe coronary insufficiency, recent myocardial infarction, retinal and cerebral thrombosis) as well as situations in which there have been large reductions in blood volume. In the latter, the contraindication exists because the drugs block the normal vasoconstrictor compensatory mechanisms necessary for homeostasis. A potentially serious complication, especially in old male patients with prostatic hypertrophy, is urinary ret-

tion. These drugs should be used with care or not at all in the presence of renal insufficiency, glaucoma, uremia, and organic pyloric stenosis.

Trimethaphan Camsylate, USP. Trimethaphan camsylate, (+)-1,3-dibenzyldecahydro-2-oxoimidazo[4,5-c]thieno[1,2- α]-thiolium 2-oxo-10-bornanesulfonate (1:1) (Arfonad), consists of white crystals or a crystalline powder with a bitter taste and a slight odor. It is soluble in water and alcohol but only slightly soluble in acetone and ether. The pH of a 1% aqueous solution is 5.0 to 6.0.

This ganglionic blocking agent is short acting and is used for certain neurosurgical procedures in which excessive bleeding obscures the operative field. Certain craniotomies are included among these operations. The action of the drug is direct vasodilation, and because of its transient action, it is subject to minute-by-minute control. This fleeting action, however, makes it useless for hypertensive control. The drug is ineffective when given orally. The usual route of administration is intravenous. Trimethaphan camsylate is indicated in the treatment of hypertensive emergencies to reduce blood pressure rapidly. These emergencies may include pulmonary hypertension associated with systemic hypertension and acute dissecting aneurysm.

Trimethaphan Camsylate

Mecamylamine Hydrochloride. The secondary amine mecamylamine hydrochloride, *N*,2,3,3-tetramethyl-2-norbornanamine hydrochloride (Inversine), has a powerful ganglionic blocking effect that is almost identical to that of hexamethonium. It has an advantage over most of the ganglionic blocking agents in being absorbed readily and smoothly from the GI tract. It is rarely used, however, for the treatment of moderate-to-severe hypertension because severe orthostatic hypotension occurs when the drug blocks sympathetic ganglia.

Mecamylamine Hydrochloride

NEUROMUSCULAR BLOCKING AGENTS

Agents that block the transmission of ACh at the motor end plate are called *neuromuscular blocking agents*. The therapeutic use of these compounds is primarily as adjuvants in surgical anesthesia to obtain relaxation of skeletal muscle. They also are used in various orthopedic procedures, such as alignment of fractures and correction of dislocations.

The therapeutically useful compounds in this group sometimes are referred to as possessing *curariform* or *curarimimetic* activity in reference to the original representatives of the class, which were obtained from curare. Since then, synthetic compounds have been prepared with similar activity. Although all of the compounds falling into this category, natural and synthetic alike, bring about substantially the same end result (i.e., voluntary-muscle relaxation), there are some significant differences in mechanisms.

The possible existence of a junction between muscle and nerve was suggested as early as 1856, when Claude Bernard observed that the site of action of curare was neither the nerve nor the muscle. Since that time, it has been agreed that ACh mediates transmission at the neuromuscular junction by a sequence of events described above in this chapter. The neuromuscular junction consists of the axon impinging onto a specialized area of the muscle known as the muscle end plate. The axon is covered with a myelin sheath, containing the nodes of Ranvier, but is bare at the ending. The nerve terminal is separated from the end plate by a gap of 200 Å. The subsynaptic membrane of the end plate contains the cholinergic receptor, the ion-conducting channels (which are opened under the influence of ACh), and AChE.

One of the anatomical differences between the neuromuscular junction and other ACh-responsive sites is the absence in the former of a membrane barrier or sheath that envelops the ganglia or constitutes the blood-brain barrier. This is important in the accessibility of the site of action to drugs, particularly quaternary ammonium compounds, because they pass through living membranes with considerably greater difficulty and selectivity than do compounds that can exist in a nonionized species. The essentially bare nature (i.e., lack of lipophilic barriers) of the myoneural junction permits ready access by quaternary ammonium compounds. In addition, compounds with considerable molecular dimensions are accessible to the receptors in the myoneural junction. As a result of this property, variations in the chemical structure of quaternaries have little influence on the potential ability of the molecule to reach the cholinergic receptor in the neuromuscular junction. Thus, the following types of neuromuscular junction blockers have been noted.

Nondepolarizing Blocking Agents

Traditionally, *nondepolarizing blocking agents* is a term applied to categorize drugs that compete with ACh for the recognition site on the nicotinic receptor by preventing depolarization of the end plate by the neurotransmitter. Thus, by decreasing the effective ACh-receptor combinations, the end plate potential becomes too small to initiate the propagated action potential. This results in paralysis of neuromuscular transmission. The action of these drugs is quite analogous to that of atropine at the muscarinic receptor sites of ACh. Many experiments suggest that the agonist (ACh) and

the antagonist compete on a one-to-one basis for the end plate receptors. Drugs in this class are tubocurarine, dimethyltubocurarine, pancuronium, and gallamine.

Depolarizing Blocking Agents

Drugs in the category of depolarizing blocking agents depolarize the membrane of the muscle end plate. This depolarization is quite similar to that produced by ACh itself at ganglia and neuromuscular junctions (i.e., its so-called nicotinic effect), with the result that the drug, if in sufficient concentration, eventually will produce a block. Either smooth or voluntary muscle, when challenged repeatedly with a depolarizing agent, eventually becomes insensitive. This phenomenon is known as *tachyphylaxis*, or *desensitization*, and is demonstrated convincingly under suitable experimental conditions with repeated applications of ACh itself, the results indicating that within a few minutes the end plate becomes insensitive to ACh. The statements above may imply that a blocking action of this type is clear-cut, but under experimental conditions, it is not quite so unambiguous, because a block that begins with depolarization may regain the polarized state even before the block. Furthermore, depolarization induced by increasing the potassium ion concentration does not prevent impulse transmission. For these and other reasons, it is probably best to consider the blocking action a desensitization until a clearer picture emerges. Drugs falling in this class are decamethonium and succinylcholine.

Curare and Curare Alkaloids

Originally *curare* was a term used to describe collectively the very potent arrow poisons used since early times by the South American Indians. The arrow poisons were prepared from numerous botanic sources and often were mixtures of several different plant extracts. Some were poisonous by virtue of a convulsant action and others by a paralyzant action. Only the latter type is of value in therapeutics and is spoken of ordinarily as curare.

Chemical investigations of the curares were not especially successful because of difficulties in obtaining authentic samples with definite botanic origin. Not until 1935 was a pure crystalline alkaloid, *d*-tubocurarine chloride, possessing in great measure the paralyzing action of the original curare, isolated from a plant. Wintersteiner and Dutcher,⁸⁶ in 1943, isolated the same alkaloid. They showed, however, that the botanic source was *Chondodendron tomentosum* (Menispermaceae) and, thus, provided a known source of the drug.

Following the development of quantitative bioassay methods for determining the potency of curare extracts, a purified and standardized curare was developed and marketed under the trade name Intocostin (purified *C. tomentosum* extract), the solid content of which consisted of almost one-half (+)-tubocurarine solids. Following these essentially pioneering developments, (+)-tubocurarine chloride and dimethyltubocurarine iodide appeared on the market as pure entities.

Tubocurarine Chloride, USP. Tubocurarine chloride, (+)-tubocurarine chloride hydrochloride pentahydrate, is prepared from crude curare by a process of purification and crystallization. Tubocurarine chloride occurs as a white or

yellowish white to grayish white, odorless, crystalline powder that is soluble in water. Aqueous solutions of it are stable to heat sterilization.

The structural formula for (+)-tubocurarine was long thought to be that of Ia (see structure diagram). Through the work of Everett et al.,⁸⁷ the structure is now known to be that of Ib. The monoquaternary nature of Ib thus revealed has caused some reassessment of thinking concerning the theoretical basis for the blocking action, because all has previously assumed a diquaternary structure (i.e., Ia). Nevertheless, this does not negate the earlier conclusions that a diquaternary nature of the molecule provides better blocking action than does a monoquaternary nature (e.g., Ib is approximately fourfold less potent than dimethyl tubocurarine iodide). Further, (+)-isotubocurarine chloride (Ic) has twice the activity of Ib in the particular test used.

Tubocurarine is a nondepolarizing blocking agent used for its paralyzing action on voluntary muscles, the site of action being the neuromuscular junction. Its action is inhibited or reversed by the administration of AChE inhibitors such as neostigmine, or by edrophonium chloride (Tensilon). Such inhibition of its action is necessitated in respiratory embarrassment caused by overdosage. Additionally, at somewhat higher concentrations, *d*-tubocurarine may enter the open ion channel and add a noncompetitive blockade. Cholinesterase inhibitors do not restore this latter action easily or fully. Often, adjunctive artificial respiration is needed until the maximal curare action has passed. The drug is inactive orally because of inadequate absorption through lipid membranes in the GI tract, and when used therapeutically, it usually is injected intravenously.

d-Tubocurarine binds for only 1 millisecond to the receptor, yet its pharmacological effect of muscle paralysis, produced by administration of the drug intravenously during surgery, lasts for up to 2 hours. The basis of this action is the pharmacokinetics of the drug. *d*-Tubocurarine is given intravenously, and although 30 to 77% is bound to plasma proteins, the drug is distributed rapidly to central body compartments, including neuromuscular junctions. About 45%

of *d*-tubocurarine is eliminated unchanged by the kidneys. Its half-life is 89 minutes.

Tubocurarine, in the form of a purified extract, was used first in 1943 as a muscle relaxant in shock therapy for mental disorders. Its use markedly reduced the incidence of bone and spine fractures and dislocations from convulsions due to shock. Following this, it was used as an adjunct in general anesthesia to obtain complete muscle relaxation, a use that persists to this day. Before its use began, satisfactory muscle relaxation in various surgical procedures (e.g., abdominal operations) was obtainable only with "deep" anesthesia with the ordinary general anesthetics. Tubocurarine permits a lighter plane of anesthesia, with no sacrifice in the muscle relaxation so important to the surgeon. A reduced dose of tubocurarine is administered with ether because ether itself has curare-like action.

Metocurine Iodide, USP. Metocurine iodide, (+)-3,4-dimethylchondrocurarine diiodide (Metubine iodide), is prepared from natural crude curare by extracting the curare with methanolic potassium hydroxide. When the extract is treated with an excess of methyl iodide, the (+)-tubocurarine is converted to the diquaternary dimethyl ether and crystallizes out as the iodide (see "Tubocurarine Chloride," above). Other ethers besides the dimethyl ether have been made and tested. For example, the dibenzyl ether was one-third as active as tubocurarine chloride, and the diisopropyl compound had only one-half the activity. For comparison, the dimethyl ether has approximately 4 times the activity of tubocurarine chloride.

The pharmacological action of this compound is the same as that of tubocurarine chloride, namely, a nondepolarizing competitive blocking effect on the motor end plate of skeletal muscles. It is considerably more potent than *d*-tubocurarine, however, and has the added advantage of exerting much less effect on respiration. The effect on respiration is not a significant factor in therapeutic doses. Accidental overdosage is counteracted best by forced respiration.

Synthetic Compounds With Curariform Activity

Curare, until relatively recent times, remained the only useful curarizing agent; and it, too, suffered from a lack of standardization. The original pronouncement in 1935 of the structure of (+)-tubocurarine chloride, unchallenged for 35 years, led other workers to hope for activity in synthetic substances of less complexity. The quaternary ammonium character of the curare alkaloids coupled with the known activity of the various simple onium compounds hardly seemed to be coincidental, and it was natural for research to follow along these lines. One of the synthetic compounds discovered was marketed in 1951 as Flaxedil (gallamine triethiodide). A variety of other neuromuscular blocking agents have followed.

Atracurium Besylate. Atracurium besylate, 2-(2-carboxyethyl)-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methyl-1-*is*-veratrylisoquinolinium benzenesulfonate pentamethylene ester (Tracrium), is a nondepolarizing neuromuscular blocking agent that is approximately 2.5 times more potent than *d*-tubocurarine. Its duration of action (half-life, 0.33 hours) is much shorter than that of *d*-tubocurarine. The drug is metabolized rapidly and nonenzymatically to yield laudanosine and a smaller quaternary compound (Fig. 17-20), which do not have neuromuscular blocking activity. In vitro experiments show that atracurium besylate breaks down at pH 7.4 and 37°C by a Hoffman elimination reaction.⁸⁸ Atracurium besylate undergoes enzymatic decomposition of its ester function to yield an inactive quaternary alcohol and quaternary acid. AChE inhibitors such as neostigmine, edrophonium, and pyridostigmine antagonize paralysis by atracurium besylate.

Doxacurium Chloride. The molecular structure of doxacurium chloride, 1,2,3,4-tetrahydro-2-(3-hydroxypropyl)-6,7,8-trimethoxy-2-methyl-1-(3,4,5-trimethoxybenzyl) isoquinolinium chloride succinate (Nuromax), provides the

Atracurium Besylate

Figure 17-20 ■ Hoffman elimination and hydrolysis reactions of atracurium.

possibility for 10 stereoisomers: 4 *d,l* pairs and two *meso* forms. Of the 10 stereoisomers, 3 are all-*trans* configuration, and these are the only active ones.⁸⁹ Doxacurium chloride is a long-acting nondepolarizing blocking agent. The drug differs from drugs such as gallium and pancuronium in that it has no vagolytic activity. It is used as a skeletal muscle relaxant in surgical procedures expected to last longer than 90 minutes.

Gallamine Triethiodide, USP. Gallamine triethiodide, [*p*-phenenyl-tris(oxyethylene)]tris[triethylammonium] triiodide (Flaxedil), is a skeletal muscle relaxant that works by blocking neuromuscular transmission in a manner similar to that of *d*-tubocurarine (i.e., a nondepolarizing blocking agent). It does have some differences, however. It has a strong vagolytic effect and a persistent decrease in neuromuscular function after successive doses that cannot be overcome by cholinesterase inhibitors. Gallamine triethiodide also has muscarinic antagonistic properties and binds with greater affinity to the M_2 receptors than to the M_1 receptor. This latter characteristic may cause its strong vagolytic action.^{89, 90}

Doxacurium Chloride. Doxacurium chloride is a long-acting nondepolarizing blocking agent. The drug differs from drugs such as gallium and pancuronium in that it has no vagolytic activity. It is used as a skeletal muscle relaxant in surgical procedures expected to last longer than 90 minutes.

Gallamine Triethiodide

The drug is contraindicated in patients with myasthenia gravis, and one should remember that its action is cumulative, as with curare. The antidote for gallamine triethiodide is neostigmine.

Mivacurium Chloride. Mivacurium chloride, 1,2,3,4-tetrahydro-2-(3-hydroxypropyl)-6,7-dimethoxy-2-methyl-1-(3,4,5-trimethoxybenzyl)isoquinolinium chloride, (E)-4-octandioate (Mivacron), is a mixture of three stereoisomers, the *trans-trans*, *cis-trans*, and *cis-cis* diesters, each of which has neuromuscular blocking properties. The *cis-cis* isomer is about one-tenth as potent as the other isomers. Mivacurium chloride is a short-acting nondepolarizing drug used as an adjunct to anesthesia to relax skeletal muscle. The drug is hydrolyzed by plasma esterases, and it is likely that anticholinesterase agents used as antidotes could prolong rather than reverse the effects of the drug.

Pancuronium Bromide. Although pancuronium bromide, 2β,16β-dipiperidino-5α-androstan-3α,17β-diol diacetate dimethobromide (Pavulon), is a synthetic product, it is based on the naturally occurring alkaloid malouetine, found in arrow poisons used by primitive Africans. Pancuronium bromide acts on the nicotinic receptor and in the ion channel, inhibiting normal ion fluxes.

This blocking agent is soluble in water and is marketed in concentrations of 1 or 2 mg/mL for intravenous administration. It is a typical nondepolarizing blocker, with a potency approximately 5 times that of (+)-tubocurarine chloride and a duration of action approximately equal to the latter. Studies indicate that it has little or no histamine-releasing potential or ganglion-blocking activity and that it has little effect on the circulatory system, except for causing a slight rise in the pulse rate. As one might expect, ACh,

anticholinesterases, and potassium ion competitively antagonize it, whereas its action is increased by inhalation anesthetics such as ether, halothane, enflurane, and methoxyflurane. The latter enhancement in activity is especially important to the anesthetist because the drug is frequently administered as an adjunct to the anesthetic procedure to relax the skeletal muscle. Perhaps the most frequent adverse reaction to this agent is occasional prolongation of the neuromuscular block beyond the usual time course, a situation that can usually be controlled with neostigmine or by manual or mechanical ventilation, since respiratory difficulty is a prominent manifestation of the prolonged blocking action.

As indicated, the principal use of pancuronium bromide is as an adjunct to anesthesia, to induce relaxation of skeletal muscle, but it is also used to facilitate the management of patients undergoing mechanical ventilation. Only experienced clinicians equipped with facilities for applying artificial respiration should administer it, and the dosage should be adjusted and controlled carefully.

Pipecurium Bromide. Pipecurium bromide, 4,4'-(3α,17β-dihydroxy-5α-androstan-2β,16β-ylene)bis(1,1-dimethylpiperazinium)dibromide diacetate (Arduan), is a nondepolarizing muscle relaxant similar, both chemically and clinically, to pancuronium bromide. It is a long-acting drug indicated as an adjunct to anesthesia and in patients undergoing mechanical ventilation.

Vecuronium Bromide. Vecuronium bromide, 1-(3α,17β-dihydroxy-2β-piperidino-5α-androstan-16β-yl)-1-methylpiperidinium bromide diacetate (Norcuron), is the monoquaternary analogue of pancuronium bromide. It belongs to the class of nondepolarizing neuromuscular blocking agents and produces effects similar to those of drugs in this class. It is unstable in the presence of acids and undergoes gradual hydrolysis of its ester functions in aqueous solution. Aqueous solutions have a pH of about 4.0. This drug is used mainly to produce skeletal muscle relaxation during surgery and to assist in controlled respiration after general anesthesia has been induced.

Succinylcholine Chloride, USP. Succinylcholine chloride, choline chloride succinate (2:1) (Anectine, Sucostrin), is a white odorless crystalline substance that is freely soluble in water to give solutions with a pH of about 4. It is stable

Mivacurium Chloride

in acidic solutions but unstable in alkali. Aqueous solutions should be refrigerated to ensure stability.

Succinylcholine chloride is characterized by a very short duration of action and a quick recovery because of its rapid hydrolysis after injection. It brings about the typical muscular paralysis caused by blocking nervous transmission at the myoneural junction. Large doses may cause temporary respiratory depression, as with similar agents. Its action, in contrast with that of (+)-tubocurarine, is not antagonized by neostigmine, physostigmine, or edrophonium chloride.

These anticholinesterase drugs actually prolong the action of succinylcholine chloride, which suggests that the drug is probably hydrolyzed by cholinesterases. The brief duration of action of this curare-like agent is said to render an antidote unnecessary if the proper supportive measures are available. Succinylcholine chloride has a disadvantage, however, in that the usual antidotes cannot terminate its action promptly.

It is used as a muscle relaxant for the same indications as other curare agents. It may be used for either short or long periods of relaxation, depending on whether one or several

injections are given. In addition, it is suitable for continuous intravenous drip administration.

Succinylcholine chloride should not be used with thiopental sodium because of the high alkalinity of the latter. If used together, they should be administered immediately after mixing; however, separate injection is preferable.

Diuretics

DANIEL A. KOECHEL

A *diuretic* is defined as a chemical that increases the rate of urine formation. The *primary action* of most diuretics is the direct inhibition of Na^+ transport at one or more of the four major anatomical sites along the nephron where Na^+ reabsorption takes place. Because the Na^+ transport systems at each of these locations are unique, there is a different set of relatively rigid structural features that a diuretic must possess to inhibit Na^+ reabsorption at each site. Of additional importance are the *secondary (or indirect) events* that are triggered as a result of the diuretic's primary action. The nature and magnitude of many of the observed secondary effects depend on the locus of action of the diuretic and the response of nephron sites "downstream" to an enhanced delivery of fluid, Na^+ , or other solutes. The secondary events are quite characteristic for each class of diuretics and are often highly predictable if the reader has an understanding of normal renal physiological processes. Collectively, the primary and secondary effects induced by a diuretic determine its electrolyte excretion pattern. A diuretic usually possesses some combination of *natriuretic, chloruretic, saluretic, kaliuretic, bicarbonatoretic, or calciuretic properties*, depending on whether it enhances the renal excretion of Na^+ , Cl^- , Na^+/Cl^- , K^+ , HCO_3^- , or Ca^{2+} , respectively.

In this chapter, the normal function of the nephron is presented, including the four major reabsorptive sites for Na^+ and other important solutes and the renal physiological events that occur when Na^+ and water reabsorption are altered by the patient's state of hydration, disease, or intake of diuretics. This is followed by a discussion of each class of diuretics in current use. A knowledge of the important structural features and the site(s) of action of each class of diuretics should give the reader a better understanding of the factors that dictate the nature and magnitude of the anticipated diuresis and the associated secondary effects.

ANATOMY AND PHYSIOLOGY OF THE NEPHRON

The functional unit of the kidney is the nephron with its accompanying glomerulus (Fig. 18-1). There are approximately a million nephrons in each kidney. The blood (or, more appropriately, the plasma), from which all urine is formed, is brought to each nephron within the glomerular capillary network (Fig. 18-2). Many plasma components are filtered into Bowman's space. During the process of urine formation, the resulting glomerular filtrate flows through the convoluted and straight portions of the proximal tubule, descending limb of Henle's loop, thin and thick portions of the ascending limb of Henle's loop, area of the macula densa

cells, distal convoluted tubule (also referred to as the *early distal tubule*), connecting tubule (also referred to as the *late distal tubule*), and the cortical and medullary collecting tubules. Each of these nephron segments consists of ultrastructurally and functionally unique cell types. The physiological role of the glomerulus and each nephron segment is discussed below as it relates to the handling of important solutes and water in normally hydrated (normovolemic) and dehydrated (hypovolemic) persons and in patients afflicted with various edematous disorders (e.g., congestive heart failure, cirrhosis of the liver with ascites, and the nephrotic syndrome).

FUNCTION

Function of the Nephron When the Plasma Volume Is Normal (Normovolemia or Euvoolemia)

As blood is delivered to each glomerulus, many (but not all) of its components are filtered into Bowman's space through the "pores" in the glomerular capillary loops. Several physicochemical properties of each blood component dictate the extent to which it is removed from the blood by glomerular filtration. These include the component's relative molecular mass (M_r), overall charge (applies primarily to large molecules), and degree and nature of binding to plasma proteins. For example, plasma proteins with an M_r in excess of 50,000 Da and red blood cells are not readily filtered, whereas low- M_r , non-protein-bound components (e.g., Na^+ , K^+ , Cl^- , HCO_3^- , glucose, and amino acids) are readily filtered.¹

The *rate* of filtration of plasma components that possess an M_r of less than 50,000 Da and are not bound to plasma proteins

- Depends directly on the hydraulic (hydrostatic) pressure in the renal vasculature (created by the pumping heart), which tends to drive water and solutes out of the glomerular capillaries into Bowman's space
- Relates inversely to the plasma oncotic pressure (the osmotic pressure created by the plasma proteins within the vasculature), which tends to hold or prevent the filtration of water and solutes across the glomerular capillaries into Bowman's space¹
- Follows the intrarenal signals that allow each nephron to adjust the filtration rate through its own glomerular capillary network (i.e., tubuloglomerular feedback)²

Clearly, the cardiovascular and renal functional status of an individual will also affect the rate of filtration of plasma components through the glomeruli. In addition, neonates and the elderly usually have a reduced glomerular filtration rate (GFR), though for different reasons.^{3,4}

Figure 18-1 ■ Anatomy of the nephron, indicating the four major sites of sodium reabsorption (1–4).

The fraction of the total renal plasma flow that is filtered collectively by the glomeruli per unit time (i.e., the filtration fraction) is about one fifth.² This means that only one fifth (or 20%) of the plasma presented to the kidneys in a given period undergoes filtration at the glomeruli (i.e., about 650 mL of plasma flow through the kidneys each minute, approximately 125 mL/minute of which is filtered through the glomerular capillaries). The remaining four fifths (or 80%) of

the renal plasma flow is directed into the peritubular capillaries (Fig. 18-1). Each minute only 1 mL of urine is formed from the 125 mL of glomerular filtrate.⁵ Thus, approximately 99% of the glomerular filtrate is normally reabsorbed.

The absolute quantity of each filtrable plasma component that reaches Bowman's space—the filtered load of a substance—depends directly on the GFR and the concentration in plasma of the portion of the filtrable substance that is not bound to plasma proteins. That is, the filtered load of a substance equals the GFR (in milliliters per minute) times the concentration of unbound, filtrable substance in plasma (in amount per milliliter).⁵ The glomerular filtrate that houses the filtered load of a given solute is referred to below as the *luminal fluid*, since it enters the lumen of each nephron immediately upon leaving Bowman's space. In the following discussion, attention focuses on the percentage of the filtered load of Na^+ and other key solutes that is reabsorbed (i.e., transported from the luminal fluid into renal tubule cells, with subsequent passage into the interstitium and ultimately into the renal vasculature) at various nephron sites.

There are four major anatomical sites along the nephron that are responsible for the bulk of Na^+ reabsorption⁶ (Fig. 18-1): *site 1*, the convoluted and straight portions of the proximal tubule; *site 2*, the thick ascending limb of Henle's loop; *site 3*, the distal convoluted tubule; and *site 4*, the connecting tubule and the cortical collecting tubule. The actual transport processes involved in Na^+ reabsorption at each of these sites are highlighted in Figures 18-3 through 18-6 and are discussed in order.

SITE 1

The convoluted and straight portions of the proximal tubule are responsible for the reabsorption of

- About 65% of the filtered loads of Na^+ , Cl^- , Ca^{2+} , and water.⁷
- 80 to 90% of the filtered loads of HCO_3^- ,⁸ phosphate,⁷ and urate⁹
- Essentially 100% of the filtered loads of glucose, amino acids, and low-M_r proteins¹⁰

Figure 18-2 ■ Juxtaglomerular apparatus (JGA). Urine is formed from the filtration of plasma through the glomerular capillary loops into Bowman's space. The JGA is of paramount importance for the operation of the tubuloglomerular feedback mechanism, which allows a nephron to regulate the glomerular filtration rate of its own glomerulus.

Thus, under normal circumstances, the proximal tubule has a tremendous reabsorptive capacity. There are primarily two driving forces for this high reabsorptive activity. First, because the plasma in the peritubular capillaries (Fig. 18-1) has a lower hydraulic pressure and a higher oncotic pressure than the luminal fluid or the plasma delivered to the glomerulus (because of the removal of water but not protein from plasma during glomerular filtration), there is a net movement of the luminal fluid contents in a reabsorptive direction.¹ Second, the Na^+/K^+ -ATPase, strategically located on the antiluminal membrane (sometimes referred to as the *basolateral*, *peritubular*, or *contraluminal membrane*) of the proximal tubule cells, catalyzes the countertransport of intracellular Na^+ into the interstitium and extracellular K^+ into the proximal tubule cells¹⁰ (Fig. 18-3). The stoichiometry for this countertransport is $3 \text{ Na}^+ : 2 \text{ K}^+$. This activity creates a deficit of intracellular Na^+ , a surplus of intracellular K^+ , and a voltage oriented negatively inside proximal tubule cells.¹⁰

In response to the action of the Na^+/K^+ -ATPase, Na^+

Figure 18-3 ■ Site 1: The Na^+ transport systems responsible for the reabsorption of Na^+ and associated solutes in the proximal tubule. **A**, Transcellular reabsorption of $\text{Na}^+/\text{HCO}_3^-$, which is controlled by carbonic anhydrase (CA). Acetazolamide and other CA inhibitors block Na^+ reabsorption by this route. **B**, Transcellular reabsorption of Na^+ coupled to glucose, amino acids, and phosphate. **C**, Paracellular transport of Na^+/Cl^- . No commercially available agents inhibit Na^+ reabsorption by routes B or C. Na^+/K^+ -ATPase is indicated by filled circles on the antiluminal membrane.

in the luminal fluid moves down the concentration gradient into proximal tubule cells by a combination of at least three distinct processes (labeled A, B, and C in Fig. 18-3). The first mechanism of Na^+ reabsorption at site 1 involves carbonic anhydrase (CA), which is located in the cytoplasm and on the brush border of proximal tubule cells (Fig. 18-3A). H^+ , generated as the result of the action of intracellular CA, is exchanged (i.e., countertransported) for the filtered Na^+ in the luminal fluid. The Na^+ that enters proximal tubule cells during the exchange for H^+ is then pumped into the interstitium by the Na^+/K^+ -ATPase in the antiluminal membrane. The H^+ secreted (i.e., transported uphill or against its gradient) into the luminal fluid reacts there with the filtered HCO_3^- to generate carbonic acid. The carbonic acid decomposes, both spontaneously and with the aid of the brush border-bound CA, to carbon dioxide and water. The carbon dioxide diffuses into the proximal tubule cells and is converted back into HCO_3^- , which subsequently passes from the proximal tubule cells, across the antiluminal membrane,

and into the interstitium by way of an $\text{Na}^+/\text{HCO}_3^-$ symporter in the antiluminal membrane. CA is very plentiful in the convoluted portion of the human proximal tubule but is nonexistent in the straight portion.⁸ Thus, the processes just described occur primarily in the convoluted portion of the proximal tubule and account for the reabsorption of about 20 to 25% of the filtered load of Na^+ (or about one third of the filtered load of Na^+ that is reabsorbed at site 1) and about 80 to 90% of the filtered load of HCO_3^- .^{8, 11}

The second mechanism by which Na^+ moves out of the luminal fluid at site 1 involves its cotransport into proximal tubule cells along with glucose, amino acids, or phosphate¹⁰ (Fig. 18-3B). The latter three solutes enter proximal tubule cells against their concentration gradients. The reabsorption of the Na^+ that enters proximal tubule cells by these processes is completed when it is subsequently pumped into the interstitium by the antiluminal membrane-bound Na^+/K^+ -ATPase and then passes into the adjacent peritubular capillaries. The amount of Na^+ reabsorbed by this type of cotransport varies and depends on the filtered loads of the three solutes. Such cotransport, however, is the mechanism by which 100% of the filtered loads of glucose and amino acids and 80 to 90% of the filtered load of phosphate are normally removed from the luminal fluid and subsequently reabsorbed.

Third, Na^+ is reabsorbed at site 1 along with Cl^- (Fig. 18-3C).¹⁰ As the reabsorption of Na^+ occurs in the early proximal convoluted tubule accompanied by bicarbonate, glucose, amino acids, and phosphate, the concentration of Cl^- within the luminal fluid tends to rise. As a result, the concentration of Cl^- in the mid to late proximal tubule luminal fluid exceeds that in the interstitium, and Cl^- moves *paracellularly* (i.e., between the proximal tubular cells) into the interstitium; Na^+ follows. Additional Na^+/Cl^- is reabsorbed *transcellularly* (i.e., through cells) in the proximal tubule by the combination of a Na^+/H^+ antiporter and one or more Cl^- /anion antiporters (not shown).¹⁰

Collectively, these site 1 Na^+ -transporting processes remove 65% of the filtered load of Na^+ from the luminal fluid, and they do so *isosmotically* (i.e., the osmolality of the luminal fluid entering the descending limb of Henle's loop is similar to that of the initial glomerular filtrate).

As the luminal fluid moves through the descending limb of Henle's loop, the high *osmolality* (i.e., concentration of solutes) in the surrounding medullary interstitium draws approximately 15% of the filtered load of water out of the luminal fluid by osmosis and allows a small amount of Na^+ from the interstitium to be added to the luminal fluid. In other words, the luminal fluid is concentrated as it flows through the descending limb of Henle's loop.¹²

SITE 2

When the luminal fluid enters the thick ascending limb of Henle's loop, it comes into contact with tubule cells that are impermeable to water and possess a capacious luminal membrane-bound transport system for Na^+ (Fig. 18-4). Here, as at site 1, the major driving force for the reabsorption of Na^+ is the creation of an intracellular deficit of Na^+ by the antiluminal membrane-bound Na^+/K^+ -ATPase. The electroneutral sodium/potassium/chloride cotransport system located on the luminal membrane of thick ascending

Figure 18-4 ■ Site 2: The Na^+ transport systems responsible for the reabsorption of Na^+ and associated solutes in the water-impermeable cortical and medullary portions of the thick ascending limb of Henle's loop. The collective actions of the antiluminal membrane-bound $\text{Na}^+/\text{K}^+-\text{ATPase}$ and the luminal membrane-bound $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system account for transcellular reabsorption of Na^+/Cl^- , in a Na^+/Cl^- ratio of 3:6, and the generation of a lumen-positive potential that drives the reabsorption of Na^+ and other cations via the paracellular pathway (dashed line). Diuretic agents that block Na^+ reabsorption in the thick ascending limb by inhibition of the luminal membrane-bound $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system include furosemide, bumetanide, torsemide, ethacrynic acid, and a number of miscellaneous agents cited in Figure 18-13.

limb cells then transports Na^+ , along with K^+ and Cl^- , from the luminal fluid into the cells of the thick ascending limb in a ratio of $1\text{Na}^+ : 1\text{K}^+ : 2\text{Cl}^-$.¹⁰ Reabsorption of the Na^+ that enters thick ascending limb cells by this mechanism is completed when it is pumped actively into the interstitium by the antiluminal membrane-bound $\text{Na}^+/\text{K}^+-\text{ATPase}$ and then passes into the surrounding vasculature. Cl^- enters the interstitium through Cl^- channels in the antiluminal membrane and by cotransport with K^+ . The luminal K^+ that accompanies Na^+ and Cl^- into the thick ascending limb cells recycles passively downhill back into the luminal fluid. The K^+ that enters the thick ascending limb cells by way of the antiluminal membrane-bound $\text{Na}^+/\text{K}^+-\text{ATPase}$ recycles back into the interstitium via cotransport with Cl^- . Hence, the net result is the transport of 3Na^+ and 6Cl^- from the luminal fluid into the interstitium. This results in the generation of a lumen-positive transepithelial voltage. This positive luminal environment drives more cations (Na^+ , K^+ , Ca^{2+} , Mg^{2+}) from the lumen into the interstitium paracellularly (i.e., between the thick ascending limb cells).^{10, 13} The combined activities of the $\text{Na}^+/\text{K}^+-\text{ATPase}$

countertransport system on the antiluminal membrane and the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system on the luminal membrane of the thick ascending limb cells normally account for the reabsorption of up to 30% of the filtered load of Na^+ .^{6, 10} the reabsorption of up to 20 to 30% of the filtered load of Ca^{2+} .¹⁰ the maintenance of the high osmolality of the medullary interstitium (which is absolutely critical for the normal functioning of the human nephron),¹² and the ability of this nephron segment to reabsorb more Na^+ and other solutes than usual when proximal tubule Na^+ transport has been inhibited.^{6, 14} This latter compensatory phenomenon explains why diuretics that act primarily at site 1 are not particularly efficacious.

The descending limb of Henle's loop is responsible for the concentration of luminal fluid (i.e., removal of water and addition of Na^+), while the thick ascending limb is responsible for the dilution of luminal fluid (i.e., removal of solute from the luminal fluid without concomitant removal of water). Hence, collectively, these two nephron segments produce a massive overall reduction of luminal fluid volume and solute content. Interestingly, the osmolality of the luminal fluid in the terminal portion of the thick ascending limb of Henle's loop is not much different from that of the fluid that enters the descending portion of the loop (though drastic changes take place in between).

As the luminal fluid leaves the thick ascending limb of Henle's loop, it comes into contact with the *macula densa cells*, a specialized group of tubule cells that communicate with the granular cells of the afferent arteriole belonging to the same nephron¹⁵ (Fig. 18-2). The macula densa cells are like the thick ascending limb cells, in that they house both the antiluminal membrane-bound $\text{Na}^+/\text{K}^+-\text{ATPase}$ and the luminal membrane-bound $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system. Their uniqueness lies in their ability to detect changes in either the rate of luminal fluid flow or the solute composition of the luminal fluid, which in part dictates how much solute they remove from the luminal fluid. Signals are then transmitted by way of the granular cells to the afferent arteriole associated with that nephron.² When fluid/solute delivery past the macula densa cells increases, a macula densa-derived substance mediates constriction of the afferent arteriole supplying that particular nephron and a reduction in GFR ensues. This is commonly referred to as *tubuloglomerular feedback*. On the other hand, when fluid/solute delivery past the macula densa cells decreases, a signal is transmitted from these cells to the granular cells surrounding the afferent arteriole, which results in the release of renin.²

SITE 3

Following its sojourn past the macula densa cells, the luminal fluid comes into contact with the third major site for the reabsorption of Na^+ , the relatively short, water-impermeable, distal convoluted tubule (Fig. 18-5). Again, the major driving force for Na^+ reabsorption from the luminal fluid at site 3 involves the deficit of intracellular Na^+ produced by the action of the antiluminal membrane-bound $\text{Na}^+/\text{K}^+-\text{ATPase}$. In this instance, the luminal membrane-bound Na^+/Cl^- cotransport system moves luminal fluid Na^+ downhill and luminal fluid Cl^- uphill into distal convoluted tubule cells. The reabsorption of Na^+ is completed when the antiluminal membrane-bound $\text{Na}^+/\text{K}^+-\text{ATPase}$ ac-

Figure 18-5 ■ Site 3: The Na^+ transport systems responsible for the reabsorption of Na^+ and Cl^- in the water-impermeable distal convoluted tubule. Inhibitors of the luminal membrane-bound Na^+/Cl^- cotransport system include the thiazide and thiazide-like diuretics.

tively pumps it into the interstitium with subsequent passage into the surrounding vasculature; intracellular Cl^- enters the interstitium through channels in the antiluminal membrane. Approximately 5 to 8% of the filtered load of Na^+ is reabsorbed at site 3.^{6, 11}

SITE 4

The connecting tubule (i.e., late distal tubule) and the cortical collecting tubule house the fourth and final major site for the reabsorption of Na^+ from the luminal fluid⁶ (Fig. 18-6). This portion of the nephron is composed of two distinct cell types, the *principal cells* and the *intercalated cells*. The principal cells are important for Na^+ reabsorption and K^+ secretion, whereas the intercalated cells (subtype A) are important for the generation and secretion of H^+ . The intercalated cells possess only small quantities of the Na^+/K^+ -ATPase on their antiluminal membranes, but they contain abundant quantities of intracellular CA, which catalyzes the formation of carbonic acid from CO_2 and water. The carbonic acid ionizes, yielding H^+ and HCO_3^- . The H^+ is then pumped actively into the luminal fluid by the luminal membrane-bound H^+ -ATPase. The driving force for the reabsorption of Na^+ in the principal cells is once again the deficit of intracellular Na^+ created by the Na^+/K^+ -ATPase on the antiluminal membrane, which countertransports 3 Na^+ uphill from the principal cells into the interstitium and 2 K^+ uphill from the interstitium into the principal cells. In response to the deficit of Na^+ in the principal cells, the Na^+ in the luminal fluid moves downhill into the principal cells through Na^+ channels in the luminal membrane and is subsequently pumped actively into the interstitium by the antiluminal membrane-bound Na^+/K^+ -ATPase. These events create a lumen-negative transepithelial voltage. In response to this voltage difference, some combination of the following three processes occurs:

- Cl^- moves paracellularly from the lumen into the interstitium (not shown)
- K^+ in the principal cells moves downhill into the luminal fluid through K^+ channels in the luminal membrane
- H^+ generated in the intercalated cells moves into the luminal fluid by way of the H^+ -ATPase¹⁰

Because the latter two processes predominate, one may view the activities at site 4 as an exchange of luminal fluid Na^+ for principal cell K^+ and intercalated cell H^+ . The exchange of luminal fluid Na^+ for intracellular H^+ or K^+ normally is associated with the reabsorption of only 2 to 3% of the filtered load of Na^+ ,⁶ and the distal location of this exchange system dictates the final acidity and K^+ content of the urine.

The amount of Na^+ reabsorbed at site 4 and, therefore, the amount of H^+ and K^+ present in the final urine are modulated by

- Plasma and renal levels of mineralocorticoids like aldosterone—the higher the levels of circulating aldosterone, the greater the Na^+ reabsorption and K^+ and H^+ excretion
- Luminal fluid flow rate and the percentage of the filtered load of Na^+ presented to the exchange sites—the greater the flow rate and the load of Na^+ , the greater the amount of exchange
- Acid-base status of the individual—acidosis favors exchange of Na^+ and H^+ , whereas alkalosis favors exchange of Na^+ and K^+ .^{6, 16}

Figure 18-6 ■ Site 4: The Na^+ transport systems responsible for the reabsorption of Na^+ in the connecting and cortical collecting tubules. Na^+ reabsorption and K^+ secretion take place in the principal cells; H^+ formation and secretion occur in the intercalated cells. Spironolactone inhibits Na^+ reabsorption by competitively antagonizing the effects of aldosterone on the principal cells. Triamterene and amiloride "plug" the Na^+ channels in the luminal membrane of the principal cells, thereby preventing Na^+ reabsorption and K^+ and H^+ secretion. Thus, while producing a modest natriuresis, these drugs prevent K^+ loss and are commonly referred to as K^+ -sparing diuretics.

The classes of diuretics that inhibit the reabsorption of Na^+ at sites 1, 2, or 3 (i.e., sites proximal to site 4) ultimately increase, to varying degrees, the luminal fluid flow rate and the percentage of the filtered load of Na^+ delivered to site 4. Thus, many diuretics acutely enhance the urinary loss of K^+ and may be associated with the induction of hypokalemia (i.e., abnormally low levels of K^+ in the circulating blood).

Function of the Nephron During Reduced Plasma Volume (Hypovolemia)

When a patient's plasma volume decreases below normal (hypovolemia) because of such events as hemorrhage, diarrhea, vomiting, excessive sweating, or overzealous use of diuretics, a cascade of intrarenal and extrarenal signals that decreases urine and electrolyte output occurs in an attempt to restore the plasma volume and mean arterial pressure.^{2,3} The many signals result in

- Decreased renal blood flow and GFR
- Increased proximal tubule reabsorption of solutes and water^{14, 17}
- Increased renin secretion from the renal granular cells, which leads to increased circulating levels of angiotensin II (a potent vasoconstrictor) and aldosterone
- Increased secretion of antidiuretic hormone (ADH), which acts on the collecting tubules to increase water reabsorption

When hypovolemia is the result of overzealous use of diuretics, the compensatory reductions in urinary water and electrolyte output that occur are commonly referred to as the "*diuretic braking phenomenon*." The compensatory cascade of events mentioned above has basically put on the brakes to continued diuretic-induced increases in water and electrolyte excretion. Thus, the efficacy of the diuretic is blunted significantly. No diuretic induces the loss of urine that has the same composition as extracellular fluid; therefore, overzealous use of these agents results in hypovolemic patients who are frequently left with electrolyte and/or acid-base derangements.

Function of the Nephron During Disease States Associated With Retention of Body Fluids (Edematous States)

Frequently, the kidneys of individuals with congestive heart failure, cirrhosis of the liver with ascites, or the nephrotic syndrome receive signals that are interpreted to mean that they are being hypoperfused. This may occur whether or not there is an actual plasma volume reduction. The kidneys attempt to retain body fluids and solutes by a combination of the processes discussed in the previous paragraph. Ultimately, edema ensues.¹⁸

INTRODUCTION TO THE DIURETICS

Before embarking on a discussion of the various classes of diuretics, one must understand the difference between the terms *potency* and *efficacy* as they relate to diuretics, the major determinants of diuretic efficacy, and the shortcom-

ings of many of the previous structure–activity relationship (SAR) studies that have involved diuretics.

A clear distinction must be made between the use of the terms *potency* and *efficacy*.¹⁹ The *potency* of a diuretic is related to the absolute amount of drug (e.g., milligrams or milligrams per kilogram) required to produce an effect. The *relative potency* is a convenient means of comparing two diuretics and is expressed as a ratio of equieffective doses. The potency of a diuretic is influenced by its absorption, distribution, biotransformation, excretion, and inherent ability to combine with its receptor (i.e., its intrinsic activity). The potency of a diuretic is important for establishing its dosage but is otherwise a relatively unimportant characteristic. *Efficacy* relates to the maximal diuretic effect attainable (usually measured in terms of urine volume per unit of time or urinary loss of Na^+ or NaCl per unit of time).

Numerous factors contribute to the efficacy of a diuretic. First, the anatomical site of action and the capacity of the Na^+ -reabsorbing sites downstream play major roles in determining the overall efficacy. That is, a diuretic's efficacy is determined in part by whether it acts at site 1, 2, 3, or 4. Diuretics that inhibit the reabsorption of Na^+ at the same anatomical site are usually equiefficacious (i.e., evoke similar maximal responses) but may vary in potency (i.e., the amount of diuretic necessary to produce similar effects). Diuretics that act at site 1 by inhibiting CA may inhibit the reabsorption of 20 to 25% of the filtered load of Na^+ but are not as efficacious as one might think, because the three major sites of Na^+ reabsorption downstream (sites 2, 3, and 4) compensate by reabsorbing most of the extra Na^+ presented to them. Diuretics that inhibit the reabsorption of Na^+ at site 2 are the most efficacious because site 2 is normally responsible for the reabsorption of up to 30% of the filtered load of Na^+ , and the two Na^+ reabsorptive sites downstream (sites 3 and 4) are relatively low capacity sites. Diuretics that act at site 2 frequently are referred to as *high-ceiling* or *loop* diuretics. Diuretics that act at sites 3 or 4 are less efficacious because these two sites are responsible for the reabsorption of only 5 to 8% and 2 to 3% of the filtered load of Na^+ , respectively.

Second, the efficacy of a diuretic depends on its concentration at the site where it inhibits Na^+ transport. In all but a few cases, diuretics interfere with the processes responsible for the reabsorption of Na^+ that are located on the luminal membrane, and hence, their intraluminal concentration is of critical importance. The concentration of a diuretic agent that ultimately is presented to a luminal site is determined by how well it is filtered at the glomerulus, whether it undergoes active tubular secretion in proximal tubules, and whether it undergoes nonionic back diffusion in the distal nephron segments. All diuretics enter luminal fluid by the process of glomerular filtration but to varying degrees. The amount that enters the luminal fluid by the filtration process depends on the GFR, the plasma concentration of the diuretic agent, and the extent to which the diuretic is bound to the predominant unfilterable plasma protein, albumin. In addition, all but a few of the diuretics attain relatively high concentrations in the luminal fluid of the proximal tubule by a two-step process commonly referred to as *active tubular secretion*²⁰ (Fig. 18-7). The antiluminal membrane of the proximal tubule houses a set of bidirectional active transport systems that participate in the first step of active tubular secretion of a

Figure 18-7 ■ Active tubular secretion of a drug is a two-step process that is localized only in the proximal tubule area of the nephron. The first step involves the active transport of a drug that can exist as an organic anion or an organic cation from the interstitium into proximal tubule cells by way of the organic anion transport system (OATS) or the organic cation transport system (OCTS), respectively. These systems are located on the antiluminal membrane of proximal tubule cells. The second step involves some combination of passive diffusion of the uncharged drug species or active transport of the charged drug species from the proximal tubule cells into the luminal fluid. Active tubular secretion contributes in a major way to the high luminal fluid levels of most diuretics.

diuretic. The organic anion transport system (OATS) transports endogenous and exogenous organic anions; the organic cation transport system (OCTS) handles endogenous and exogenous organic cations. Because most diuretics are weak organic acids (e.g., carboxylic acids or sulfonamides) or weak organic bases (e.g., amines), they exist as organic anions and cations, respectively, and are likely to be handled by the OATS or the OCTS. Although the OATS and OCTS are bidirectional, they transport diuretics primarily in a secretory direction (i.e., from the interstitium into proximal tubule cells). Even diuretics that are extensively bound to plasma proteins may be secreted avidly. Importantly, neither the OATS nor the OCTS possesses rigid structural requirements for the respective organic anion or cation being transported. The second step of active tubular secretion of a diuretic involves its passage from proximal tubule cells into the luminal fluid, probably by a combination of passive diffusion and active transport.

In addition to the filtration and secretion processes, the concentration of a diuretic in the luminal fluid of the more distal segments of the tubule is determined by the agent's lipid/water partition coefficient and pK_a , as well as the pH of the distal luminal fluid. These factors modulate the concentration of diuretic at sites 3 and 4. Weakly acidic diuretics, whose undissociated forms possess a favorable balance of lipid and water solubility, may undergo pH-dependent diffusion (referred to as *nonionic back diffusion*) from the distal tubular luminal fluid back into the bloodstream. This frequently decreases the luminal fluid concentration and the renal excretion rate of the diuretic but prolongs its plasma half-life. Diuretics that are weak bases

follow a similar course if the urinary pH is on the alkaline side, which favors the presence of the uncharged drug species. Weak organic acids or bases, whose uncharged forms possess an unfavorable lipid/water partition coefficient, will not undergo nonionic back diffusion. These diuretics will be retained within the luminal fluid and, ultimately, will be excreted. Thus, diuretic agents may reach high concentrations in luminal fluid following glomerular filtration, active tubular secretion, and little or no subsequent nonionic back diffusion. Diuretics that act at sites 2 and 3 as well as some that act at site 4 inhibit Na^+ transport processes on the luminal membrane and must attain relatively high luminal fluid concentrations. In contrast, the CA-inhibiting diuretics that act at site 1 must attain adequate concentrations within luminal fluid as well as intracellularly, and the aldosterone antagonist spironolactone must attain adequate intracellular concentrations at site 4.

Finally, the efficacy of a diuretic is also determined by the patient's plasma volume and renal function status, concurrently administered drugs that reduce the GFR, and concurrently administered drugs that bind competitively to the OATS or OCTS and reduce the active tubular secretion and luminal fluid concentration of the diuretic.

Many of the past SAR studies involving diuretics were conducted in whole animals, and the results may be misinterpreted unless caution is exercised. Generally, compounds of varied chemical structure are administered to animals and ranked according to their ability to produce changes in urine volume or Na^+ output over a prescribed period. Conclusions are then drawn about which functional groups are the most important for optimal diuretic activity. The novice must re-

member that the results from such studies cannot necessarily be interpreted as a ranking of the intrinsic activity of the agents under study. Diuretic SAR studies conducted in whole animals yield results that are a composite of differences in the absorption, plasma protein binding, distribution, biotransformation, excretion, active tubular secretion, intrinsic activity, and secondary effects (e.g., changes in the GFR) of the various agents. Unfortunately, most, if not all, of these variables are neglected during initial diuretic screening procedures; therefore, it may be assumed erroneously that differences in diuretic activity are due to differences in intrinsic activity. If one is interested in the intrinsic activity of the members of a group of diuretics, a closer approximation can be achieved by examining the agents on isolated nephron segments on which related or prototypic diuretics are known to act. Several such studies have been conducted.^{21, 22} It should not be a surprise when results from *in vivo* and *in vitro* SAR studies differ. This occurs because of the interplay between numerous parameters in the *in vivo* studies (i.e., absorption, distribution, and such) that can be eliminated in a properly designed *in vitro* study. Almost all structure–activity data cited in the upcoming portion of this chapter came from whole animal and human investigations.

SITE 1 DIURETICS: CARBONIC ANHYDRASE INHIBITORS

Although the available CA inhibitors are used infrequently as diuretics, they not only played an important role in the development of other major classes of diuretics that are currently in widespread use but also aided in our understanding of basic renal physiology. Shortly after its introduction for the treatment of bacterial infections, sulfanilamide (Fig. 18-8) was observed to produce a mild diuresis characterized by the presence of urinary Na^+ and a substantial amount of HCO_3^- .²³ It was subsequently shown that it induced this effect through inhibition of renal CA.^{24, 25} However, it was a relatively weak inhibitor of renal CA, and the dose needed to exert adequate diuresis was associated with severe adverse effects. To improve on the CA-inhibitory property of sulfanilamide, many sulfamoyl-containing compounds ($-\text{SO}_2\text{NH}_2$) were synthesized and screened for their diuretic activity *in vivo* and their ability to inhibit CA *in vitro*. Two groups of CA inhibitors emerged: simple heterocyclic sulfonamides and *meta*-disulfamoylbenzene derivatives (Fig. 18-8).

STRUCTURE–ACTIVITY RELATIONSHIPS

SAR studies involving the *simple heterocyclic sulfonamides* yielded the prototypic CA inhibitor, acetazolamide^{26–30} (Fig. 18-8). The sulfamoyl group is essential for *in vitro* CA-inhibitory activity and for diuresis production *in vivo*. The sulfamoyl nitrogen atom must remain unsubstituted to retain both *in vivo* and *in vitro* activities. This feature explains why all antibacterial sulfonamides except sulfanilamide are incapable of inhibiting CA or exerting diuresis. In contrast, substitution of a methyl group on one of acetazolamide's ring nitrogens yields methazolamide (Fig. 18-8), a product

that retains CA-inhibitory activity. The moiety to which the sulfamoyl group is attached must possess aromatic character. In addition, within a given series of heterocyclic sulfonamides, the derivatives with the highest lipid/water partition coefficients and the lowest pK_a values have the greatest CA-inhibitory and diuretic activities.

The SAR studies involving the *meta*-disulfamoylbenzenes revealed that the parent 1,3-disulfamoylbenzene lacked diuretic activity, but key substitutions (summarized in Fig. 18-8) led to compounds with diuretic activity.³¹ The first commercially available analogue, dichlorphenamide (Fig. 18-8), is similar to acetazolamide in its CA-inhibitory activity, but it is also a chloruretic agent. Subsequently, chloraminophenamide (Fig. 18-8) when given by the intravenous route was shown to possess less CA-inhibitory activity but more chloruretic activity. Poor diuretic activity following the oral administration of chloraminophenamide precluded its marketing.

PHARMACOKINETICS

The clinically available CA inhibitors are absorbed well from the gastrointestinal tract, are distributed to the sites of major importance for CA inhibition, undergo little, if any biotransformation, and are excreted primarily by the kidneys. All CA inhibitors attain relatively high concentrations in renal luminal fluid (by a combination of glomerular filtration and active tubular secretion) and in proximal tubule cells.

SITE AND MECHANISM OF ACTION

CA is located both intracellularly (type II CA) and in the luminal brush border membrane (type IV CA) of proximal convoluted tubule cells (Fig. 18-3A). Both of these site 1 locations are major targets of the CA inhibitors.⁸ This group of diuretics also inhibits intracellular CA in the intercalated cells of the connecting and cortical collecting tubules (i.e., site 4; Fig. 18-6).

During the first 4 to 7 days of continuous therapy with a CA inhibitor, several noteworthy events occur that lead to an increase in Na^+ and HCO_3^- excretion: (a) inhibition of the intracellular CA in proximal tubule cells decreases the available H^+ normally exchanged for luminal fluid Na^+ , thus decreasing proximal tubule reabsorption of Na^+ (Fig. 18-3); and (b) inhibition of CA on the luminal brush border membrane of proximal tubule cells causes a decrease in the production of carbon dioxide within the luminal fluid and a decrease in the proximal tubule uptake of carbon dioxide. The net result is a decrease in the reabsorption of HCO_3^- . One might assume that a massive diuresis would follow inhibition of the portion of proximal tubule Na^+ reabsorption under the control of CA (i.e., one third of the 65% of the filtered load of Na^+ normally reabsorbed from the proximal luminal fluid, or about 22% of the filtered load of Na^+). However, Na^+ reabsorption sites downstream (especially site 2) compensate for such an action by reabsorbing much of the additional Na^+ presented to them.^{6, 11, 13} Some of the luminal fluid HCO_3^- is reabsorbed downstream by a non-CA-mediated system.³² Thus, the actions of the CA inhibitors ultimately result in the urinary loss of only 2 to

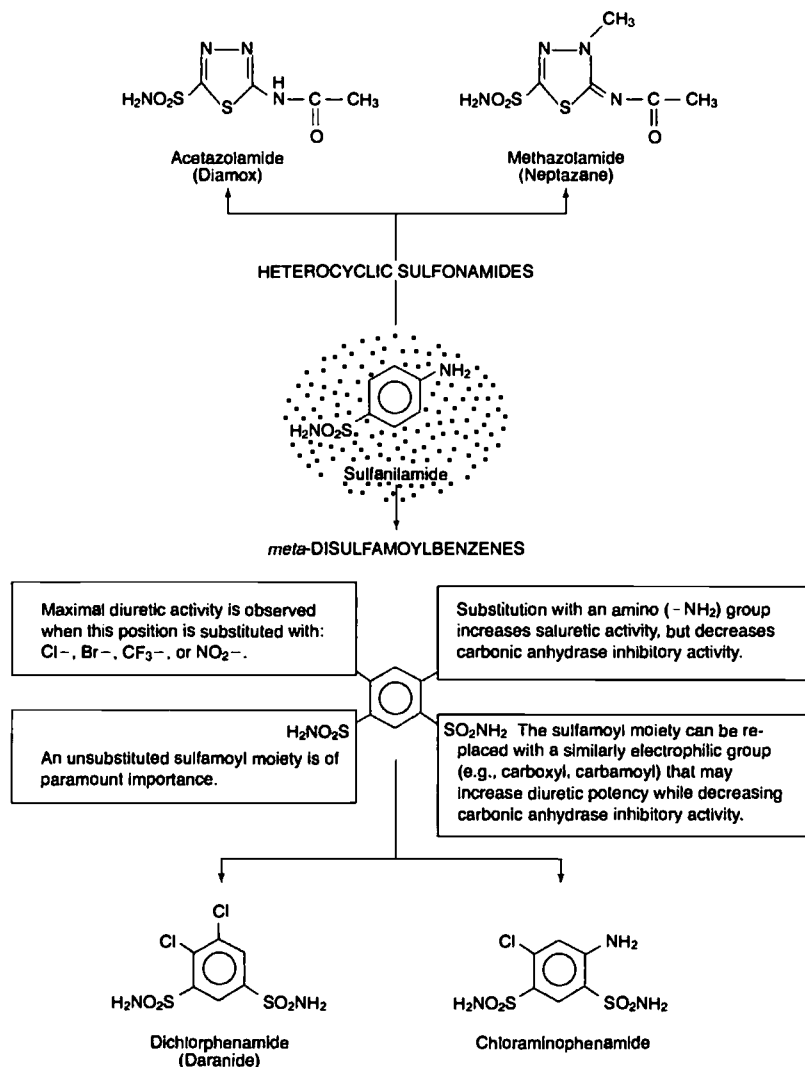

Figure 18-8 ■ Development of two classes of carbonic anhydrase inhibitors based on the actions of sulfanilamide.

5% of the filtered load of Na⁺ and up to 30% of the filtered load of HCO₃⁻.

Secondarily, the CA inhibitors enhance the urinary excretion of a substantial amount of K⁺.^{11, 33} The urinary loss of K⁺ increases because the proximal tubule actions of CA inhibitors present a greater percentage of the filtered load of Na⁺ to site 4, increase the flow rate of luminal fluid through the distal convoluted tubule and collecting tubule, and decrease the availability of intracellular H⁺ at site 4. All three changes favor enhanced exchange of luminal fluid Na⁺ for intracellular K⁺ at site 4. The urinary concentration of Cl⁻ actually decreases after the administration of CA in-

hibitors.³² Hence, CA inhibitors are primarily natriuretic, bicarbonatoretic, and kaliuretic agents.

Toward the end of the first week of continuous therapy with a CA inhibitor, resistance develops to its diuretic effect.³⁴ This is primarily due to two factors. First, there is a marked reduction in the filtered load of HCO₃⁻ because the CA inhibitors produce both a 20% reduction in the GFR via the tubuloglomerular feedback mechanism, and a reduction in the plasma concentration of HCO₃⁻. When there is less HCO₃⁻ present in the luminal fluid, there is less HCO₃⁻ reabsorption to inhibit. Second, the metabolic acidosis created by these diuretics provides a sufficient amount of

non-CA-generated intracellular H^+ to exchange for the luminal fluid Na^+ . The Na^+ reabsorption at site 1 progressively returns to a near-normal rate, and diuresis wanes.

ADVERSE EFFECTS

Four highly predictable adverse effects are associated with the CA inhibitors:

1. Development of metabolic acidosis due to the renal loss of HCO_3^-
2. Hypokalemia due to the renal loss of K^+
3. Up to a 20% reduction in the GFR, which appears to be mediated via the juxtaglomerular apparatus because of either the increased flow rate of luminal fluid past the macula densa cells or the increased reabsorption of the additional solute presented to the macula cells (i.e., tubuloglomerular feedback).^{33, 35}
4. Typical sulfonamide-associated hypersensitivity reactions, such as urticaria, drug fever, blood dyscrasias, and interstitial nephritis

CA inhibitors may also be associated with the production of paresthesias (tingling in the extremities), drowsiness, fatigue, anorexia, gastrointestinal disturbances, and urinary calculi. The latter occur because of a reduction in the urinary excretion rate of citrate, a normal urinary component that assists in maintaining urinary Ca^{2+} salts in a solubilized form.^{32, 33}

CA inhibitors can exacerbate the symptoms associated with cirrhosis of the liver.^{32, 36} Consequently, their use should be avoided in patients with this disorder. CA inhibitor-induced alkalization of the urine decreases the normal luminal fluid trapping of ammonia (NH_3) in the form of ammonium ions (NH_4^+). This leads to a subsequent reduction in the urinary excretion of ammonium ions. Under these circumstances the highly diffusible ammonia is diverted from the luminal fluid into the systemic circulation, where it may contribute to the development of hepatic encephalopathy.

USES

The major use of the CA inhibitors is in the treatment of glaucoma.³⁶ CA is a functionally important enzyme in the eye, where it plays a key role in the formation of aqueous humor. Inhibition of this ocular enzyme reduces the rate of formation of the aqueous humor, thereby reducing the intraocular pressure associated with glaucoma. Interestingly, a reduction in the intraocular pressure usually persists at a time when resistance has developed to the renal effects of the CA inhibitors.³³ CA inhibitors have been used prophylactically to counteract acute mountain sickness,³⁶ to act as adjuvants for the treatment of epilepsy, and to create an alkaline urine in an attempt to hasten the renal excretion of certain noxious weak acids or to maintain the urinary solubility of certain poorly water soluble, endogenous weak acids (e.g., uric acid).³⁶

PRODUCTS

Acetazolamide, USP. Acetazolamide, *N*-[5-(aminosulfonyl)-1,3,4-thiadiazol-2-yl]acetamide (Diamox) (Fig. 18-8), was introduced in 1953 as the first orally effective, non-mercurial diuretic available to the physician. It has a rela-

tively restricted use today because of its limited efficacy and the refractoriness that develops to its diuretic action within the first week of continuous therapy. However, it remains the most important CA inhibitor available and serves as the prototypic agent in its class. Acetazolamide is absorbed extremely well from the gastrointestinal tract, is bound extensively to plasma proteins, and is not biotransformed. Peak plasma levels are attained within 2 to 4 hours. Its onset of action is about 1 hour, and its duration of action ranges from 6 to 12 hours. Acetazolamide is removed totally from the plasma by the kidneys within 24 hours. The renal handling of acetazolamide involves its filtration at the glomeruli, active tubular secretion exclusively in the proximal tubules, and a varying degree of pH-dependent nonionic back diffusion in the distal segments of the nephron.

Methazolamide, USP. Although in vitro studies have shown methazolamide, *N*-[5-(aminosulfonyl)-3-methyl-1,3,4-thiadiazol-2(3H)-ylidene]acetamide (Neptazane) (Fig. 18-8), to be a more potent CA inhibitor than the prototypic acetazolamide, it is seldom used as a diuretic (for the same reasons stated for acetazolamide). Methazolamide displays improved penetration into the eye,²⁸ a property that contributes to its usefulness in the treatment of glaucoma.

Dichlorphenamide, USP. Like the other CA inhibitors, dichlorphenamide, 4,5-dichloro-1,3-benzenedisulfonamide (Daranide) (Fig. 18-8), is seldom used as a diuretic. Little is known about its pharmacokinetics. Like other CA inhibitors, it reduces intraocular pressure and may be useful in the treatment of glaucoma. The importance of dichlorphenamide and chloraminophenamide is that they ultimately served as stepping stones away from the "pure" CA-inhibiting diuretics and toward the development of the thiazide and thiazide-like diuretics, which are effective natriuretic and chloruretic agents with minimal CA-inhibitory activity.^{28, 30}

SITE 3 DIURETICS: THIAZIDE AND THIAZIDE-LIKE DIURETICS

Chloraminophenamide became a logical key intermediate in the development of diuretics that lacked the undesirable properties of the CA inhibitors. When chloraminophenamide was treated with acylating reagents, cyclization resulted in the formation of 1,2,4-benzothiadiazine-1,1-dioxides²⁸ (Fig. 18-9). The use of aldehydes or ketones in place of the acylating reagents yielded the corresponding dihydro derivatives. The products of these reactions became known as thiazides and hydrothiazides, respectively. Hereafter, they are referred to collectively as the *thiazide diuretics*. The thiazides were the first orally effective saluretic agents whose diuretic activity was not influenced by the patient's acid-base status.

STRUCTURE-ACTIVITY RELATIONSHIPS

Exhaustive SAR studies have been conducted with the thiazide diuretics^{28, 30} (see Fig. 18-9 for the numbering of the thiazide ring positions). Briefly, the 2 position can tolerate the presence of relatively small alkyl groups, such as CH_3 . The 3 position is an extremely important site of molecular

Figure 18-9 ■ Development of thiazide and hydrothiazide diuretics from chloraminophenamide.

modification. Substituents in the 3 position play a dominant role in determining the potency and duration of action of the thiazide diuretics. In addition, certain substituents in the 3 position have yielded compounds that are relatively specific inhibitors of the diuretic action of the thiazides.¹⁷⁻²¹ Loss of the carbon-carbon double bond between the 3 and 4 positions of the benzothiadiazine-1,1-dioxide nucleus increases the potency of this class of diuretics approximately 3- to 10-fold. Direct substitution of the 4, 5, or 8 position with an alkyl group usually diminishes diuretic activity. Substitution at the 6 position with an "activating" group is essential for diuretic activity. The best substituents include Cl, Br-, CF₃-, and NO₂-groups. The sulfamoyl group in the 7 position is a prerequisite for diuretic activity. Table 18-1 depicts the commercially available diuretics derived from the many alterations performed on the benzothiadiazine-1,1-dioxide nucleus.

When it was discovered that the sulfamoyl group *para* to the activating group in the *meta*-disulfamoylbenzenes could be replaced by several other electronegative groups with re-

Figure 18-10 ■ Representatives from six classes of thiazide-like diuretics. These diuretics were developed as an outgrowth of the thiazide research that involved molecular modification of aromatic sulfamoyl-containing compounds.

zation of diuretic activity (Fig. 18-8), a host of diuretics emerged that have become known as *thiazide-like diuretics*. The diuretics shown in Figure 18-10 represent the most active member(s) of each series. Clearly, these diuretics are not benzothiadiazines, but their sites of action, efficacies, electrolyte excretion patterns, and adverse effects resemble those of the thiazides. For these reasons, the thiazide and thiazide-like diuretics are discussed as a group.

PHARMACOKINETICS

Most of the thiazide and thiazide-like diuretics are absorbed well after oral administration, except chlorothiazide (only about 10% of which is absorbed).³² Their onset of action usually occurs within 1 to 2 hours, and their peak diuretic effect is expressed within 3 to 6 hours.⁴¹ Most diuretics in this class are bound extensively to plasma proteins (or to red blood cell CA for chlorthalidone and metolazone^{32, 42}),

undergo little, if any, biotransformation (except mefruside and metolazone⁴²), and are excreted primarily by the kidneys.^{32, 42, 43} Relatively high luminal fluid concentrations of these diuretics are attained, usually by a combination of glomerular filtration and active tubular secretion by the OATS in the proximal tubule (Fig. 18-7). The luminal fluid concentration of these diuretics is critical for elicitation of diuresis.⁴⁴

The diuretics in this class differ primarily in potency and duration of action.^{32, 41, 43, 45, 46} The differences in potency (which are reflected in their dosages) are determined mainly by the chemical nature of the moiety attached to the 3 position of the benzothiadiazine nucleus, which modulates the overall lipophilicity of the diuretic.^{28, 30} The differences in duration of action are dictated primarily by the degree of plasma protein binding (or red blood cell binding) and their lipid/water partition coefficients.^{45, 47} The latter values along with the pK_a of the drug and the pH of the luminal fluid

^a Data are from Oates, J. A., and Brown, N. J.: Antihypertensive agents and the drug therapy of hypertension. In Hardman, J. G., and Limbird, L. E. (eds.), Goodman & Gilman's The Pharmacological Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001, p. 873.

determine the extent to which each member of the class undergoes reabsorption in the distal convoluted tubule by nonionic back diffusion. Many of the diuretics in this class have long half-lives, in part because they undergo significant nonionic back diffusion. Pertinent pharmacological data on the thiazide and thiazide-like diuretics are presented in Tables 18-2 and 18-3, respectively.

SITE AND MECHANISM OF ACTION

The site of action of the thiazide and thiazide-like diuretics differs slightly from one species to another. In humans, however, it appears safe to conclude that all of these diuretics block the reabsorption of Na⁺ (and, thereby, the reabsorption of Cl⁻) in the distal convoluted tubules by inhibiting the luminal membrane-bound Na⁺/Cl⁻ cotransport system^{6, 44, 48, 49} (Fig. 18-5). Thus, all diuretics in this class are responsible for the urinary loss of about 5 to 8% of the filtered load of Na⁺. Although they differ in their potencies (i.e., the amount of drug needed to produce a given diuretic response), they are equally efficacious (i.e., they can all exert a similar maximal diuretic response).^{28, 30, 50}

As a result of their action at site 3, the thiazide and thiazide-like diuretics secondarily alter the renal excretion rate of important ions other than Na⁺ and Cl⁻. Inhibition of Na⁺

and Cl⁻ reabsorption at site 3 ultimately results in the delivery of more of the filtered load of Na⁺ to site 4. As a result, there is enhanced exchange of luminal fluid Na⁺ for principal cell K⁺, which results in an increase in the urinary excretion of K⁺. Most of the thiazide and thiazide-like diuretics possess residual CA-inhibitory activity that can be associated with a slight increase in the renal excretion rate of HCO₃⁻. Unlike the "pure" CA inhibitors, the thiazide and thiazide-like diuretics usually do not evoke development of resistance due to drug-induced derangements in acid-base balance. Hence, diuretics in this class may be referred to as *natriuretic*, *chloruretic*, *saluretic*, *kaliuretic*, and extremely weak *bicarbonatoretic* agents. Importantly, short-term therapy with a thiazide or thiazide-like diuretic results in little or no change in Ca²⁺ excretion; however, long-term therapy with these agents may lead to reduced Ca²⁺ excretion.³⁶

ADVERSE EFFECTS

Four of the adverse effects associated with the thiazide and thiazide-like diuretics are highly predictable because of their chemical makeup or their site of action along the nephron

1. All of these diuretics possess a sulfamoyl moiety, which has been associated with hypersensitivity reactions such as urticaria.

drug fever, blood dyscrasias, and interstitial nephritis. Persons who are hypersensitive to one of the agents in this class will probably be hypersensitive to all of them. Cross-hypersensitivity also may occur between the thiazide and thiazide-like diuretics, CA inhibitors, and the sulfamoyl-containing loop diuretics such as furosemide and bumetanide.

2 Hypokalemia is a product of the diuretic-induced increase in the renal excretion of K⁺.

3 Initially, these diuretics produce a slight reduction in the cardiac output. Slight reductions in plasma volume and blood pressure occur with continued use. These latter changes are frequently associated with increases in the proximal tubule reabsorption of water and solutes, renin release, angiotensin II formation, and aldosterone secretion. The combination of the events is frequently referred to as the *diuretic braking phenomenon*. These changes usually help mitigate the diuretic effect, but the blood pressure reduction persists.⁵¹

4 Occasionally, a patient may experience hypercalcemia or hyperuricemia after long-term use of a thiazide or thiazide-like diuretic. This results from diuretic-induced reduction of the patient's plasma volume and a concomitant compensatory increase in the proximal tubule reabsorption of luminal fluid and solutes. In such a situation, more Ca²⁺ and uric acid than usual will be reabsorbed proximally.³⁶ The seriousness of these two adverse effects depends in part on the duration and extent of the plasma volume reduction.

The precise mechanisms behind some of the adverse effects of the thiazide and thiazide-like diuretics are not well understood. These include an acute reduction in the GFR (especially after intravenous administration³²) and hyperglycemia. It is unlikely that the reduced GFR is related to the tubuloglomerular feedback mechanism, because the major site of action of these diuretics is distal to the macula densa cells. Some investigators have suggested that the thiazide and thiazide-like diuretics act directly on the renal vascula-

ture to depress the GFR.^{32, 43} Nonetheless, the acute reduction in the GFR involves all diuretics in this class, with the possible exceptions of metolazone and indapamide.⁵² This is particularly important to individuals with preexisting impaired renal function who require diuretic therapy. Thiazide and thiazide-like drugs are frequently ineffective in individuals who have a GFR below 15 to 25 mL/minute. Metolazone^{43, 45, 46, 53, 54} and indapamide⁵² may be useful in such circumstances.

Thiazide and thiazide-like diuretics can be involved in several potentially serious drug interactions. The first of these may occur if unadjusted doses of Li⁺ are administered to individuals on long-term thiazide or thiazide-like diuretic therapy. The proximal tubule handles Li⁺ and Na⁺ similarly. During long-term thiazide treatment, the resulting reduction in plasma volume triggers a compensatory increase in the proximal tubule reabsorption of fluid and solutes. Thus, more Li⁺ is reabsorbed than would be in normovolemic individuals. The resulting elevated plasma levels of Li⁺ may provoke serious Li⁺ toxicity.⁴⁵ Second, concurrent administration of a thiazide or thiazide-like diuretic with large doses of Ca²⁺-containing substances may result in hypercalcemia because of the Ca²⁺-retaining property of these diuretics. Third, concurrent use of thiazides and thiazide-like diuretics and nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit prostaglandin synthesis, can result in the NSAIDs antagonizing the induced diuresis. In addition, NSAIDs can increase the risk of renal failure in patients whose marginal renal function is being maintained by the intrarenal release of prostaglandins. Fourth, when thiazide and thiazide-like diuretics are used along with cardiac glycosides (e.g., digoxin or digitoxin) in the treatment of congestive heart failure, serious toxicity can result if hypokalemia occurs (see discussion below).

USES

Thiazide and thiazide-like diuretics are extremely useful in the treatment of edema associated with mild-to-moderate congestive heart failure, cirrhosis of the liver, or the nephrotic syndrome. Because edema is a symptom of an underlying disease and not a disease itself, the underlying disease should be treated first if possible. If treatment of the underlying disease does not remove the edema fluid, then diuretic therapy may be indicated. Caution is always necessary when thiazide or thiazide-like diuretics are coadministered with cardiac glycosides for the treatment of edema associated with congestive heart failure. These diuretics tend to promote hypokalemia, a condition that enhances the general toxicity of the cardiac glycosides.^{36,45} Combination diuretic therapy (i.e., a thiazide or thiazide-like diuretic plus a K^+ -sparing diuretic) may prevent K^+ loss under these circumstances. If combination diuretic therapy is instituted, the recipient should be advised not to take K^+ supplements, to avoid serious hyperkalemia.³²

Thiazide and thiazide-like diuretics are also useful in the treatment of certain nonedematous disorders. These include hypertension, diabetes insipidus (either the nephrogenic or the neurohypophyseal form), type II renal tubular acidosis, and hypercalciuria. These diuretics are primary agents in the treatment of hypertension—either alone or in combination with other drugs, depending on the severity of the condition. Thiazides generally lower blood pressure 10 to 15 mm Hg within the first 3 to 4 days of continuous treatment.⁵⁵ After approximately a week of continuous treatment (about when there is a concomitant reduction in plasma volume), the kidneys readjust to the initial effects of the diuretic, and the diuretic effect wanes while the blood pressure reduction is maintained.⁵¹ This readjustment occurs provided Na^+ intake is not increased.

Some individuals with hypercalciuria (an elevated urinary concentration of calcium) are prone to the formation of Ca^{2+} -containing stones within the urinary tract. Because long-term use of thiazide and thiazide-like diuretics decreases the urinary excretion rate of Ca^{2+} , they may help prevent Ca^{2+} -containing stone formation.^{36, 56}

SITE 2 DIURETICS: HIGH-CEILING OR LOOP DIURETICS

The diuretics in this class have extremely diverse chemical structures.³⁷ Although brief mention is made of the organomercurial diuretics, primary attention is focused on the agents with clinical utility; for example, furosemide (a 5-sulfamoyl-2-aminobenzoic acid or anthranilic acid derivative), bumetanide (a 5-sulfamoyl-3-aminobenzoic acid or metanilic acid derivative), tirsemide (a 4-amino-3-pyridine-sulfonylurea), and ethacrynic acid (a phenoxyacetic acid derivative).

Organomercurials

The organomercurials were the mainstay of diuretic therapy from 1920 to the early 1950s.²⁸ They elicit diuresis by inhibiting Na^+ reabsorption at site 2,⁵⁸ and they blunt the subsequent exchange of Na^+ for K^+ at site 4.⁵⁹ Thus, they are natriuretic and chloruretic and minimally kaliuretic. Al-

though these properties are true attributes for any class of diuretics, the organomercurials have a number of serious limitations. First, when given orally they cannot be relied on to elicit diuresis because of poor and erratic absorption. Second, after parenteral administration there is a 1- to 2-hour lag in the onset of diuresis.⁶⁰ Third, their ability to trigger a diuretic response depends on the acid-base status of the individual (i.e., they are ineffective when the urine is alkaline).^{61, 62} Fourth, they are cardiotoxic and nephrotoxic. The organomercurials became obsolete with the introduction of the thiazides and thiazide-like diuretics, furosemide, bumetanide, and ethacrynic acid. All of the latter agents are orally effective, equally effective in both acidotic and alkalotic conditions, capable of inducing relatively rapid diuresis when given parenterally, and relatively nontoxic.

5-Sulfamoyl-2-aminobenzoic Acid and 5-Sulfamoyl-3-aminobenzoic Acid Derivatives

Bumetanide, USP. The structure of bumetanide, 3-(butylamino)-4-phenoxy-5-sulfamoylbenzoic acid (Bumex), is shown in Figure 18-11.

Furosemide, USP. The structure of furosemide, 4-chloro-*N*-furfuryl-5-sulfamoylanthranilic acid (Lasix), is shown in Figure 18-11.

STRUCTURE-ACTIVITY RELATIONSHIPS

The development of the loop diuretics is an outgrowth of the research involving the thiazide and thiazide-like diuretics.⁴¹ There are important structural requirements that are common to the 5-sulfamoyl-2-aminobenzoic acid derivatives and the 5-sulfamoyl-3-aminobenzoic acid derivatives (Fig. 18-11). First, the substituent at the 1 position must be acidic. The carboxyl group provides optimal diuretic activity, but other groups, such as a tetrazole, may impart respectable diuretic activity. Second, a sulfamoyl group in the 5 position is a prerequisite for optimal high-ceiling diuretic activity. Third, the "activating" group ($-X$) in the 4 position can be Cl^- or CF_3^- , as was the case with the thiazides and thiazide-like diuretics, or better yet, a phenoxy, alkoxy, anilino, benzyl, or benzoyl group. Interestingly, substitution of one of the latter five functional groups for the Cl^- or CF_3^- group in the thiazides or thiazide-like diuretics decreases their diuretic activity.

These two series of 5-sulfamoylbenzoic acids differ greatly in the nature of the functional groups that can be substituted into the 2 and 3 positions with retention of maximal diuretic activity (Fig. 18-11). The substituents that can be tolerated on the 2-amino group of the 5-sulfamoyl-2-aminobenzoic acids are extremely limited, and no acceptable deviations are allowed on the few moieties. For example, only the furfuryl, benzyl, and thienylmethyl (in decreasing order) moieties yield derivatives with maximal diuretic activity. The substituents allowable on the 3-amino group of the 5-sulfamoyl-3-aminobenzoic acids can vary widely; however, without jeopardizing optimal diuretic activity. High-ceiling diuretics that have emerged from the 5-sulfamoyl-2-aminobenzoic acid series include furosemide and azosemide, those from the 5-sulfamoyl-3-aminobenzoic acid series include bumetanide and piretanide. Only furosemide

Figure 18-11 ■ Results from structure-activity relationship studies that led to the development of furosemide and bumetanide.

and bumetanide are commercially available in the United States.

PHARMACOKINETICS

Furosemide and bumetanide differ pharmacologically primarily in their potencies and bioavailabilities. Bumetanide is more potent than furosemide; it produces an equieffective diuresis in about 1/40th the dose.^{63, 64} The bioavailability of furosemide when administered orally is about 60 to 69% in normal subjects but only 43 to 46% in individuals with end-stage renal disease.⁴⁵ The bioavailability of bumetanide in normal individuals is 80 to 90%.⁶³

After parenteral administration, both furosemide and bumetanide have an extremely rapid onset of action (3 to 5 minutes). Duration of action following parenteral therapy is 2 hours for furosemide and 3.5 to 4 hours for bumetanide. Both diuretics have an onset of action of approximately 30 to 60 minutes after oral therapy, but furosemide has a slightly longer duration of action than bumetanide (6 to 8 hours versus 4 to 6 hours).⁴¹ Once these agents reach the bloodstream, they are extensively bound to plasma proteins (93 to 95%).⁶³ This degree of plasma protein binding severely limits the amount of each drug that can be removed from the plasma by glomerular filtration, but it does not prevent either drug from attaining high renal luminal fluid concentrations by active tubular secretion. Both diuretics are weak organic acids and are secreted avidly into the luminal fluid of the proximal tubule (Fig. 18-7).^{20, 65} This is important for two reasons. First, it is responsible for the relatively rapid renal excretion (hence, the short duration of action) of both diuretics; and second, it provides for the delivery of substantial amounts of each diuretic to their luminal site of action.

The factors discussed above that determine the luminal concentration of diuretics are critical when these agents are used in individuals with uremia. Uremic individuals frequently have a low GFR and high circulating levels of endogenous weak organic acids, both of which lower the

luminal fluid concentrations of the loop diuretics. The endogenous weak organic acids compete with the weakly acidic diuretics for active tubular secretion into proximal tubule luminal fluid. Often, the effects of the endogenous weak acids can be overridden by increasing the dose of these diuretics. Caution must be exercised, however, because an increased incidence of adverse effects is likely to accompany higher doses.

A small percentage of furosemide is converted to the corresponding glucuronide, and 88% of the administered drug is excreted by the kidneys. Bumetanide undergoes more extensive biotransformation in the human, and 81% of it is excreted in the urine (45% as unchanged drug).⁴¹

SITE AND MECHANISM OF ACTION

The events that contribute to the tremendous efficacy of furosemide and bumetanide are multifaceted. First, these diuretics inhibit the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system located on the luminal membrane of cells of the thick ascending limb of Henle's loop^{21, 57} (Fig. 18-4). Importantly, the carboxylate moieties of furosemide and bumetanide are thought to compete with Cl^- for the Cl^- -binding site on the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system. Because site 2 is such a high-capacity site for Na^+ reabsorption, up to 30% of the filtered load of Na^+ that is normally reabsorbed in this nephron segment may be excreted in the urine. In addition, reabsorption of this 30% of the filtered load of Na^+ (and Cl^-) is required to maintain the hypertonicity of the medullary interstitium.¹² The hypertonic medullary interstitium allows us to produce concentrated urine by drawing water out of the descending limb of Henle's loop by osmosis and out of the collecting duct by osmosis when ADH is present. Thus, when these diuretics inhibit the reabsorption of up to 30% of the filtered load of Na^+ at site 2, within minutes they also destroy the hypertonicity of the medullary interstitium.⁶ The net result is that when Na^+ and Cl^- are not reabsorbed at site 2, water is no longer removed by osmosis from the

luminal fluid in the descending limb of Henle's loop or from the collecting tubule. Large amounts of water, Na^+ , and Cl^- are excreted. *Second*, high concentrations of furosemide and bumetanide are attained in proximal luminal fluid by way of the OATS and delivered to the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system at site 2. *Third*, although these diuretics increase the flow rate of luminal fluid past the macula densa cells, the expected reduction in GFR (which normally would mitigate the diuresis) does not occur. This is because these efficacious diuretics inhibit the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system in the luminal membrane of the macula densa cells and so decrease the uptake of these solutes, which in turn inhibits the tubuloglomerular feedback mechanism from decreasing the GFR.⁶⁶ *Fourth*, these diuretics also transiently increase total renal blood flow by enhancing the intrarenal release of vasodilatory prostaglandins. *Fifth*, they induce a redistribution of intrarenal blood flow that is thought to participate in a positive way toward the magnitude of the diuresis.⁵⁷

All diuretics that act at site 2 are equally efficacious and far more efficacious than diuretics that act at sites 1, 3, or 4. As mentioned above, because of their site of action and efficacy, these agents are commonly referred to as *loop* and *high-ceiling diuretics*.⁵⁷

High-ceiling diuretics secondarily enhance the urinary loss of K^+ and H^+ . First, by inhibiting the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport complex at site 2, they prevent the generation of a lumen-positive transepithelial voltage and, therefore, the paracellular reabsorption of K^+ and other cations. Second, inhibition of Na^+ reabsorption at site 2 ultimately delivers more of the filtered load of Na^+ , at a faster rate, to site 4. This leads to an enhanced exchange of the Na^+ in the luminal fluid for the K^+ in the principal cells and the H^+ in the intercalated cells (Fig. 18-6).

When the loop diuretics are used in "submaximal" doses for the treatment of hypertension, they are intended to create a diuresis similar in magnitude to that produced by the thiazide and thiazide-like diuretics. Under these circumstances, loop diuretics usually are associated with a lower frequency of hypokalemia than the thiazide and thiazide-like diuretics because their duration of action is shorter, and the kidneys have more time to readjust.^{30, 67} When the loop diuretics are used to treat acute edema, however, higher dosages are frequently used, and the Na^+ and K^+ losses exceed those accompanying thiazide therapy.³⁰

When the loop diuretics inhibit the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system in the luminal membrane of thick ascending limb cells, they in turn decrease the lumen-positive transepithelial voltage that promotes the paracellular movement of luminal fluid cations such as Ca^{2+} into the interstitium (Fig. 18-4). Hence, loop diuretics may induce the renal excretion of up to 20 to 30% of the filtered load of Ca^{2+} , provided the plasma volume is not allowed to decrease.¹⁰ If plasma volume decreases as a result of the diuresis, there is an accompanying compensatory increase in the proximal tubule reabsorption of fluid and solutes. About 60% of the filtered load of Ca^{2+} is reabsorbed in the proximal tubule during normovolemia, and the percentage of proximally reabsorbed Ca^{2+} will increase in a state of plasma volume reduction. Therefore, during diuretic-induced hypovolemia, less Ca^{2+} is delivered to the thick ascending limb for the loop diuretics to inhibit, which will blunt the loop diuretic's calciuretic effect.

ADVERSE EFFECTS

Four highly predictable adverse effects are associated with furosemide and bumetanide:

1. Hypokalemic alkalosis results from the enhanced exchange of luminal fluid Na^+ for intracellular K^+ or H^+ ions at site 4. Caution should be exercised when concurrent therapy with loop diuretics and cardiac glycosides is instituted because hypokalemia intensifies the toxicity of the cardiac glycosides.⁴¹
2. In the short term, fluid and electrolyte losses may not be accompanied by changes in the GFR because of the effect of these agents on the tubuloglomerular feedback mechanism. The long-term use of these diuretics, however, may reduce plasma volume. If this condition is allowed to persist, the above-mentioned compensatory changes take place, one of which is a reduction in GFR.
3. Because diuretic-induced plasma volume reduction leads to increased reabsorption of solutes normally handled by the proximal tubule (e.g., uric acid), some borderline hyperuricemic individuals may develop symptoms of gout on long-term loop diuretic therapy. For similar reasons, concurrent administration of loop diuretics and unadjusted doses of Li^+ may lead to severe Li^+ toxicity.⁴¹
4. Furosemide and bumetanide are similar to the CA inhibitors, thiazides, and thiazide-like diuretics in possessing a sulfamoyl moiety. This functional group has been associated with hypersensitivity reactions such as urticaria, drug fever, blood dyscrasias, and interstitial nephritis.

Several unforeseen adverse effects are associated with the loop diuretics. For example, they are unique among diuretics in producing ototoxicity. Usually, hearing loss is temporary, but it may be permanent. Ototoxicity may be associated directly with rising plasma concentrations of the loop diuretics. Accordingly, individuals with impaired renal function appear to be at increased risk because they have a reduced ability to excrete these efficacious diuretics.⁴⁵ Although the milligram dose of bumetanide is 1/40th that of furosemide, these agents appear to be quite similar in their ototoxic potential. Caution is needed if loop diuretics are administered to patients who are receiving any of the available aminoglycoside antibiotics. The ototoxicity of these two classes of drugs may be additive.⁴¹ Other adverse effects of furosemide and bumetanide include hyperglycemia, nausea, vomiting, and myalgia.

NSAIDs, which inhibit prostaglandin synthesis, may blunt the natriuresis produced by loop diuretics. In patients with preexisting impaired renal function who are on diuretic therapy, NSAIDs may increase the risk of renal failure by blocking the intrarenal synthesis of vasodilatory prostaglandins, the one thing that may be sustaining renal blood flow in these patients.⁴¹

USES

High-ceiling diuretics are effective for the treatment of edema that may accompany congestive heart failure, cirrhosis of the liver, and the nephrotic syndrome. A most important use of furosemide or bumetanide is in the treatment of pulmonary edema associated with congestive heart failure. No group of diuretics is more effective than the loop diuretics in this situation, but they must be used with extreme caution. Overzealous use may reduce plasma volume so severely that the resulting decreased venous return and cardiac output exacerbate the heart failure.⁶⁸

Loop diuretics may be used for the treatment of certain nonedematous disorders. Symptomatic hypercalcemia may be treated with a loop diuretic, provided no reduction in plasma volume occurs and the fluid used for replacement of the urinary losses is calcium free.⁶⁹ In addition, furosemide has been used for the treatment of hypertension. Some investigators believe, however, that because of its relatively short duration of action, it may be less effective than the thiazide or thiazide-like diuretics. It has been suggested that furosemide be reserved for hypertensive patients with fluid retention refractory to thiazides or patients with impaired renal function.⁴⁶

In general, furosemide or bumetanide is preferred over ethacrynic acid (another site 2 diuretic) because they have a broader dose-response curve, less ototoxicity, and less gastrointestinal toxicity.⁴⁵

4-Amino-3-Pyridinesulfonylureas

Torsemide. The structure of torsemide, 1-isopropyl-3-[4-(3-methylphenylamino)pyridine]-3-sulfonyl urea (Demadex), is shown below.

STRUCTURE-ACTIVITY RELATIONSHIPS

Initial screening of many 4-amino-3-pyridinesulfonylureas revealed that maximum diuretic activity was attained with torsemide.⁷⁰ Torsemide is closely related structurally to trifluocin, a loop diuretic that was studied extensively in the late 1960s and early 1970s but abandoned because it produced transitional cell carcinoma in the urinary bladders of over 50% of the rats that had received high doses over an 18- to 22-month period.

PHARMACOKINETICS

Torsemide is approximately 80% bioavailable after oral administration. Its extensive plasma protein binding (98 to 99%) is similar to that of other loop diuretics. Peak serum concentrations are generally attained within 1 hour, and the half-life is 3 to 4 hours, somewhat longer than that of furosemide (2 hours) and bumetanide (1 to 1.5 hours). Torsemide is metabolized by the hepatic cytochrome P-450 system. The primary products result from the oxidation of the aromatic methyl group to hydroxy and carboxyl derivatives and *para* hydroxylation of the methylphenylamino moiety.

Approximately 20% of the dose is excreted unchanged in the urine.^{71, 72}

SITE AND MECHANISM OF ACTION

Like furosemide and bumetanide, torsemide induces diuresis by inhibition of the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransport system on the luminal membrane of thick ascending limb cells (Fig. 18-4). Thus, torsemide must reach adequate levels in the luminal fluid. Higher doses, which have been studied in isolated nephron segments, also inhibit the efflux of Cl^- from the thick ascending limb cells by the Cl^- channels on the basolateral membrane.⁷³ Whether this second site of action is clinically relevant remains to be determined.

ADVERSE EFFECTS

Torsemide may produce fatigue, dizziness, muscle cramps, nausea, and orthostatic hypotension. At this early date, no evidence of ototoxicity has appeared in humans, but studies in cats have shown torsemide to be similar to furosemide in ototoxic potential.⁷⁴

USES

Torsemide is useful in the treatment of mild-to-moderate hypertension in doses of 2.5 to 5 mg given once daily. These doses lower blood pressure as effectively as 25 mg of hydrochlorothiazide but without producing diuresis. Higher doses of torsemide (10 to 20 mg) are associated with significant diuresis and are effective in treating edema associated with congestive heart failure and cirrhosis of the liver.^{71, 75}

Phenoxyacetic Acids

The phenoxyacetic acid group of high-ceiling diuretics was developed and introduced into clinical use about the same time as furosemide.

Ethacrynic Acid, USP. The structure of ethacrynic acid, [2,3-dichloro-4-(2-methylene-1-oxobutyl)phenoxy]acetic acid (Edecrin), is shown in Figure 18-12.

STRUCTURE-ACTIVITY RELATIONSHIPS

As mentioned above, certain organomercurials can elicit a diuretic response, but because of their heavy metal content, they are too toxic for widespread use. Consequently, a search was undertaken for a non-mercury-containing compound that like the organomercurials would react with sulfhydryl-containing receptors in renal tissue but be devoid of heavy metal-type toxicity. Because none of the commercially available organomercurials (mersalyl, Salyrgan) possessed a phenoxyacetic acid moiety, the phenoxyacetic acids served as the chemical root for development of new non-mercury-containing diuretics. Hundreds of phenoxyacetic acids were examined.^{76, 77}

Within the phenoxyacetic acid series (Fig. 18-12), optimal diuretic activity is achieved when (a) an oxyacetic acid moiety is placed in the 1 position on the benzene ring, (b) a sulfhydryl-reactive acryloyl moiety is located *para* to the oxyacetic acid group, (c) activating groups (i.e., Cl^- or CH_3) occupy either the 3 position or the 2 and 3 positions.

Figure 18-12 ■ Ethacrynic acid is a high-ceiling diuretic that readily reacts with many sulfhydryl-containing nucleophiles (top). Indacrinone, a structurally related high-ceiling diuretic, lacks sulfhydryl reactivity (bottom).

(d) alkyl substituents of two to four carbon atoms in length occupy the position α to the carbonyl on the acryloyl moiety, and (e) hydrogen atoms occupy the terminal position of the carbon-carbon double bond of the acryloyl moiety. These structural features seemed to maximize both the diuretic activity and the *in vitro* rate of reaction with various sulfhydryl-containing nucleophiles. The correlation between diuretic activity and chemical reactivity within this series of diuretics was strengthened by the finding that reduction or epoxidation of the carbon-carbon double bond in the acryloyl moiety yielded compounds with little or no diuretic activity or chemical reactivity.^{78, 79} The design and synthesis of ethacrynic acid appeared to be the ultimate in terms of "the rational approach to drug design." The need for designing a diuretic with high sulfhydryl reactivity was foiled, however, when indacrinone was found to be a highly efficacious diuretic, incapable of reacting with sulfhydryl-containing nucleophiles (Fig. 18-12).⁸⁰ Indacrinone was withdrawn from clinical trials because some individuals developed abnormal liver function test results.

PHARMACOKINETICS

In spite of ethacrynic acid's unique chemical structure and avid reactivity toward various nucleophiles, it has many pharmacological features in common with the sulfamoyl-containing loop diuretics. After oral administration, onset of action is about 30 minutes, and duration of action is 6 to 8 hours. After parenteral administration, onset of action and

duration of action are 3 to 5 minutes and 2 to 3 hours, respectively. Ethacrynic acid is highly bound to plasma proteins (>95%). Ethacrynic acid is handled and excreted predominantly by the kidneys. Very little of the drug is removed from the plasma by glomerular filtration because of its extensive binding to unfiltrable plasma proteins such as albumin. However, the drug is secreted avidly into the luminal fluid of the proximal tubule with the assistance of the OATS (Fig. 18-7).^{65, 81, 82} High luminal fluid concentrations of ethacrynic acid are essential for its diuretic action and ultimate excretion.

Ethacrynic acid is biotransformed by a pathway completely different from that of furosemide or bumetanide. Ethacrynic acid alkylates the thiol group of glutathione *in vivo* (Fig. 18-12; RSH = glutathione), and the resulting conjugate subsequently is converted to the ethacrynic acid-cysteine and ethacrynic acid-*N*-acetylcysteine (the mercapturic acid) conjugates. Ethacrynic acid-cysteine is quite unstable *in vivo* and *in vitro*; it readily releases cysteine and ethacrynic acid. Ethacrynic acid, ethacrynic acid-glutathione, and ethacrynic acid-cysteine are equipotent diuretics because of the aforementioned interconversions.⁷⁶ Approximately two thirds of the ethacrynic acid appears in the urine in the various forms cited; the remaining one third is found in the bile.

SITE AND MECHANISM OF ACTION

Like furosemide and bumetanide, ethacrynic acid

- Blocks reabsorption of up to 30% of the filtered load of Na⁺ at site 2 by inhibiting the 1Na⁺/1K⁺/2Cl⁻ cotransport system located on the luminal membrane of cells in the thick ascending limb of Henle's loop and in the macula densa cells (Fig. 18-4)
- Reaches high levels in luminal fluid because of its active tubular secretion by the OATS in proximal tubular cells
- Blocks the tubuloglomerular feedback mechanism that normally would result in an acute reduction of the GFR when the flow of luminal fluid is increased through the nephron segments possessing the macula densa cells⁸³
- Increases total renal blood flow transiently by enhancing the intrarenal release of vasodilatory prostaglandins⁸⁴
- Induces a transient redistribution of intrarenal blood flow, which contributes in a positive way toward the magnitude of the diuresis⁸⁵

Because ethacrynic acid induces a short-term increase in the renal excretion rate of Na⁺, Cl⁻, K⁺, and Ca²⁺, it is a natriuretic, chloruretic, saluretic, kaliuretic, and calciuretic agent.

ADVERSE EFFECTS

Ethacrynic acid may produce all of the adverse effects noted with furosemide and bumetanide except those related to the presence of a sulfamoyl group. Use of ethacrynic acid has waned because it is more ototoxic than furosemide and bumetanide and it produces more serious gastrointestinal effects (i.e., gastrointestinal hemorrhage) than the sulfamoyl-containing loop diuretics. In addition, as with furosemide and bumetanide, serious drug interactions may occur when ethacrynic acid is used concurrently with Li⁺, cardiac glycosides, aminoglycoside antibiotics, or NSAIDs (see drug

tion above of adverse effects of furosemide and bumetanide).

USES

Ethacrynic acid has the indications cited for furosemide and bumetanide. However, when a high-ceiling diuretic is indicated in the treatment of an individual who has a known hypersensitivity to sulfamoyl-containing drugs, ethacrynic acid may be an appropriate substitute.

Miscellaneous Site 2 Diuretics

Three nondiuretic agents are biotransformed to high-ceiling diuretics in vivo by sulfation of their $-OH$ moieties (Fig. 18-13). The sulfated metabolites exert a diuresis by inhibition of the $1Na^+/1K^+/2Cl^-$ cotransport system on the luminal membrane of thick ascending limb cells (Fig. 18-4). These agents include 2-(*p*-fluorophenoxy), 1-(*o*-hydroxy-

phenyl)ethane (CRE 10904)⁸⁶; 2-(aminomethyl)-4-(1,1-dimethylethyl)-4-iodophenol (MK-447)⁸⁷; and 6-chloro-2,3-dihydro-1-(1-oxopropyl)-4(*H*)-quinolinone 4-oxime (M12285).⁸⁸

In each case the sulfated metabolite undergoes active tubular secretion by the OATS in proximal tubular cells and, hence, attains high levels in luminal fluid. The negatively charged sulfate moiety probably binds to the Cl^- -binding site on the luminal membrane-bound $1Na^+/1K^+/2Cl^-$ cotransport system of thick ascending limb and macula densa cells.

In addition, etozoline (only after being hydrolyzed in vivo to ozolinone, a carboxylic acid) and muzolimine possess diuretic activity by virtue of their actions on the transport processes in the cells of the thick ascending limb of Henle's loop. Ozolinone is secreted actively into proximal tubule luminal fluid by the OATS. The high concentrations of ozolinone delivered to the thick ascending limb cells of Henle's

Figure 18-13 ■ Various seemingly unrelated agents that block Na^+ reabsorption in the thick ascending limb of Henle's loop. The precise mechanism of action of muzolimine is unknown. All of the other agents are inactive as such and must be biotransformed to active metabolites before their diuretic activity can be expressed. In each case, like furosemide, bumetanide, torsemide, and ethacrynic acid, the active metabolites have an anionic moiety that may permit binding to the Cl^- -binding site on the $1Na^+/1K^+/2Cl^-$ cotransport system in thick ascending limb cells.

loop inhibit the luminal membrane-bound $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system^{89, 90} (Fig. 18-4). The precise mechanism(s) by which muzolimine exerts a diuresis remains to be determined.⁹¹ It has been suggested, however, that muzolimine inhibits the K^+/Cl^- cotransport system on the basolateral membrane of the thick ascending limb cells, which in turn inhibits the $1\text{Na}^+/1\text{K}^+/2\text{Cl}^-$ cotransport system.⁹² None of these miscellaneous site 2 agents has been marketed in the United States.

SITE 4 DIURETICS: POTASSIUM-SPARING DIURETICS

A negative feature of all of the above-discussed classes of diuretics in current use is that they increase the renal excretion rate of K^+ and thus can induce hypokalemia. Over the years, three chemically distinct diuretics have emerged that increase Na^+ and Cl^- excretion without a concomitant increase in the urinary excretion rate of K^+ . These agents are known as *potassium-sparing diuretics* or *antikaliuretic agents*. Although the K^+ -sparing diuretics are derived from completely different chemical roots, they act at site 4 (though not all by the same mechanism), have similar efficacies and electrolyte excretion patterns, and share certain adverse effects. The K^+ -sparing diuretics include spironolactone (a spiro lactone), triamterene (a 2,4,7-triamino-6-arylpteridine), and amiloride (a pyrazinoylguanidine). A recently approved spiro lactone, eplerenone, is discussed later in this chapter.

Spirolactones, Aldosterone Antagonists

Spironolactone, USP. The structure of spironolactone, 7α -(acetylthio)- 17β -hydroxy-3-oxopregn-4-ene-21-carboxylic acid γ -lactone (Aldactone), is shown in Figure 18-14.

STRUCTURE-ACTIVITY RELATIONSHIPS

In the mid-1950s, it was observed that progesterone inhibited the antinatriuretic and kaliuretic effects of aldosterone, the primary mineralocorticoid in humans.^{93, 94} An intensive effort was launched to develop steroidal derivatives that possessed only the antimineralocorticoid activity of progesterone.⁹⁵⁻⁹⁸ Spironolactone was selected from a host of derivatives for further examination.⁹⁷

PHARMACOKINETICS

Spironolactone is absorbed well after oral administration (bioavailability, >90%), biotransformed rapidly and extensively by the liver (~80%) to canrenone, an active metabolite (Fig. 18-14), bound extensively to plasma proteins (most likely as canrenone), and excreted primarily as metabolites in the urine. Some biliary excretion of metabolites also occurs. Its onset of action is slow (12 to 72 hours),⁹⁹ and its duration of action is quite long (2 to 3 days).⁴¹

SITE AND MECHANISM OF ACTION

Spironolactone inhibits the reabsorption of 2 to 3% of the filtered load of Na^+ at site 4 by competitively inhibiting the actions of aldosterone^{6, 46} (Fig. 18-6). Under normal circum-

Figure 18-14 Aldosterone enhances the passage of Na^+ from the luminal fluid into tubular cells and the passage of intracellular K^+ into the luminal fluid at site 4. Progesterone inhibits these actions of aldosterone but has undesirable hormonal side effects. Spironolactone and canrenone also competitively inhibit the actions of aldosterone at site 4 and are associated with a lower frequency of hormonal side effects.

stances, aldosterone enters the principal cells of the connecting tubule (i.e., the late distal tubule) and the cortical collecting tubule, where it combines with a cytosolic receptor. The complex moves into the nucleus, where it turns on the synthesis of additional quantities of the Na^+/K^+ -ATPase,¹⁰⁰⁻¹⁰¹ and luminal membrane channels that are involved in the exchange of Na^+ for K^+ . Intercalated cell H^+ -ATPase that actively pumps H^+ into the luminal fluid at site 4 is also affected. Thus, passage of luminal fluid Na^+ into, and K^+ and H^+ out of, the connecting tubule cells and the cortical collecting tubule cells is enhanced. Increased intracellular levels of Na^+ elicited by the actions of aldosterone stimulate the basolateral membrane-bound Na^+/K^+ -ATPase.¹¹ Because spironolactone competitively inhibits these actions of aldosterone,¹⁰¹ it enhances water, Na^+ , and Cl^- excretion. Therefore, spironolactone is a natriuretic, chloruretic, saluretic, and antikaliuretic agent. Unlike the other K^+ -sparing diuretics, spironolactone requires the presence of endogenous aldosterone to exert its diuretic action. Because it inhibits the reabsorption of only 2 to 3% of

the filtered load of Na^+ , it (and the site 4 K^+ -sparing diuretics) has relatively low efficacy.

ADVERSE EFFECTS

One might anticipate that inhibition of the exchange of luminal fluid Na^+ for intracellular K^+ and H^+ would lead to retention of the latter two ions in certain individuals. Important adverse effects of spironolactone include hyperkalemia and mild metabolic acidosis, especially in individuals with poor renal function.^{6, 36} Therefore, patients taking spironolactone should be warned not to take K^+ supplements. Caution must also be exercised when administering spironolactone with other drugs, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, and β -adrenergic blockers, that may also evoke increases in $[\text{K}^+]_{\text{plasma}}$. In addition, spironolactone may produce gynecomastia in men and breast tenderness and menstrual disturbances in women because of its residual hormonal activity.¹⁰² Gynecomastia occurs in approximately 6 to 10% of males given 50 mg/day or less and in up to 52% in doses above 150 mg/day. Other adverse effects include minor gastrointestinal symptoms and rashes.^{32, 45}

USES

Spironolactone may be used alone as an extremely mild diuretic to remove edema fluid in individuals with congestive heart failure, cirrhosis of the liver with ascites, or the nephrotic syndrome or as an antihypertensive agent. Its primary use, however, has been in combination with diuretics that act at site 2 or 3 in an attempt to reduce the urinary K^+ loss associated with these latter groups of diuretics.

2,4,7-Triamino-6-arylpteridines

Triamterene, USP. The structure of triamterene, 2,4,7-triamino-6-phenylpteridine (Dyrenum), is shown below.

STRUCTURE-ACTIVITY RELATIONSHIPS

Triamterene is the primary compound selected from a host of synthetic pteridine analogues.¹⁰³ Although it bears a structural resemblance to folic acid and certain dihydrofolate reductase inhibitors, it has little, if any, of their activities.³²

PHARMACOKINETICS

Triamterene is absorbed rapidly but incompletely (30 to 70%) from the gastrointestinal tract,⁴¹ bound to plasma proteins to the extent of about 60%, biotransformed extensively in the liver, and excreted primarily by the biliary route and secondarily via the renal route as unchanged drug (20%) and metabolites (80%). It enters the luminal fluid of the nephrons by glomerular filtration and active tubular secretion in the

proximal tubule. Because it is a weak organic base, it is assumed to be handled by the proximal tubule OCTS³² (Fig. 18-7). Its onset of action following a single oral dose is 2 to 4 hours, and its duration of action is 7 to 9 hours.⁴¹

SITE AND MECHANISM OF ACTION

Triamterene "plugs" the Na^+ channels in the luminal membrane of the principal cells at site 4 and thereby inhibits the electrogenic entry of 2 to 3% of the filtered load of Na^+ into these cells^{6, 11} (Fig. 18-6). As triamterene's action decreases the principal cell concentration of Na^+ , the antiluminal membrane-bound Na^+/K^+ -ATPase activity also decreases. This leads to decreases in the cellular extrusion of Na^+ and the cellular uptake of K^+ . Because the secretion of K^+ and H^+ at site 4 is linked to Na^+ reabsorption, a concomitant reduction in the excretion rate of K^+ and H^+ occurs. *Unlike spironolactone, triamterene's diuretic action does not depend on the presence of aldosterone.* Triamterene, like the other K^+ -sparing diuretics, has a low efficacy and is a mild natriuretic, chloruretic, saluretic, and antikaliuretic agent.

ADVERSE EFFECTS

Like the other K^+ -sparing diuretics whose primary actions are elicited at site 4, triamterene's major adverse effect is hyperkalemia.³⁶ Therefore, patients taking triamterene should be warned not to take K^+ supplements. Caution is also needed when administering triamterene along with other drugs, such as ACE inhibitors, angiotensin II receptor antagonists, and β -adrenergic blockers, that may also give rise to increases in $[\text{K}^+]_{\text{plasma}}$. In addition, it appears to be unique among the K^+ -sparing diuretics in being associated with the formation of renal stones. Approximately 1 of 1,500 individuals taking a triamterene-containing diuretic experiences nephrolithiasis.^{104, 105} The stones consist of triamterene (with or without its metabolite) or triamterene along with calcium oxalate or uric acid. It also may produce nausea, vomiting, leg cramps, and dizziness.³²

USES

Triamterene may be used alone in the treatment of mild edema associated with congestive heart failure or cirrhosis of the liver with ascites, but it should not be given to patients with impaired renal function.¹⁰⁶ It is not to be used alone in the treatment of hypertension.^{46, 106} Its primary use is in combination with hydrochlorothiazide (or other diuretics that act at site 2 or 3) to prevent the hypokalemia associated with the latter diuretics.

Pyrazinoylguanidines

Amiloride Hydrochloride, USP. The structure of amiloride hydrochloride, 3,5-diamino-*N*-(aminoiminomethyl)-6-chloropyrazinecarboxamide monohydrochloride dihydrate (Midamor), is shown below.

STRUCTURE-ACTIVITY RELATIONSHIPS

An extensive screening procedure that examined over 25,000 agents was undertaken in an attempt to discover an antidiuretic agent that did not have overlapping hormonal activity like that of spironolactone.¹⁰⁷ Promising activity was noted with appropriately substituted pyrazinoylguanidines. Optimal diuretic activity in this series is observed when the 6 position is substituted with chlorine, the amino groups in the 3 and 5 positions are unsubstituted, and the guanidino nitrogens are not multiply substituted with alkyl groups. Amiloride emerged as the most active compound in the series.

PHARMACOKINETICS

Amiloride contains the strongly basic guanidine moiety and possesses a pK_a of 8.7. Thus, it exists predominantly as the charged guanidinium ion in the pH range of most body tissues and fluids. It is not surprising that amiloride is absorbed incompletely and erratically (15 to 20%) from the gastrointestinal tract, an event that occurs by passive diffusion of the uncharged form of most drugs. Amiloride is bound to plasma proteins to a moderate degree, is not biotransformed, and is excreted in the urine (20 to 50%) and in the feces (40%). The fecal content may represent unabsorbed drug. Amiloride reaches the luminal fluid by glomerular filtration and active tubular secretion. The proximal tubule OCTS (Fig. 18-7) is involved in the latter process.³² Onset of action occurs within 2 hours after oral administration, and duration of action may extend to 24 hours.⁴¹

SITE AND MECHANISM OF ACTION

Like triamterene, amiloride inhibits the electrogenic entry of 2 to 3% of the filtered load of Na^+ into the principal cells of the connecting tubule and cortical collecting tubule (i.e., site 4) by "plugging" the sodium channels in the luminal membrane (Fig. 18-6). In turn, the driving force for K^+ secretion is reduced or eliminated.^{6, 11, 36} Like triamterene, amiloride does not require the presence of aldosterone to produce diuresis. It induces the urinary loss of Na^+ , Cl^- , and water and, therefore, is a natriuretic, chloruretic, saluretic, and antidiuretic agent, though with low efficacy.

ADVERSE EFFECTS

The major adverse effect of amiloride is hyperkalemia, which also may be observed with the other K^+ -sparing diuretics that act at site 4. Therefore, patients taking amiloride should be warned not to take K^+ supplements. Caution is also needed when administering amiloride along with other drugs, such as ACE inhibitors, angiotensin II receptor antagonists, and β -adrenergic blockers, that may also give rise to increases in $[K^+]_{plasma}$. Nausea, vomiting, diarrhea, and headache may also accompany the use of amiloride.³²

USES

Amiloride may be used alone in the treatment of mild edema associated with congestive heart failure, cirrhosis of the liver with ascites, or the nephrotic syndrome or in the treatment

of hypertension. Its most common use is in combination with diuretics that act at sites 2 or 3, to circumvent the renal loss of K^+ commonly associated with the latter agents.

MISCELLANEOUS DIURETICS

Mannitol, USP. The prototypic osmotic diuretic D-mannitol is a water-soluble, lipid-insoluble, hexahydroxy alcohol. Because of its lack of lipid solubility, mannitol does not diffuse across the gastrointestinal epithelium and must be given by the intravenous route to obtain systemic effects. Once it enters the bloodstream, little, if any, is bound to plasma albumin; its distribution is confined to extracellular fluids, and it is not biotransformed. It enters renal luminal fluid only by glomerular filtration; it is neither secreted nor reabsorbed. The net result of its renal handling is twofold. First, it is excreted primarily by the kidneys; up to 80% of a 100-g intravenous dose appears in the urine within a 3-hour period.⁴¹ Second, high luminal fluid concentrations of mannitol create an osmotic effect, and a great deal of the water in the luminal fluid is retained within the lumens of the nephrons. This osmotic effect prevents the reabsorption of up to 28% of the filtered load of water.⁹⁹ Mannitol, therefore, may be used prophylactically in a hospital setting to keep the nephrons open (i.e., prevent them from collapsing) in an attempt to avoid acute renal failure in certain circumstances. It has also been useful for the reduction of cerebrospinal fluid volume and pressure. Because intravenous solutions of mannitol may expand the extracellular fluid volume, they should not be used in patients with severe renal disease or cardiac decompensation who may not be able to excrete the additional fluid load and may subsequently develop pulmonary edema. Aqueous solutions are available in a range of concentrations for intravenous use. The adult dosage range for the induction of diuresis is from 50 to 200 g/24 hours.

Theophylline. The prototypic xanthine, theophylline, is known to promote a weak diuresis by stimulation of cardiac function and by a direct action on the nephron. Although it is infrequently used as a diuretic, diuresis may be an observed side effect when it is used as a bronchodilator.

EMERGING DEVELOPMENTS IN THE USE OF DIURETICS TO TREAT HYPERTENSION AND CONGESTIVE HEART FAILURE

Although the precise mechanism(s) by which the thiazide, thiazide-like, and loop diuretics lower blood pressure in hypertensive patients is not known, it is thought to involve slight reductions in plasma volume and cardiac output as well as direct relaxation of the vasculature. Over the years, the adverse effects associated with these drugs were considered relatively mild. Recently, however, several of the well-known adverse effects of these drugs have attracted attention because they appear to be more troubling than previously thought. First, diuretic-induced increased K^+ excretion leads not only to varying degrees of hypokalemia, but also to decreased cardiac and skeletal muscle $[K^+]$. Such changes

$m[K^+]$ impair cardiac performance and damage heart, brain, and kidney vessels.¹⁰⁸ Second, diuretic-induced reductions in plasma volume trigger increased sympathetic tone and increased renal secretion of renin and, ultimately, increased plasma levels of angiotensin II. In addition to being a potent vasoconstrictor, angiotensin II stimulates aldosterone secretion. Although the mechanism of aldosterone's actions at site 4 in the nephron have been known for a long time, its extrarenal actions have largely been ignored. Recently, it has been observed that diuretic-induced increased aldosterone levels not only cause changes in electrolyte transport at site 4 with ultimate damaging hypokalemia but also produce effects at extrarenal aldosterone receptors in the vasculature, which lead to vascular damage, and in the heart, which lead to cardiac fibrosis.¹⁰⁹ These observations help to explain why diuretic-induced reductions in blood pressure do not necessarily protect some hypertensive individuals from other cardiovascular problems.

Laragh and Sealey^{108, 110} have amassed clinical evidence that spironolactone, a *nonselective aldosterone antagonist*, when used alone is as effective as the thiazides in treating mild hypertension without inducing hypokalemia or increased secretion of aldosterone. Furthermore, when spironolactone is used in combination with a thiazide, thiazide-like, or loop diuretic, it markedly blunts the renal and extrarenal actions of the elevated levels of aldosterone brought about by these latter diuretics.

In the past, spironolactone has not enjoyed widespread use for several well-documented reasons.^{108, 110} First, its maximal effectiveness is usually not observed for 3 to 5 weeks. Second, its residual hormonal side effects have produced unacceptable rates of gynecomastia in males and menstrual irregularities in females, especially when doses exceeded 50 to 100 mg/day. These hormonal side effects can be largely avoided by giving spironolactone in doses of 12.5 to 25 mg/day.

Eplerenone, a *specific aldosterone antagonist* recently approved by the Food and Drug Administration, appears to have a much lower affinity for androgen and progesterone receptors than spironolactone and a reduced incidence of sexual disturbances.¹⁰⁹ If this finding is confirmed in additional clinical studies, eplerenone or another drug with the specificity of eplerenone may emerge as a very useful agent and improve the treatment of hypertension (and congestive heart failure) when used alone or in combination with other diuretics or ACE inhibitors.

Eplerenone

SUMMARY

The major driving force for the reabsorption of Na^+ at all four Na^+ reabsorption sites is the deficit of intracellular Na^+ created by the activity of the basolateral membrane-bound $Na^+/K^+-ATPase$. In response, the luminal fluid Na^+ moves into the Na^+ -deficient cells by a luminal membrane-bound Na^+ transport system that is unique to each of the four sites. Most diuretics must attain sufficient concentration in luminal fluid to inhibit a luminal membrane-bound Na^+ transport system; this is usually accomplished by a combination of glomerular filtration and active tubular secretion. The chemical structure of a diuretic dictates which of the four Na^+ -transporting sites will be inhibited. The site that is inhibited is one of the major determinants of the efficacy of the diuretic. The historical development of many diuretics has involved molecular modification of the chemical structure of sulfamoyl-containing compounds. This has yielded CA inhibitors, which inhibit the reabsorption of Na^+/HCO_3^- at site 1; the thiazide and thiazide-like diuretics, which inhibit the reabsorption of Na^+/Cl^- at site 3; and the high-ceiling diuretics, which block $Na^+/Cl^-/K^+/Ca^{2+}/Mg^{2+}$ reabsorption at site 2. Diuretic efficacy has increased with the corresponding changes in the site of action of each of the three classes of diuretics. Predictable secondary effects that depend on a diuretic's site of action have also surfaced.

DIURETIC PREPARATIONS⁴¹

Carbonic Anhydrase Inhibitors

Acetazolamide, USP (Diamox, Generic)

Oral: 125-, 250-mg tablets; 500-mg extended-release capsules

Parenteral: 500-mg powder (as the sodium salt)

Dichlorophenamide, USP (Darandide)

Oral: 50-mg tablets

Methazolamide, USP (Neptazane, Generic)

Oral: 25-, 50-mg tablets

Thiazide and Thiazide-Like Diuretics

Acetazolamide, USP (Naturetin)

Oral: 5-, 10-mg tablets

Benzthiazide (Exna, Hydrex)

Oral: 50-mg tablets

Chlorothiazide, USP (Diuril, Generic)

Oral: 250-, 500-mg tablets; 50-mg/mL oral suspension

Parenteral: 500-mg base for injection

Chlorthalidone, USP (Hygroton, Thalitone, Generic)

Oral: 25-, 50-, 100-mg tablets

Clopamide (Aquex, Brinaldix)

Not available in the United States

Clorexolone (Nefrolan)

Not available in the United States

Cyclothiazide (Anhydron)

Oral: 2-mg tablets

Hydrochlorothiazide, USP (Esidrix, HydroDIURIL, Oretic, Generic)

Oral: 25-, 50-, 100-mg tablets; 12.5-mg capsules (Microzide); 10-, 100-mg/mL oral solutions

Hydroflumethiazide, USP (Diucardin, Saluron, Generic)

Oral: 50-mg tablets

Indapamide (Lozol, Generic)

Oral: 1.25-, 2.5-mg tablets

Mefruside (Baycaron)

Not available in the United States

Methyclothiazide, USP (Aquatensen, Enduron, Generic)

Oral: 2.5-, 5-mg tablets

Metolazone

Oral: 2.5-, 5-, 10-mg extended tablets (Diulo, Zaroxolyn); 0.5-mg prompt tablets (Mykrox)

Polythiazide, USP (Renese)

Oral: 1-, 2-, 4-mg tablets

Quinethazone, USP (Hydromox)

Oral: 50-mg tablets

Trichlormethiazide, USP (Metahydrin, Naqua, Generic)

Oral: 2-, 4-mg tablets

Xipamide (Aquaphor, Diurexan)

Not available in the United States

Loop or High-Ceiling Diuretics**Bumetanide, USP (Bumex, Generic)**

Oral: 0.5-, 1-, 2-mg tablets

Parenteral: 0.25 mg/mL for IV or IM use

Ethacrynic Acid, USP (Edecrin)

Oral: 25-, 50-mg tablets

Parenteral: 50-mg (base) for IV use

Furosemide, USP (Lasix, Generic)

Oral: 20-, 40-, 80-mg tablets; 8-, 10-mg/mL oral solution

Parenteral: 10 mg/mL for IV or IM use

Torsemide (Demadex)

Oral: 5-, 10-, 20-, 100-mg tablets

Parenteral: 10 mg/mL for IV use

K⁺-Sparing Diuretics**Amiloride Hydrochloride, USP (Midamor, Generic)**

Oral: 5-mg tablets

Eplerenone (Inspra)

Oral: 25-, 50-, 100-mg tablets

Spironolactone, USP (Aldactone, Generic)

Oral: 25-, 50-, 100-mg tablets

Triamterene (Dyrenium)

Oral: 50-, 100-mg tablets; 50-, 100-mg capsules

Diuretic Combinations**Amiloride/Hydrochlorothiazide, USP (Moduretic, Generic)**

Oral: 5 mg amiloride hydrochloride/50 mg hydrochlorothiazide

Spironolactone/Hydrochlorothiazide, USP (Aldactazide)

Oral:

25 mg spironolactone/25 mg hydrochlorothiazide

50 mg spironolactone/50 mg hydrochlorothiazide

Triamterene/Hydrochlorothiazide, USP (Dyazide, Maxzide)

Oral—capsules:

37.5 mg triamterene/25 mg hydrochlorothiazide (Dyazide)

50 mg triamterene/25 mg hydrochlorothiazide (Generic)

75 mg triamterene/50 mg hydrochlorothiazide (Generid)

Oral—tablets:

37.5 mg triamterene/25 mg hydrochlorothiazide (Maxzide)

75 mg triamterene/50 mg hydrochlorothiazide (Maxzide)

Osmotic Diuretics**Mannitol (Osmitol, Generic)**

Parenteral: 5, 10, 15, 20, 25% for IV use

Cardiovascular Agents

STEPHEN J. CUTLER AND GEORGE H. COCOLAS

The treatment and therapy of cardiovascular disease have undergone dramatic changes since the 1950s. Data show that since 1968 and continuing through the 1990s, there has been a noticeable decline in mortality from cardiovascular disease. The bases for advances in the control of heart disease have been (a) a better understanding of the disease state, (b) the development of effective therapeutic agents, and (c) innovative medical intervention techniques to treat problems of the cardiovascular system.

The drugs discussed in this chapter are used for their action on the heart or other parts of the vascular system, to modify the total output of the heart or the distribution of blood to the circulatory system. These drugs are used in the treatment of angina, cardiac arrhythmias, hypertension, hyperlipidemias, and disorders of blood coagulation. This chapter also includes a discussion of hypoglycemic agents, thyroid hormones, and antithyroid drugs.

ANTIANGINAL AGENTS AND VASODILATORS

Most coronary artery disease conditions are due to deposits of atheromas in the intima of large and medium-sized arteries serving the heart. The process is characterized by an insidious onset of episodes of cardiac discomfort caused by ischemia from inadequate blood supply to the tissues. Angina pectoris (angina), the principal symptom of ischemic heart disease, is characterized by a severe constricting pain in the chest, often radiating from the precordium to the left shoulder and down the arm. The syndrome has been described since 1772 but not until 1867 was amyl nitrite introduced for the symptomatic relief of angina pectoris.¹ It was believed at that time that anginal pain was precipitated by an increase in blood pressure and that the use of amyl nitrite reduced both blood pressure and, concomitantly, the work required of the heart. Later, it was generally accepted that nitrites relieved angina pectoris by dilating the coronary arteries and that changes in the work of the heart were of only secondary importance. We now know that the coronary blood vessels in the atherosclerotic heart already are dilated and that ordinary doses of dilator drugs do not significantly increase blood supply to the heart; instead, anginal pain is relieved by a reduction of cardiac consumption of oxygen.²

Although vasodilators are used in the treatment of angina, a more sophisticated understanding of the hemodynamic response to these agents has broadened their clinical usefulness to other cardiovascular conditions. Because of their ability to

reduce peripheral vascular resistance, vasodilators, including organonitrates, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor–blocking agents, are used to improve cardiac output in some patients with congestive heart failure (CHF).

The coronary circulation supplies blood to the myocardial tissues to maintain cardiac function. It can react to the changing demands of the heart by dilating its blood vessels to provide sufficient oxygen and other nutrients and to remove metabolites. Myocardial metabolism is almost exclusively aerobic, which makes blood flow critical to the support of metabolic processes of the heart. This demand is met effectively by the normal heart because it extracts a relatively large proportion of the oxygen delivered to it by the coronary circulation. The coronary blood flow depends strongly on myocardial metabolism, which in turn is affected by work done by the heart and the efficiency of the heart. The coronary system normally has a reserve capacity that allows it to respond by vasodilation to satisfy the needs of the heart during strenuous activity by the body.

Coronary atherosclerosis, one of the more prevalent cardiovascular diseases, develops with increasing age and may lead to a reduction of the reserve capacity of the coronary system. It most often results in multiple stenosis and makes it difficult for the coronary system to meet adequately the oxygen needs of the heart that occur during physical exercise or emotional duress. Insufficient coronary blood flow (*myocardial ischemia*) in the face of increased oxygen demand produces angina pectoris.

The principal goal in the prevention and relief of angina is to limit the oxygen requirement of the heart so that the amount of blood supplied by the stenosed arteries is adequate. Nitrate esters, such as nitroglycerin, lower arterial blood pressure and, in turn, reduce the work of the left ventricle. This action is produced by the powerful vasodilating effect of the nitrates on the arterial system and, to an even greater extent, on the venous system. The result is reduced cardiac filling pressure and ventricular size. This reduces the work required of the ventricle and decreases the oxygen requirements, allowing the coronary system to satisfy the oxygen demands of myocardial tissue and relieve anginal pain.

Intermediary Myocardial Metabolism

Energy metabolism by heart tissue provides an adequate supply of high-energy phosphate compounds to replace the adenosine triphosphate (ATP) that is continually being consumed in contraction, ion exchange across membranes, and other energy-demanding processes. Because of the high

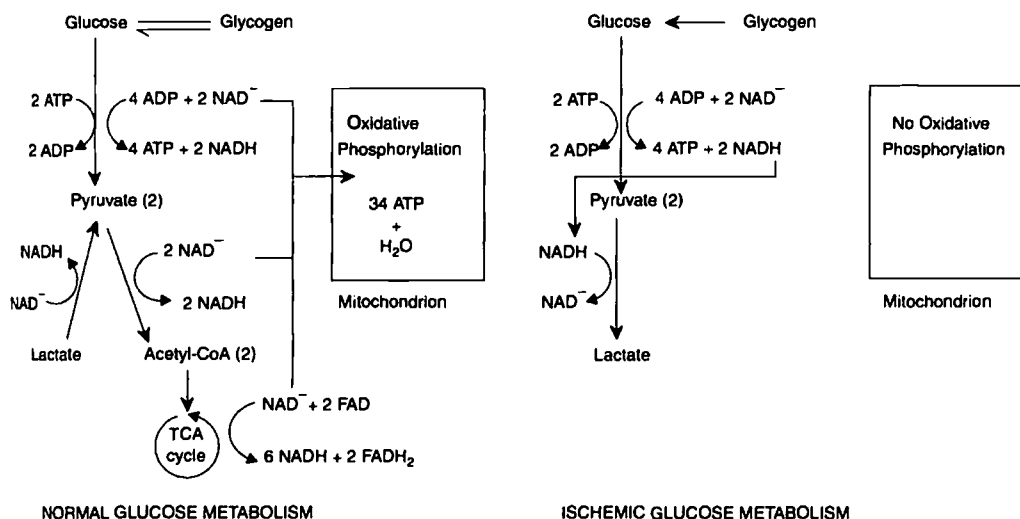

Figure 19-1 ■ Normal and ischemic myocardial metabolism of glucose. A total production of 36 moles of ATP results from the aerobic catabolism of 1 mole of glucose and use of NADH and FADH_2 in the oxidative phosphorylation process in mitochondria. When oxygen is not available, NADH and FADH_2 levels rise and shut off the tricarboxylic acid (TCA) cycle. Pyruvate is converted to lactate. Only 2 moles of ATP are formed from anaerobic catabolism of 1 mole of glucose. (Adapted from Giuliani, E. R., et al.: *Cardiology: Fundamentals and Practice*, 2nd ed. By permission of the Mayo Foundation, Rochester, MN.)

turnover rate of ATP in heart muscle, a correspondingly high rate of ATP production in the mitochondria is required.

Normal myocardial metabolism is aerobic, and the rate of oxygen use parallels the amount of ATP synthesized by the cells.² Free fatty acids (FFAs) are the principal fuel for myocardial tissue, but lactate, acetate, acetoacetate, and glucose are also oxidized to CO_2 and water. A large volume of the myocardial cell consists of mitochondria in which two-carbon fragments from FFA breakdown are metabolized through the Krebs cycle. The reduced flavin and nicotinamide dinucleotides formed by this metabolism are reoxidized by the electron-transport chain because of the presence of oxygen (Fig. 19-1). In the hypoxic or ischemic heart, the lack of oxygen inhibits the electron-transport chain function and causes an accumulation of reduced flavin and nicotinamide coenzymes. As a result, fatty acids are converted to lipids rather than being oxidized. To compensate for this, glucose use and glycogenolysis increase, but the resulting pyruvate cannot be oxidized; instead, it is converted to lactate. A great loss of efficiency occurs as a result of the change of myocardial metabolism from aerobic to anaerobic pathways. Normally, 36 moles of ATP are formed from the oxidation of 1 mole of glucose, but only 2 moles are formed from its glycolysis. This great loss of high-energy stores during hypoxia thus limits the functional capacity of the heart during stressful conditions and is reflected by the production of anginal pain.

Nitrovasodilators

SMOOTH MUSCLE RELAXATION

The contractile activity of all types of muscle (smooth, skeletal) is regulated primarily by the reversible phosphorylation of myosin. Myosin of smooth muscle consists of two heavy chains (MW 200,000 each) that are coiled to produce a filamentous tail. Each heavy chain is associated with two pairs of light chains (MW 20,000 and 16,000) that serve as substrates for calcium- and calmodulin-dependent protein kinases in the contraction process. Together with actin (MW 43,000) they participate in a cascade of biochemical events that are part of the processes of muscle contraction and relaxation (Fig. 19-2).

Cyclic nucleotides, cyclic adenosine monophosphate (cAMP), and, especially, cyclic guanosine monophosphate (cGMP) play important roles in the regulation of smooth muscle tension. cAMP is the mediator associated with the smooth muscle relaxant properties of drugs such as β -adrenergic agonists. It activates the protein kinases that phosphorylate myosin light-chain kinase (MLCK). Phosphorylation of MLCK inactivates this kinase and prevents its action with Ca^{2+} and calmodulin to phosphorylate myosin, which interacts with actin to cause contraction of smooth muscle (Fig. 19-2).

The activity of cGMP in smooth muscle relaxation is affected by exogenous and endogenous agents. It is suggested³ that nitrovasodilators undergo metabolic transformation in

Figure 19-2 ■ Regulation of smooth muscle contraction. Contraction is triggered by an influx of Ca^{2+} . The increase of free Ca^{2+} causes binding to calmodulin (CM). The Ca^{2+} -CM complex binds to myosin light-chain kinase (MLCK) and causes its activation (MLCK*). MLCK* phosphorylates myosin, which combines with actin to produce contraction of smooth muscle. Myosin is dephosphorylated in the presence of myosin phosphatase to cause muscle relaxation. The β agonists activate adenylate cyclase (AC) to raise levels of cAMP, which in turn activates kinases that phosphorylate MLCK, inactivating it to prevent muscle contraction.

vascular smooth muscle cells to form nitric oxide (NO). NO mediates smooth muscle relaxation by activating guanylate cyclase to increase intracellular concentrations of cGMP. cGMP activates protein kinases that can regulate free Ca^{2+} levels in the muscle cell and cause relaxation of smooth muscle by phosphorylating MLCK.

A short-lived free radical gas, NO is widely distributed in the body and plays an important role by its effect through cGMP on the smooth muscle vasculature. It is synthesized in the vascular endothelial cell from the semiessential amino acid L-arginine by NO synthase. After production in the cell, it diffuses to the smooth muscle cell, where it activates the enzyme guanylate cyclase, which leads to an increase in cGMP and then muscle relaxation (Fig. 19-3). Endothelium-derived relaxing factor (EDRF), released from the endothelial cell to mediate its smooth muscle-relaxing properties through cGMP, is identical with NO.

Inhibitors of phosphodiesterases of cAMP and cGMP also cause smooth muscle relaxation. These inhibitors increase cellular levels of cAMP and cGMP by preventing their hy-

drolysis to AMP and GMP, respectively. Drugs such as papaverine (see Chapter 17) and theophylline (see Chapter 18), which relax smooth muscle, do so in part by inhibiting phosphodiesterases.

METABOLISM OF NITROVASODILATORS

After oral administration, organic nitrates are metabolized rapidly by the liver, kidney, lungs, intestinal mucosa, and vascular tissue. Buccal absorption reduces the immediate hepatic destruction of the organic nitrates because only 15% of the cardiac output is delivered to the liver; this allows a transient but effective circulating level of the intact organic nitrate before it is inactivated.⁵

Organic nitrates, nitrites, nitroso compounds, and a variety of other nitrogen-containing substances, such as sodium nitroprusside, for the most part cause their pharmacological effects by generating or releasing NO in situ. In some ways these drugs are viewed as "replacement agents" for the endogenous NO generated by the NO synthase pathway from arginine. The mechanisms by which vasodilatory drugs release NO have become better understood recently. Table 19-1 shows the oxidation state of various nitrosyl compounds that are common in nitrovasodilatory drugs. A common feature of these drugs is that they release nitrogen in the form of NO and contain nitrogen in an oxidation state higher than +3 (as would occur in ammonia, amines, amides, and most biological nitrogen compounds). The nitrogen in NO has an oxidation state of +2. Compounds such as nitroprusside, nitrosoamines, and nitrothiols with oxidation states of +3 release NO nonenzymatically. Although their spontaneous liberation of NO is by an unknown mechanism, it involves only a one-electron reduction, which may occur on exposure of these chemicals to the variety of reducing agents in the tissue of vascular smooth muscle membranes. Organic nitrates such as amyl nitrite react with available thiol groups to form unstable S-nitrosothiols, which rapidly decompose NO by homolytic cleavage of their S-N bond. In mammalian smooth muscle, this will occur almost exclusively with glutathione as the most abundant thiol compound.⁶

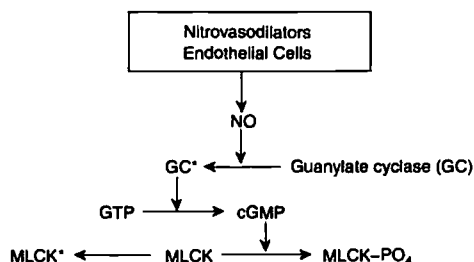

Figure 19-3 ■ Mechanism of nitrovasodilators. Nitric oxide (NO) formed in smooth muscle from nitrovasodilators or from endothelial cells (EDRF) activates guanylate cyclase (GC^*). GC^* activates cGMP-dependent protein kinases that phosphorylate myosin light-chain kinase (MLCK), causing its inactivation and subsequent muscle relaxation (see also Fig. 19-2).

TABLE 19-1 Nitrosyl Vasodilatory Substances and Their Oxidation State

Nitrosyl Compound	Structure	Nitrogen Oxidation State
Nitric oxide	$\text{N}=\text{O}$	+2
Nitrite	$-\text{ONO}$	+3
Nitrate	$-\text{ONO}_2$	+5
Organic nitrite	$\text{R}-\text{O}-\text{N}=\text{O}$	+3
Nitrosothiol	$\text{R}-\text{S}-\text{N}=\text{O}$	+3
Organic nitrate	$\text{R}-\text{O}-\text{NO}_2$	+5
Thionitrate	$\text{R}-\text{S}-\text{NO}_2$	+5
Nitroprusside	$[(\text{CN})_5\text{Fe}-\text{N}=\text{O}]^-$	+3

Reprinted from Harrison, D. G., and Bates, J. M., *Circulation* 87: 1462, 1993, with permission from the American Heart Association.

The pharmacodynamic action of nitroglycerin is preceded by metabolic changes that follow a variety of paths. Bio-transformation of nitroglycerin to the dinitrates and the increase of intracellular cGMP precede vascular relaxation. Sulfhydryl-containing compounds, such as cysteine, react chemically with organic nitrates to form inorganic nitrite ions. The release of NO from an organic nitrate, such as nitroglycerin, appears to occur in a stepwise fashion involving nonenzymatic and enzymatic steps. Because nitroglycerin requires a three-electron reduction to release NO, thiols may be involved in the process. Nitroglycerin may decompose nonenzymatically by interaction with a variety of thiols, such as cysteine or *N*-acetylcysteine, which may be present in tissue, to form a nitrosothiol intermediate before undergoing enzymatic transformation to release NO. Nitroglycerin also readily releases NO by acting on an enzyme system attached to the cellular surface membrane of smooth muscle. The process may include glutathione-*S*-transferases, which convert nitroglycerin to a vasoinactive nitrite, which then may release NO nonenzymatically.⁷

ESTERS OF NITROUS AND NITRIC ACIDS

Inorganic acids, like organic acids, will form esters with an alcohol. Pharmaceutically, the important ones are sulfate, nitrite, and nitrate. Sulfuric acid forms organic sulfates, of which methyl sulfate and ethyl sulfate are examples.

Nitrous acid (HNO_2) esters may be formed readily from an alcohol and nitrous acid. The usual procedure is to mix sodium nitrite, sulfuric acid, and the alcohol. Organic nitrites are generally very volatile liquids that are only slightly soluble in water but soluble in alcohol. Preparations containing water are very unstable because of hydrolysis.

The organic nitrates and nitrites and the inorganic nitrites have their primary utility in the prophylaxis and treatment of angina pectoris. They have a more limited application in treating asthma, gastrointestinal spasm, and certain cases of migraine headache. Their application may be regarded as causal therapy, since they act by substituting an endogenous factor, the production or release of NO, which may be impaired under pathophysiological circumstances associated with dysfunction of the endothelial tissue. Nitroglycerin (glyceryl trinitrate) was one of the first members of this group to be introduced into medicine and remains an important member of the group. Varying the chemical structure of the organic nitrates yields differences in speed of onset, duration of action, and potency (Table 19-2). Although the number of nitrate ester groups may vary from two to six or more, depending on the compound, there is no direct relationship between the number of nitrate groups and the level of activity.

It appears that the higher the oil/water partition coefficient of the drug, the greater the potency. The orientation of the groups within the molecule also may affect potency. Lipophilicity of the nitrogen oxide-containing compound produces a much longer response of vasodilatory action. The highly lipophilic ester nitroglycerin permeates the cell membrane, allowing continual formation of NO within the cell. The same effect appears to occur for sodium nitroprusside, nitroso compounds, and other organic nitrate and nitrite esters.⁴

ANTIANGINAL ACTION OF NITROVASODILATORS

The action of short-acting sublingual nitrates in the relief of angina pectoris is complex. Although the sublingual nitrates relax vascular smooth muscle and dilate the coronary arteries of normal humans, there is little improvement of coronary blood flow when these chemicals are administered to individuals with coronary artery disease. Nitroglycerin is an effective antianginal agent because it causes redistribution of coronary blood flow to the ischemic regions of the heart and reduces myocardial oxygen demand. This latter effect

TABLE 19-2 Relationship Between Speed and Duration of Action of Sodium Nitrite and Certain Inorganic Esters

Compound	Action Begins (minutes)	Maximum Effect (minutes)	Duration of Action (minutes)
Amyl nitrite	0.25	0.5	1
Nitroglycerin	2	8	30
Isosorbide dinitrate	3	15	60
Sodium nitrite	10	25	60
Erythryl tetranitrate	15	32	180
Pentaerythritol tetranitrate	20	70	330

is produced by a reduction of venous tone resulting from the nitrate vasodilating effect and a pooling of blood in the peripheral veins, which results in a reduction in ventricular volume, stroke volume, and cardiac output. It also causes reduction of peripheral resistance during myocardial contractions. The combined vasodilatory effects cause a decrease in cardiac work and reduce oxygen demand.

PRODUCTS

Amyl Nitrite, USP. Amyl nitrite, isopentyl nitrite $[(CH_3)_2CHCH_2CH_2ONO]$, is a mixture of isomeric amyl nitrites but is principally isoamyl nitrite. It may be prepared from amyl alcohol and nitrous acid by several procedures. Usually, amyl nitrite is dispensed in ampul form and used by inhalation or orally in alcohol solution. Currently, it is recommended for treating cyanide poisoning; although not the best antidote, it does not require intravenous injections.

Amyl nitrite is a yellowish liquid with an ethereal odor and a pungent taste. It is volatile and inflammable at room temperature. Amyl nitrite vapor forms an explosive mixture in air or oxygen. Inhalation of the vapor may involve definite explosion hazards if a source of ignition is present, as both room and body temperatures are within the flammability range of amyl nitrite mixtures with either air or oxygen. It is nearly insoluble in water but is miscible with organic solvents. The nitrite also will decompose into valeric acid and nitric acid.

Nitroglycerin. Glyceryl trinitrate is the trinitrate ester of glycerol and is listed as available in tablet form in the *United States Pharmacopoeia*. It is prepared by carefully adding glycerin to a mixture of nitric and fuming sulfuric acids. This reaction is exothermic, and the reaction mixture must be cooled to between 10 and 20°C.

The ester is a colorless oil, with a sweet, humming taste. It is only slightly soluble in water, but it is soluble in organic solvents.

Nitroglycerin	Nitrogard
Transmucosal	Nitrolingual
Translingual	Nitrobid
Oral	Nitroglyn
Ointment	Nitroglyn
Injection	Nitrobid IV
	Tridil
Transdermal	Nitrodur
	Nitrodisc
	Minitran
	Deponit
	Transderm-Nitro

Nitroglycerin is used extensively as an explosive in dynamite. A solution of the ester, if spilled or allowed to evaporate, will leave a residue of nitroglycerin. To prevent an explosion of the residue, the ester must be decomposed by the addition of alkali. Even so, the material dispensed is so dilute that the risk of explosions does not exist. It has a strong

vasodilating action and, because it is absorbed through the skin, is prone to cause headaches among workers associated with its manufacture. This transdermal penetration is why nitroglycerin is useful in a patch formulation. In medicine, it has the action typical of nitrites, but its action develops more slowly and is of longer duration. Of all the known coronary vasodilatory drugs, nitroglycerin is the only one capable of stimulating the production of coronary collateral circulation and the only one able to prevent experimental myocardial infarction by coronary occlusion.

Previously, the nitrates were thought to be hydrolyzed and reduced in the body to nitrites, which then lowered the blood pressure. This is not true, however. The mechanism of vasodilation of nitroglycerin through its formation of NO is described above.

Nitroglycerin tablet instability was reported in molded sublingual tablets.⁸ The tablets, although uniform when manufactured, lost potency both because of volatilization of nitroglycerin into the surrounding materials in the container and intertablet migration of the active ingredient. Nitroglycerin may be stabilized in molded tablets by incorporating a "fixing" agent such as polyethylene glycol 400 or polyethylene glycol 4000.⁹ In addition to sublingual tablets, the drug has been formulated into an equally effective lingual aerosol for patients who have problems with dissolution of sublingual preparations because of dry mucous membranes. Transdermal nitroglycerin preparations appear to be less effective than other long-acting nitrates, as absorption from the skin is variable.

Diluted Erythrityl Tetranitrate, USP. Erythritol tetranitrate, 1,2,3,4-butanetetrol, tetranitrate (*R*, S**)-(Cardilate), is the tetranitrate ester of erythritol and nitric acid. It is prepared in a manner analogous to that used for nitroglycerin. The result is a solid, crystalline material. This ester is also very explosive and is diluted with lactose or other suitable inert diluents to permit safe handling; it is slightly soluble in water and soluble in organic solvents.

Erythrityl Tetranitrate
(Cardilate)

Erythrityl tetranitrate requires slightly more time than nitroglycerin to produce its effect, which is of longer duration. It is useful when mild, gradual, and prolonged vascular dilation is warranted. The drug is used in the treatment of, and as prophylaxis against, attacks of angina pectoris and to reduce blood pressure in arterial hypertension.

Erythrityl tetranitrate produces a reduction of cardiac preload as a result of pooling blood on the venous side of the circulatory system by its vasodilating action. This action results in a reduction of blood pressure on the arterial side during stressful situations and is an important factor in preventing the precipitation of anginal attacks.

Diluted Pentaerythritol Tetranitrate, USP. Pentaerythritol tetranitrate, 2,2-bis(hydroxymethyl)-1,3-propanediol tetranitrate (Peritrate, Pentritol), is a white, crystalline material with a melting point of 140°C. It is insoluble in water, slightly soluble in alcohol, and readily soluble in acetone. The drug is a nitric acid ester of the tetrahydric alcohol pentaerythritol and is a powerful explosive. Accordingly, it is diluted with lactose, mannitol, or other suitable inert diluents to permit safe handling.

It relaxes smooth muscle of smaller vessels in the coronary vascular tree. Pentaerythritol tetranitrate is used prophylactically to reduce the severity and frequency of anginal attacks and is usually administered in sustained-release preparations to increase its duration of action.

Diluted Isosorbide Dinitrate, USP. Isosorbide dinitrate, 1,4:3,6-dianhydro-D-glucitol dinitrate (Isordil, Sorbitrate), occurs as a white, crystalline powder. Its water solubility is about 1 mg/mL.

Isosorbide dinitrate, as a sublingual or chewable tablet, is effective in the treatment or prophylaxis of acute anginal attacks. When it is given sublingually, the effect begins in about 2 minutes, with a shorter duration of action than when it is given orally. Oral tablets are not effective in acute anginal episodes; the onset of action ranges from 15 to 30 minutes. The major route of metabolism involves denitration to isosorbide 5-mononitrate. This metabolite has a much longer half-life than the parent isosorbide dinitrate. As such, this particular metabolite is marketed in a tablet form that has excellent bioavailability with much less first-pass metabolism than isosorbide dinitrate.

Calcium Antagonists

EXCITATION-CONTRACTION COUPLING MUSCLE

Stimulation of the cardiac cell initiates the process of excitation, which has been related to ion fluxes through the cell membrane. Depolarization of the tissue in the atria of the

Figure 19-4 ■ Diagrammatic representation of the membrane action potential, as recorded from a Purkinje fiber, and an electrogram recorded from an isolated ventricular fiber. The membrane resting potential is 90 mV relative to the exterior of the fiber. At the point of depolarization, there is a rapid change (phase 0) to a more positive value. 0-4 indicate the phases of depolarization and repolarization. Note that phases 0 and 3 of the membrane action potential correspond in time to the inscription of the QRS and T waves, respectively, of the local electrogram.

heart is mediated by two inwardly directed ionic currents. When the cardiac cell potential reaches its threshold, ion channels in the membrane are opened, and Na^+ enters the cell through ion channels. These channels give rise to the fast sodium current that is responsible for the rapidly rising phase, phase 0, of the ventricular action potential (Fig. 19-4). The second current is caused by the slow activation of an L-type Ca^{2+} ion channel that allows the movement of Ca^{2+} into the cell. This "slow channel" contributes to the maintenance of the plateau phase (phase 2) of the cardiac action potential. We now understand that the Ca^{2+} that enters with the action potential initiates a second and larger release of Ca^{2+} from the sarcoplasmic reticulum in the cell. This secondary release of Ca^{2+} is sufficient to initiate the contractile process of cardiac muscle.

Contraction of cardiac and other muscle occurs from a reaction between actin and myosin. In contrast to smooth vascular muscle, the contractile process in cardiac muscle involves a complex of proteins (troponins I, C, and T and tropomyosin) attached to myosin, which modulates the interaction between actin and myosin. Free Ca^{2+} ions bind to troponin C, uncovering binding sites on the actin molecule and allowing interaction with myosin, causing contraction of the muscle. The schematic diagram in Figure 19-5 shows the sequence of events.¹⁰ Contraction of vascular smooth muscle, like that of cardiac muscle, is regulated by the concentration of cytoplasmic Ca^{2+} ions. The mechanism by which the contraction is effected, however, includes a calcium- and calmodulin-dependent kinase as opposed to a Ca^{2+} -sensitive troponin-tropomyosin complex (Fig. 19-2). The activating effect depends on a different type of reaction. The elevated free cytosolic Ca^{2+} in vascular smooth muscle cells binds to a high-affinity binding protein, calmodulin.

ION CHANNELS AND CALCIUM

Calcium ions play an important role in the regulation of many cellular processes, such as synaptic transmission and

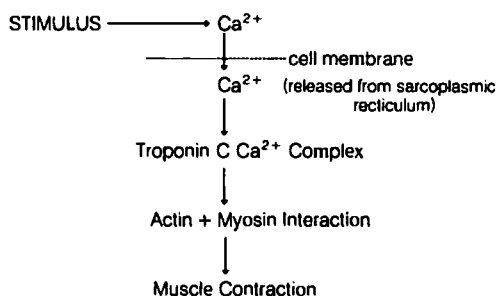

Figure 19-5 ■ Sequence of events showing excitation-contraction coupling in cardiac muscle.

muscle contraction. The role of calcium in these cellular functions is as a second messenger, for example, regulating enzymes and ion channels. The entry of extracellular Ca^{2+} into the cytosol of myocardial cells and the release of Ca^{2+} from intracellular storage sites is important for initiating contractions of the myocardium. Normally, the concentration of Ca^{2+} in the extracellular fluid is in the millimolar range, whereas the intracellular concentration of free Ca^{2+} is less than 10^{-7} M, even though the total cellular concentration may be 10^{-3} M or higher. Most of the Ca^{2+} is stored within intracellular organelles or tightly bound to intracellular proteins. The free Ca^{2+} needed to satisfy the requirements of a contraction resulting from a stimulus may result from activation of calcium channels on the cell membrane and/or the release of calcium from bound internal stores. Each of these methods of increasing free cytosolic Ca^{2+} involves channels that are selective for the calcium ion. Calcium channel blockers reduce or prevent the increase of free cytosolic calcium ions by interfering with the transport of calcium ions through these pores.

Calcium is one of the most common elements on earth. Most calcium involved in biological systems occurs as hydroxyapatite, a static, stabilizing structure like that found in bone. The remaining calcium is ionic (Ca^{2+}). Ionic calcium functions as a biochemical regulator, more often within the cell. The importance of calcium ions to physiological functions was realized first by Ringer, who observed in 1883 the role of Ca^{2+} in cardiac contractility.

The ionic composition of the cytosol in excitable cells, including cardiac and smooth muscle cells, is controlled to a large extent by the plasma membrane, which prevents the free movement of ions across this barrier. Present in the membranes are ion-carrying channels that open in response to either a change in membrane potential or binding of a ligand. Calcium-sensitive channels include (a) Na^+ to Ca^{2+} exchanger, which transports three Na^+ ions in return for one Ca^{2+} ; (b) a voltage-dependent Ca^{2+} channel, which provides the route for entry of Ca^{2+} for excitation and contraction in cardiac and smooth muscle cells and is the focus of the channel-blocking agents used in medicine; and (c) receptor-operated Ca^{2+} channels mediated by ligand binding to membrane receptors as in the action of epinephrine on the α -adrenergic receptor. The membrane of the sarcolemma within the cell also has ion-conducting channels that facili-

tate movement of Ca^{2+} ions from storage loci in the sarcoplasmic reticulum.

Four types of calcium channels, differing in location and function, have been identified: (a) L type, located in skeletal, cardiac, and smooth muscles, causing contraction of muscle cells; (b) T type, found in pacemaker cells, causing Ca^{2+} entry, inactivated at more negative potentials and more rapidly than the L type; (c) N type, found in neurons and acting in transmitter release; and (d) P type, located in Purkinje cells but whose function is unknown at this time.

Calcium antagonists act only on the L-type channel to produce their pharmacological effects. The L channels are so called because once the membrane has been depolarized, their action is long lasting. Once the membrane has been depolarized, L channels must be phosphorylated to open. Although there are similarities between L-type calcium channels that exist in cardiac and smooth muscle, there are distinct differences between the two. Cardiac L channels are activated through β -adrenergic stimulation via a cAMP-dependent phosphorylation process,¹¹ while L channels in smooth muscle may be regulated by the inositol phosphate system linked to G-protein-coupled, receptor-linked phospholipase C activation.¹²

CALCIUM CHANNEL BLOCKERS

The L-type calcium channel, acted on by calcium channel blockers, consists of five different subunits, designated α_1 , α_2 , β , γ , and δ . The α_1 subunit provides the central pore of the channel (Fig. 19-6). Calcium channel blockers can be divided conveniently into the three different chemical classes of the prototype drugs that have been used: phenylalkylamines (verapamil), 1,4-dihydropyridines (nifedipine), and benzothiazepines (diltiazem). These prototype compounds sometimes are termed the "first generation" of calcium channel blockers because two of the groups of drug classes have been expanded by the introduction of a "second" generation of more potent analogues (Table 19-3).

The specific Ca^{2+} channel antagonists verapamil, nifedipine, and diltiazem interact at specific sites on the calcium channel protein. These blockers do not occlude the channel physically but bind to sites in the channel, as they can promote both channel activation and antagonism. Affinity for binding sites on the channel varies, depending on the state of the channel. The channel can exist in either an open (O), resting (R), or inactivated (I) state, and the equilibrium between them is determined by stimulus frequency and mem-

Figure 19-6 ■ Schematic representation of an L-type Ca^{2+} channel.

TABLE 19-3 First- and Second-Generation Calcium Channel Blockers

Chemical Classification	First Generation	Second Generation
Phenylalkylamines	Verapamil	Anipamil Bepridil
1,4-Dihydropyridine	Nifedipine	Amlodipine Felodipine Isradipine Nicardipine Nimodipine
Benzothiazepine	Diltiazem	—

brane potential (Fig. 19-7). Verapamil and diltiazem do not bind to a channel in the resting state, only after the channel has been opened. They are ionized, water-soluble Ca^{2+} -entry blockers that reach their binding sites by the hydrophilic pathway when the channel is open. Verapamil and diltiazem are use dependent (i.e., their Ca^{2+} -blocking activity is a function of the frequency of contractions). An increase in contraction frequency causes a reduction, rather than an augmentation, of contractions. Nifedipine is a neutral molecule at physiological pH and can cause interference with the Ca^{2+} in the open or closed state. In the closed state, nifedipine can traverse the phospholipid bilayer to reach its binding site because of its lipid solubility.

CARDIOVASCULAR EFFECTS OF CALCIUM ION CHANNEL BLOCKERS

All Ca^{2+} antagonists yet developed are vasodilators. Vasodilation is due to the uncoupling of the contractile mechanism of vascular smooth muscle, which requires Ca^{2+} . Coronary artery muscle tone is reduced in healthy humans but is particularly pronounced in a condition of coronary spasm. Peripheral arteriole resistance is reduced more than venous beds. The vasodilatory effect of these drugs is the basis for their use in the control of angina and hypertension.¹³

Although verapamil, nifedipine, and diltiazem can cause vasodilation, they are not equally effective at blocking the Ca^{2+} channels found in various tissues. The phenylalkylamine verapamil and the benzothiazepine diltiazem have both cardiac and vascular actions. These drugs have antiar-

rhythmic, antianginal, and antihypertensive activity. They depress the cardiac neural network, and so slow sinus node automaticity, prolong atrioventricular (AV) nodal conduction, and depress myocardial contractility, as well as reduce peripheral vascular resistance to prevent a coronary vascular spasm. Nifedipine and other 1,4-dihydropyridines are more effective at causing vasodilation than affecting pacemaker and tension responses in the heart. This is especially important because selectivity occurs as a consequence of disease states. Hypertensive smooth muscle is more sensitive to Ca^{2+} channel blockers than is normotensive tissue.¹⁴ This makes verapamil and diltiazem more useful in ischemic conditions, as they have a more profound effect on cardiac muscle calcium channels.¹⁵

The inhibition of Ca^{2+} influx into cardiac tissue by Ca^{2+} antagonists is also the basis for the use of these drugs as antiarrhythmic agents. The Ca^{2+} channel blockers dampen Ca^{2+} -dependent automaticity in the regular pacemaker cells in the sinoatrial (SA) node and depress the origination of ectopic foci. Calcium antagonists can block reentry pathways in myocardial tissue, an integral component of arrhythmias. Numerous side effects in the heart, such as bradycardia, decreased cardiac contractility, and reduced AV conduction, are traced to Ca^{2+} channel-blocking activity.

PRODUCTS

Verapamil. Verapamil, 5-[3,4-dimethoxyphenethyl]-methylamino]-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile (Calan, Isoptin), was introduced in 1962 as a coronary vasodilator and is the prototype of the Ca^{2+} antagonists used in cardiovascular diseases. It is used in the treatment of angina pectoris, arrhythmias from ischemic myocardial syndromes, and supraventricular arrhythmias.

Verapamil's major effect is on the slow Ca^{2+} channel. The result is a slowing of AV conduction and the sinus rate. This inhibition of the action potential inhibits one limb of the reentry circuit believed to underlie most paroxysmal supraventricular tachycardias that use the AV node as a reentry point. It is categorized as a class IV antiarrhythmic drug (see "Classes of Antiarrhythmic Drugs" below). Hemodynamically, verapamil causes a change in the preload, afterload, contractility, heart rate, and coronary blood flow. The drug reduces systemic vascular resistance and mean blood pressure, with minor effects on cardiac output.

Verapamil is a synthetic compound possessing slight structural similarity to papaverine. It can be separated into its optically active isomers, of which the levorotatory enantiomer is the most potent. It is absorbed rapidly after oral administration. The drug is metabolized quickly and, as a result, has low bioavailability. The liver is the main site of first-pass metabolism, forming several products. The preferential metabolic step involves N-dealkylation, followed by O-demethylation, and subsequent conjugation of the product before elimination. The metabolites have no significant biological activity. Verapamil has an elimination half-life of approximately 5 hours.

Figure 19-7 ■ Schematic representation of an ion channel existing in an equilibrium of resting (R), open (O), and inactivated (I) states.

Figure 19-8 ■ Biotransformations of diltiazem.

The route traveled by a Ca^{2+} channel blocker, such as verapamil, to its receptor site parallels that observed with many local anesthetic-like antiarrhythmic agents. It is believed that verapamil, like most of the Ca^{2+} channel blockers, crosses the cell membrane in an uncharged form to gain access to its site of action on the intracellular side of the membrane. Data show a greater affinity of verapamil and other Ca^{2+} channel blockers to the inactivated state of the channel.¹⁶

Diltiazem Hydrochloride. Diltiazem hydrochloride, (+)-*cis*-3-(acetox)-5-[2(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5H)-one hydrochloride (Cardizem), was developed and introduced in Japan as a cardiovascular agent to treat angina pectoris. It was observed to dilate peripheral arteries and arterioles. The drug increases myocardial oxygen supply by relieving coronary

artery spasm and reduces myocardial oxygen demand by decreasing heart rate and reducing overload. Diltiazem hydrochloride is used in patients with variant angina. The drug has electrophysiological properties similar to those of verapamil and is used in clinically similar treatment conditions as an antiarrhythmic agent, but it is less potent.

The drug is absorbed rapidly and almost completely from the digestive tract. It reaches peak plasma levels within 1 hour after administration in gelatin capsules. Oral formulations on the market are sustained-release preparations providing peak plasma levels 3 to 4 hours after administration.

Diltiazem hydrochloride is metabolized extensively after oral dosing, by first-pass metabolism. As a result, the bioavailability is about 40% of the administered dose. The drug undergoes several biotransformations, including deacetylation, oxidative O- and N-demethylations, and conjugation of the phenolic metabolites. Of the various metabolites (Fig 19-8), only the primary metabolite, deacetyldiltiazem, is pharmacologically active. Deacetyldiltiazem has about 40 to 50% of the potency of the parent compound.

Nifedipine. Nifedipine, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylate dimethyl ester (Adalat, Procardia), is a dihydropyridine derivative that bears no structural resemblance to the other calcium antagonists. It is not a nitrate, but its nitro group is essential for its antianginal effect.¹⁷ As a class, the dihydropyridines possess a central pyridine ring that is partially saturated. To this, positions 2 and 6 are substituted with an alkyl group that may play a role in the agent's duration of action. Also, positions 3 and 4 are carboxylic groups that must be protected with an ester functional group. Depending on the type of ester used at these sites, the agent can be distributed to various parts of the body. Finally, position 4 requires an aromatic substitution possessing an electron-withdrawing group (i.e., Cl or NO_2) in the *ortho* and/or *meta* position.

The prototype of this class, nifedipine, has potent peripheral vasodilatory properties. It inhibits the voltage-dependent calcium channel in the vascular smooth muscle but has little or no direct depressant effect on the SA or AV nodes, even though it inhibits calcium current in normal and isolated

Figure 19-9 ■ Nifedipine metabolism.

cardiac tissues. Nifedipine is more effective in patients whose anginal episodes are due to coronary vasospasm and is used in the treatment of vasospastic angina as well as classic angina pectoris. Because of its strong vasodilatory properties, it is used in selected patients to treat hypertension.

Nifedipine is absorbed efficiently on oral or buccal administration. A substantial amount (90%) is protein bound. Systemic availability of an oral dose of the drug may be approximately 65%. Two inactive metabolites are the major products of nifedipine metabolism and are found in equilibrium with each other (Fig. 19-9). Only a trace of unchanged nifedipine is found in the urine.¹⁸

Amlodipine. Amlodipine, 2-[(2-aminoethoxy)methyl]-4-(2-chlorophenyl)-1,4-dihydro-6-methyl-3,5-pyridinedicarboxylic acid 3-ethyl 5-methyl ester (Norvasc), is a second-generation 1,4-dihydropyridine derivative of the prototypical molecule nifedipine. Like most of the second-generation dihydropyridine derivatives, it has greater selectivity for the vascular smooth muscle than myocardial tissue, a longer half-life (34 hours), and less negative inotropy than the prototypical nifedipine. Amlodipine is used in the treatment of chronic stable angina and in the management of mild-to-moderate essential hypertension. It is marketed as the benzenesulfonic acid salt (besylate).

Felodipine. Felodipine, 3,5-pyridinedicarboxylic acid, 4-(2,3-dichlorophenyl)-1,4-dihydro-2,6-dimethyl-, ethyl methyl ester (Plendil), is a second-generation dihydropyridine channel blocker of the nifedipine type. It is more selective for vascular smooth muscle than for myocardial tissue and serves as an effective vasodilator. The drug is used in the treatment of angina and mild-to-moderate essential hypertension. Felodipine, like most of the dihydropyridines, exhibits a high degree of protein binding and has a half-life ranging from 10 to 18 hours.

Isradipine. Isradipine, 4-(4-benzofuran-2-yl)-1,4-dihydro-2,6-dimethyl-3,5-pyridinedicarboxylic acid methyl 1-methylethyl ester (DynaCirc), is another second-generation dihydropyridine-type channel blocker. This drug, like the other second-generation analogues, is more selective for vascular smooth muscle than for myocardial tissue. It is effective in the treatment of stable angina, reducing the frequency of anginal attacks and the need to use nitroglycerin.

Nicardipine Hydrochloride. Nicardipine hydrochloride, 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylic acid methyl 2-[methyl(phenylmethyl)amino]ethyl ester hydrochloride (Cardene), is a more potent vasodilator of the systemic, coronary, cerebral, and renal vasculature and has been used in the treatment of mild, moderate, and severe hypertension. The drug is also used in the management of stable angina.

Nimodipine. Nimodipine, 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylic acid 2-methoxyethyl 1-methylethyl ester (Nimotop), is another dihydropyridine calcium channel blocker but differs in that it dilates the cerebral blood vessels more effectively than do the other dihydropyridine derivatives. This drug is indicated for treatment of subarachnoid hemorrhage-associated neurological deficits.

Nisoldipine. In vitro studies show that the effects of nisoldipine, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylic acid methyl 2-methylpropyl ester (Sular), on contractile processes are selective, with greater potency on vascular smooth muscle than on cardiac muscle.

Nisoldipine is highly metabolized, with five major metabolites identified. As with most of the dihydropyridines, the cytochrome P-450 (CYP) 3A4 isozyme is mainly responsible for the metabolism of nisoldipine. The major biotransformation pathway appears to involve the hydroxylation of the isobutyl ester side chain. This particular metabolite has approximately 10% of the activity of the parent compound.

Nitrendipine. Nitrendipine, 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylic acid methyl ethyl

ester (Baypress), is a second-generation dihydropyridine channel blocker of the nifedipine type. It is more selective for vascular smooth muscle than for myocardial tissue and serves as an effective vasodilator. The drug is used in the treatment of mild-to-moderate essential hypertension.

Bepridil Hydrochloride. Bepridil hydrochloride, β [(2-methylpropoxy)methyl]-N-phenyl-N-(phenylmethyl)-1-pyrrolidineethylamine hydrochloride (Vascor), is a second-generation alkylamine-type channel blocker, structurally unrelated to the dihydropyridines. Its actions are less specific than those of the three prototypical channel blockers, verapamil, diltiazem, and nifedipine. In addition to being a Ca^{2+} channel blocker, it inhibits sodium flow into the heart tissue and lengthens cardiac repolarization, causing bradycardia. Caution should be used if it is given to a patient with hypokalemia. Bepridil hydrochloride is used for stable angina. The drug has a half-life of 33 hours and is highly bound to protein (99%).

Antithrombotic Agents

Platelet activation and platelet aggregation play an important role in the pathogenesis of thromboses. These, in turn, play an important role in unstable angina, myocardial infarction, stroke, and peripheral vascular thromboses. Since many cardiovascular diseases are associated with platelet activation, many agents possessing antiplatelet or antithrombotic effects have been investigated. This has revolutionized cardiovascular medicine, in which vascular stenting or angioplasty can be used without compromising normal hemostasis or wound healing. Although most of these agents act by different mechanisms, many of the newer agents are being developed to antagonize the GPIIb/IIIa receptors of platelets.

Aspirin. Aspirin, acetylsalicylic acid, has an inhibitory effect on platelet aggregation not only because of its ability to inhibit cyclooxygenase but also because of its ability to acetylate the enzyme. Aspirin irreversibly inhibits cyclooxygenase (COX) (prostaglandin H synthase), which is the enzyme involved in converting arachidonate to prostaglandin

G₂ and ultimately thromboxane 2, an inducer of platelet aggregation. Aspirin's mechanism of action includes not only the inhibition in the biosynthesis of thromboxane 2, but also its ability to acetylate the serine residue (529) in the polypeptide chain of platelet prostaglandin H synthetase-1. This explains why other nonsteroidal anti-inflammatory agents that are capable of inhibiting the COX enzyme do not act as antithrombotics—they aren't capable of acetylating this enzyme. Since platelets cannot synthesize new enzymes, aspirin's ability to acetylate COX lasts for the life of the platelet (7 to 10 days) and is, thus, irreversible.

Aspirin

Dipyridamole. Dipyridamole, 2,2',2'',2'''-[(4,8-di-1-piperidinylpyrimido[5,4-*d*]pyrimidine-2,6-diyl)dinitrilo]tetrakisethanol (Persantine), may be used for coronary and myocardial insufficiency. Its biggest use today, however, is as an antithrombotic in patients with prosthetic heart valves. It is a bitter, yellow, crystalline powder, soluble in dilute acids, methanol, or chloroform. A formulation containing dipyridamole and aspirin (Aggrenox) is currently being marketed as an antithrombotic.

Dipyridamole is a long-acting vasodilator. Its vasodilating action is selective for the coronary system; it is indicated for long-term therapy of chronic angina pectoris. The drug also inhibits adenosine deaminase in erythrocytes and interferes with the uptake of the vasodilator adenosine by erythrocytes. These actions potentiate the effect of prostacyclin (PGI₂), which acts as an inhibitor to platelet aggregation.

Clopidogrel. Clopidogrel, methyl (+)-(*S*)- α -(2-chlorophenyl)-6,7-dihydrothieno[3,2-*c*]pyridine-5(4*H*)-acetate sulfate (Plavix), is useful for the preventative management of secondary ischemic events, including myocardial infarction, stroke, and vascular deaths. It may be classified as a thienopyridine because of its heterocyclic system. Several agents

possessing this system have been evaluated as potential anti-thrombotic agents. These agents have a unique mechanism, in that they inhibit the purinergic receptor located on platelets. Normally, nucleotides act as agonists on these receptors, which include the P2Y type. Two P2Y receptor subtypes (P2Y₁ and P2Y₂) found on platelets, when stimulated by ADP, cause platelet aggregation. Clopidogrel acts as an antagonist to the P2Y₂ receptor. It is probably a prodrug that requires metabolic activation, since *in vitro* studies do not interfere with platelet aggregation. Although platelet aggregation is not normally seen in the first 8 to 11 days after administration to a patient, the effect lasts for several days after the drug therapy is discontinued. Unlike other thienopyridines currently used, clopidogrel does not seriously reduce the number of white cells in the blood, and therefore, routine monitoring of the white blood cell count is not necessary during treatment.

Clopidogrel
(Plavix)

Ticlopidine. Ticlopidine, 5-[(2-chlorophenyl)methyl]-4,5,6,7-tetrahydrothieno [3,2-*c*]pyridine hydrochloride (Ticlid), is useful in reducing cardiac events in patients with unstable angina and cerebrovascular events in secondary prevention of stroke. It belongs to the thienopyridine class and facilitated the development of clopidogrel. One of the drawbacks to this agent is its side effect profile, which includes neutropenia, and patients receiving this antithrombotic should have their blood levels monitored. Its mechanism of action is similar to that of clopidogrel, in that it inhibits the purinergic receptors on platelets.

Ticlopidine
(Ticlid)

GP11B/IIIA RECEPTORS

Located on platelets is a site that serves to recognize and bind fibrinogen. This site is a dimeric glycoprotein that allows fibrinogen to bind, leading to the final step of platelet aggregation. The receptor must be activated before it will associate with fibrinogen, and this may be accomplished by thrombin, collagen, or thromboxane A₂. Once the receptor is activated, fibrinogen most likely binds to the platelet through the arginine-glycine-aspartic acid (RGD) sequences at residues 95-96-97 and 572-573-574 of the α chain of fibrinogen. This particular feature has been used in the design of nonpeptide

antagonists that mimic the RGD system in which a distance of 15 to 17Å (16 to 18 atoms) separates the amine group of arginine and the carbonyl oxygen of aspartic acid.

Eptifibatide. Eptifibatide (Integrilin) is a synthetic cyclic heptapeptide that acts as a GPIIb/IIIa receptor antagonist, thus causing inhibition of platelet aggregation. Its structure is based on the natural product barbourin, a peptide isolated from the venom of a pygmy rattlesnake (*Sistrurus milarud barbouri*). As part of the structure, there is a sequence arginine-glycine-aspartic acid (RGD) that can bind to the RGD receptor found on platelets and block its ability to bind with fibrinogen. This agent is used in the treatment of unstable angina and for angioplastic coronary interventions.

Tirofiban. Tirofiban is a nonpeptide that appears unrelated chemically to eptifibatide, but actually has many similarities. The chemical architecture incorporates a system that is mimicking the arginine-glycine-aspartic acid (RGD) moiety that is present in eptifibatide. This can be seen in the distance between the nitrogen of the piperidine ring, which mimics the basic nitrogen of arginine in the RGD sequence, and the carboxylic acid, which mimics the acid of aspartate in the RGD sequence. The basic nitrogen and the carboxylic acid of tirofiban are separated by approximately 15 to 17Å (16 to 18 atoms). This is the optimum distance seen in the RGD sequence of the platelet receptor. Tirofiban is useful in treating non-Q wave myocardial infarction and unstable angina.

Abciximab. Abciximab (ReoPro) is a chimeric Fab fragment monoclonal antibody that can bind to the GPIIa/IIIb receptor of platelets and block the ability of fibrinogen to associate with the platelet. This results in less platelet aggregation. Abciximab is useful in treating unstable angina and as an adjunct to percutaneous coronary intervention (PCI). The half-life of abciximab is about 30 minutes, while its effects when bound to the GPIIa/IIIb may last up to 24 hours. A significant drawback to using abciximab lies in its cost, which is approximately \$1,500 for a single dose.

ANTIARRHYTHMIC DRUGS

Cardiac arrhythmias are caused by a disturbance in the conduction of the impulse through the myocardial tissue, by disorders of impulse formation, or by a combination of these factors. The antiarrhythmic agents used most commonly affect impulse conduction by altering conduction velocity and the duration of the refractory period of heart muscle tissue. They also depress spontaneous diastolic depolarization, causing a reduction of automaticity by ectopic foci.

Many pharmacological agents are available for the treatment of cardiac arrhythmias. Agents such as oxygen, potassium, and sodium bicarbonate relieve the underlying cause of some arrhythmias. Other agents, such as digitalis, propranolol, phenylephrine, edrophonium, and neostigmine, act

on the cardiovascular system by affecting heart muscle or on the autonomic nerves to the heart. Finally, there are drugs that alter the electrophysiological mechanisms causing arrhythmias. The latter group of drugs is discussed in this chapter.

Within the past five decades, research on normal cardiac tissues and, in the clinical setting, on patients with disturbances of rhythm and conduction has brought to light information on the genesis of cardiac arrhythmias and the mode of action of antiarrhythmic agents. In addition, laboratory tests have been developed to measure blood levels of antiarrhythmic drugs such as phenytoin, disopyramide, lidocaine, procainamide, and quinidine, to help evaluate the pharmacokinetics of these agents. As a result, it is possible to maintain steady-state plasma levels of these drugs, which allows the clinician to use these and other agents more effectively and with greater safety. No other clinical intervention has been more effective at reducing mortality and morbidity in coronary care units.

Cardiac Electrophysiology

The heart depends on the synchronous integration of electrical impulse transmission and myocardial tissue response to carry out its function as a pump. When the impulse is released from the SA node, excitation of the heart tissue takes place in an orderly manner by a spread of the impulse throughout the specialized automatic fibers in the atria, the AV node, and the Purkinje fiber network in the ventricles. This spreading of impulses produces a characteristic electrocardiographic pattern that can be equated to predictable myocardial cell membrane potentials and Na^+ and K^+ fluxes in and out of the cell.

A single fiber in the ventricle of an intact heart during the diastolic phase (see phase 4, Fig. 19-4) has a membrane potential (resting potential) of 90 mV. This potential is created by differential concentrations of K^+ and Na^+ in the intracellular and extracellular fluid. An active transport system (pump) on the membrane is responsible for concentrating the K^+ inside the cell and maintaining higher concentrations of Na^+ in the extracellular fluid. Diastolic depolarization is caused by a decreased K^+ ionic current into the extracellular tissue and a slow inward leakage of Na^+ until the threshold potential (60 to 55 mV) is reached. At this time the inward sodium current suddenly increases, and a self-propagated wave occurs to complete the membrane depolarization process. Pacemaker cells possess this property, which is termed *automaticity*. This maximal rate of depolarization (MRD) is represented by phase 0 or the spike action potential (Fig. 19-4).

The form, duration, resting potential level, and amplitude of the action potential are characteristic for different types of myocardial cells. The rate of rise of the response (phase 0) is related to the level of the membrane potential at the time of stimulation and has been termed *membrane responsiveness*. Less negative potentials produce smaller slopes of phase 0 and are characterized by slower conduction times. The phase 0 spike of the SA node corresponds to the inscription of the P wave on the electrocardiogram (Fig. 19-10). Repolarization is divided into three phases. The greatest amount of repolarization is represented by phase 3, in which there is a passive flux of K^+ ions out of the cell. Phase 1

Figure 19-10 ■ Normal electrocardiogram. (From Ganong, W. F.: Review of Medical Physiology, 9th ed. San Francisco, Lange Medical Publications, 1985.)

repolarization is caused by an influx of Cl^- ions. During phase 2, a small inward movement of Ca^{2+} ions occurs through a slow channel mechanism that is believed to be important in the process of coupling excitation with contraction. The process of repolarization determines the duration of the action potential and is represented by the QT interval. The action potential duration is directly related to the refractory period of cardiac muscle.

Mechanisms of Arrhythmias

The current understanding of the electrophysiological mechanisms responsible for the origin and perpetuation of cardiac arrhythmias is that they are due to altered impulse formation (i.e., change in automaticity), altered conduction, or both, acting simultaneously from different locations of the heart. The generation of cardiac impulses in the normal heart is usually confined to specialized tissues that spontaneously depolarize and initiate the action potential. These cells are located in the right atrium and are referred to as the *SA node* or the *pacemaker cells*. Although the spontaneous electrical depolarization of the SA pacemaker cells is independent of the nervous system, these cells are innervated by both sympathetic and parasympathetic fibers, which may cause an increase or decrease of the heart rate, respectively. Other special cells in the normal heart that possess the property of automaticity may influence cardiac rhythm when the normal pacemaker is suppressed or when pathological changes occur in the myocardium to make these cells the dominant source of cardiac rhythm (i.e., ectopic pacemakers). Automaticity of subsidiary pacemakers may develop when myocardial cell damage occurs because of infarction or from digitalis toxicity, excessive vagal tone, excessive catecholamine release from sympathomimetic nerve fibers to the heart, or even high catecholamine levels in plasma. The development of automaticity in specialized cells, such as that found in special atrial cells, certain AV node cells, bundle of His, and Purkinje fibers, may lead to cardiac arrhythmias. Because production of ectopic impulses is often due to a

Figure 19-11 ■ Reentry mechanism of Purkinje fibers. **a.** Normal conduction of impulses through triangular arrangement of cardiac fibers. **b.** Unidirectional block on left arm of triangular section allows impulse to reenter the regional conducting system and recycle.

defect in the spontaneous phase 4 diastolic depolarization ("T wave"), drugs that can suppress this portion of the cardiac stimulation cycle are effective agents for these types of arrhythmia.

Arrhythmias are also caused by disorders in the conduction of impulses and changes in the refractory period of the myocardial tissue. Pharmacological intervention is based on these two properties. The Purkinje fibers branch into a network of interlacing fibers, particularly at their most distant positions. This creates several pathways in which a unidirectional block in a localized area may establish circular (circus) microcellular or macrocellular impulse movements that reenter the myocardial fibers and create an arrhythmia (Fig. 19-11). Unidirectional block results from localized myocardial disease (*infarcts*) or from a change in dependence of the tissue to Na^+ fluxes that causes a longer conduction time and allows the tissue to repolarize to propagate the retrograde impulse.

Classes of Antiarrhythmic Drugs

Antiarrhythmic drugs can be placed into four separate classes, based on their mechanism of action or pattern of electrophysiological effects produced on heart tissue. Table 19-4 summarizes the four-part classification of antiarrhythmic drugs as first proposed by Vaughan Williams in 1970¹⁹ and expanded in 1984.²⁰ Note that drugs within the same

category are placed there because they demonstrate similar clinical actions. That patients do not respond to a drug in this class, however, should not rule out use of other drugs in the same class.²¹ Despite the well-intentioned use of these agents, most antiarrhythmic drugs have the potential to aggravate the arrhythmia they treat (*proarrhythmia*). Proarrhythmia develops from an increase in the density of single ectopic beats and is more likely to occur in patients who have a dysfunction in the left ventricle or sustained ventricular tachycardia. Class I antiarrhythmic agents (see below) are especially proarrhythmic in myocardial infarction patients.

CLASS I. MEMBRANE-DEPRESSANT DRUGS

Class I antiarrhythmic agents are drugs that have membrane-stabilizing properties (i.e., they shift membranes to more negative potentials). Drugs in this class act on the fast Na^+ channels and interfere with the process by which the depolarizing charge is transferred across the membrane. It is assumed that these drugs bind to the Na^+ channel and block its function, preventing Na^+ conductance as long as the drug is bound. The prototypical drugs in this class are quinidine and procainamide. During the 1970s, several drugs were studied for their antiarrhythmic effects. Most of them were local anesthetics that affected Na^+ membrane channels, and they were grouped in a single class (class I). Studies on the antiarrhythmic properties of these chemicals have shown that there are sufficient differences to place them into separate subgroups.²¹

Class I antiarrhythmic drugs can be subdivided on the basis of the relative ease with which they dissociate from the Na^+ ion channel. Drugs in class IC, such as encainide, flecainide and moricizine, are the most potent sodium channel-blocking agents of the class I antiarrhythmic drugs. They slowly dissociate from the Na^+ channel, causing a slowing of the conduction time of the impulse through the heart. Class IB drugs, which include lidocaine, tocainide, and mexiletine, dissociate rapidly from the Na^+ channel and thus have the lowest potency as sodium channel blockers. They produce little, if any, change in action potential duration. Quinidine, procainamide, and disopyramide are drugs that have an intermediate rate of dissociation from Na^+ channels. These are categorized as class IA antiarrhythmic agents, and they lengthen the refractory period of cardiac tissue to cause cessation of arrhythmias.²²

Studies have shown that Na^+ channels on the membrane of Purkinje fiber cells normally exist in at least three states: *R*, rested, closed near the resting potential but able to be opened by stimulation and depolarization; *A*, activated, allowing Na^+ ions to pass selectively through the membrane; and *I*, inactivated and unable to be opened (i.e., inactive). The affinity of the antiarrhythmic drug for the receptor or the ion channel varies with the state of the channel or with the membrane potential. Because of this, *R*, *A*, and *I* channels can have different kinetics of interaction with antiarrhythmic drugs. A review of the recent literature shows that the antiarrhythmic drugs have low affinity for *R* channels but relatively high affinity for the *A* or *I* channels or both. Regardless of which channel state is blocked by class I antiarrhythmic drugs, the unblocking rate directly determines the amount of depression present at normal heart rates.

TABLE 19-4 Classes of Antiarrhythmic Drugs

Class	Drugs	Mechanism of Action
IA	Quinidine, procainamide, disopyramide	Lengthens refractory period
IB	Lidocaine, phenytoin, tocainide, mexiletine	Shortens duration of action potential
IC	Encainide, flecainide, flecainide, moricizine, propafenone	Slows conduction
II	β -Adrenergic blockers (e.g., propranolol)	Slows AV conduction time, suppresses automaticity
III	Amiodarone, bretylium, sotalol	Prolongs refractoriness
IV	Calcium channel blockers (e.g., verapamil, diltiazem)	Blocks slow inward Ca^{2+} channel

CLASS II. β -ADRENERGIC BLOCKING AGENTS

β -Adrenergic blocking drugs cause membrane-stabilizing or depressant effects on myocardial tissue. Their antiarrhythmic properties, however, are considered to be principally the result of inhibition of adrenergic stimulation to the heart. The principal electrophysiological property of these β -blocking agents is reduction of the phase 4 slope of potential sinus or ectopic pacemaker cells such that the heart rate decreases and ectopic tachycardias are either slowed or converted to sinus rhythm.

CLASS III. REPOLARIZATION PROLONGATORS

Drugs in this class (e.g., amiodarone, bretylium, sotalol, ibutilide, dofetilide) cause several different electrophysiological changes on myocardial tissue but share one common effect, prolonging the action potential, which increases the effective refractory period of the membrane action potential without altering the phase of depolarization or the resting membrane potential. Drugs in this class produce their effects by more than one mechanism. Sotalol is a K^+ channel blocker and has some β -adrenergic blocking properties.²⁴ Amiodarone and bretylium, drugs that also prolong the action potential by means that are unclear, also have Na^+ channel-blocking properties.

CLASS IV. CALCIUM CHANNEL BLOCKERS

Although not all Ca^{2+} channel blockers possess antiarrhythmic activity, some members of this class of antiarrhythmic drugs (verapamil, diltiazem) block the slow inward current of Ca^{2+} ions during phase 2 of the membrane action potential in cardiac cells. For example, the prototypical drug in this group, verapamil, selectively blocks entry of Ca^{2+} into the myocardial cell. It acts on the slow-response fibers found in the sinus node and the AV node, slowing conduction velocity and increasing refractoriness in the AV node.

pH and Activity

The action of class I local anesthetic-type antiarrhythmic drugs is pH dependent and may vary with each drug.²⁵ Antiarrhythmic drugs are weak bases, with most having pK_a values ranging from 7.5 to 9.5. At physiological pH of 7.40, these bases exist in an equilibrium mixture consisting of both the free base and the cationic form. Ionizable drugs, such as lidocaine (pK_a 7.86), have stronger electrophysiological effects in ischemic rather than normal myocardial cells. This potentiation has been attributed in part to the increase in H^+ concentration within the ischemic areas of the heart. Acidosis increases the proportion of Na^+ ion channels occupied by the protonated form of the antiarrhythmic agent. Nevertheless, the effect of pH on the antiarrhythmic activity of drugs can be complex, as both the free base and cationic species have been proposed as the active form of some drugs. The uncharged form of the Na^+ channel blocker can penetrate directly from the lipid phase of the surrounding cell membrane to block the channel.

Small changes in pH can alter these drugs' effectiveness by changing the charged-to-uncharged molecular ratio in the myocardial cells. Acidosis external to the myocardial cell promotes the cationic form. Because this species does not

partition in the membrane as readily, onset of these drugs' action would be delayed. Furthermore, concentration of these drugs in the membrane would be reduced. Therefore, drugs that act on the channel only in the inactivated (closed) state would have a reduced effect in acidotic conditions. Acidosis may also prolong the effect of these drugs. External acidosis facilitates protonation of receptor-bound drugs. Because only neutral drugs can dissociate from closed channels, recovery is prolonged by acidosis.

Alkalosis tends to hyperpolarize the cell membrane and, thereby, reduces the effect of antiarrhythmic drugs. Because of this, alkalosis promotes the formation of more of the free-base antiarrhythmic agent, increasing the rate of recovery from the block. Alkalosis-inducing salts such as sodium lactate have been used to counteract toxicity caused by the antiarrhythmic quinidine.

CLASS I ANTIARRHYTHMICS

Quinidine Sulfate, USP. Quinidine sulfate is the sulfate of an alkaloid obtained from various species of *Cinchona* and their hybrids. It is a dextrorotatory diastereoisomer of quinine. The salt crystallizes from water as the dihydrate, in the form of fine, needle-like, white crystals. Quinidine sulfate contains a hydroxymethyl group that serves as a link between a quinoline ring and a quinuclidine moiety. The structure contains two basic nitrogens, of which the quinuclidine nitrogen is the stronger base (pK_a 10). Quinidine sulfate is bitter and light sensitive. Aqueous solutions are nearly neutral or slightly alkaline. It is soluble to the extent of 1% in water and more highly soluble in alcohol or chloroform.

Quinidine
(Cardioquin)
(Quinora)
(Quinidex)

Quinidine sulfate is the prototype of antiarrhythmic drugs and a class IA antiarrhythmic agent according to the Vaughan Williams classification. It reduces Na^+ current by binding the open ion channels (i.e., state A). The decreased Na^+ entry into the myocardial cell depresses phase 4 diastolic depolarization and shifts the intracellular threshold potential toward zero. These combined actions diminish the spontaneous frequency of pacemaker tissues, depress the automaticity of ectopic foci, and, to a lesser extent, reduce impulse formation in the SA node. This last action results in bradycardia. During the spike action potential, quinidine sulfate decreases transmembrane permeability to passive influx of Na^+ , thus slowing the process of phase 0 depolarization, which decreases conduction velocity. This is shown as

a prolongation of the QRS complex of electrocardiograms. Quinidine sulfate also prolongs action potential duration, which results in a proportionate increase in the QT interval. It is used to treat supraventricular and ventricular ectopic arrhythmias, such as atrial and ventricular premature beats, atrial and ventricular tachycardia, atrial flutter, and atrial fibrillation.

Quinidine sulfate is used most frequently as an oral preparation and is occasionally given intramuscularly. Quinidine sulfate that has been absorbed from the gastrointestinal tract or from the site of intramuscular injection is bound 80% to serum albumin.¹⁸ The drug is taken up quickly from the bloodstream by body tissues; consequently, a substantial concentration gradient is established within a few minutes. Onset of action begins within 30 minutes, with the peak effect attained in 1 to 3 hours. Quinidine is metabolized primarily in the liver by hydroxylation, and a small amount is excreted by the liver.²⁵ Because of serious side effects and the advent of more effective oral antiarrhythmic agents, quinidine is now used less, except in selected patients for long-term oral antiarrhythmic therapy.

Quinidine Gluconate, USP. Quinidinium gluconate (Duraquin, Quinaglute) occurs as an odorless, very bitter, white powder. In contrast with the sulfate salt, it is freely soluble in water. This is important because there are emergencies when the condition of the patient and the need for a rapid response make the oral route of administration inappropriate. The high water solubility of the gluconate salt along with a low irritant potential makes it valuable when an injectable form is needed in these emergencies. Quinidine gluconate forms a stable aqueous solution. When used for injection, it usually contains 80 mg/mL, equivalent to 50 mg of quinidine or 60 mg of quinidine sulfate.

Quinidine Polygalacturonate. Quinidine polygalacturonate (Cardioquin) is formed by reacting quinidine and polygalacturonic acid in a hydroalcoholic medium. It contains the equivalent of approximately 60% quinidine. This salt is only slightly ionized and slightly soluble in water, but studies have shown that although equivalent doses of quinidine sulfate give higher peak blood levels earlier, a more uniform and sustained blood level is achieved with the polygalacturonate salt.

In many patients, the local irritant action of quinidine sulfate in the gastrointestinal tract causes pain, nausea, vomiting, and especially diarrhea, often precluding oral use in adequate doses. Studies with the polygalacturonate salt yielded no evidence of gastrointestinal distress. It is available as 275-mg tablets. Each tablet is the equivalent of 200 mg of quinidine sulfate or 166 mg of free alkaloid.

Procainamide Hydrochloride, USP. Procainamide hydrochloride, *p*-amino-*N*-[2-(diethylamino)ethyl]benzamide monohydrochloride, procainamidium chloride (Pronestyl, Procan SR), has emerged as a major antiarrhythmic drug. It was developed in the course of research for compounds structurally similar to procaine, which had limited effect as an antiarrhythmic agent because of its central nervous system (CNS) side effects and short-lived action due to rapid hydrolysis of its ester linkage by plasma esterases. Because of its amide structure, procainamide hydrochloride is also

more stable in water than is procaine. Aqueous solutions of procainamide hydrochloride have a pH of about 5.5. A kinetic study of the acid-catalyzed hydrolysis of procainamide hydrochloride showed it to be unusually stable to hydrolysis in the pH range 2 to 7, even at elevated temperatures.²⁶

Procainamide
(Pronestyl)
(Procan SR)

Procainamide hydrochloride is metabolized through the action of *N*-acetyltransferase. The product of enzymatic metabolism of procainamide hydrochloride is *N*-acetylprocainamide (NAPA), which possesses only 25% of the activity of the parent compound.²⁵ A study of the disposition of procainamide hydrochloride showed that 50% of the drug was excreted unchanged in the urine, with 7 to 24% recovered as NAPA.^{27,28} Unlike quinidine, procainamide hydrochloride is bound only minimally to plasma proteins. Between 75 and 95% of the drug is absorbed from the gastrointestinal tract. Plasma levels appear 20 to 30 minutes after administration and peak in about 1 hour.²⁹

Procainamide hydrochloride appears to have all of the electrophysiological effects of quinidine. It diminishes automaticity, decreases conduction velocity, and increases action potential duration and, thereby, the refractory period of myocardial tissue. Clinicians have favored the use of procainamide hydrochloride for ventricular tachycardias and quinidine for atrial arrhythmias, even though the two drugs are effective in either type of disorder.

Disopyramide Phosphate, USP. Disopyramide phosphate, α -[2(diisopropylamino)ethyl]- α -phenyl-2-pyridineacetamide phosphate (Norpace), is an oral and intravenous class IA antiarrhythmic agent. It is quite similar to quinidine and procainamide in its electrophysiological properties, in that it decreases phase 4 diastolic depolarization, decreases conduction velocity, and has vagolytic properties.³⁰ It is used clinically in the treatment of refractory, life-threatening ventricular tachyarrhythmias. Oral administration of the drug produces peak plasma levels within 2 hours. The drug is bound approximately 50% to plasma protein and has a half-life of 6.7 hours in humans. More than 50% is excreted unchanged in the urine. Therefore, patients with renal insufficiency should be monitored carefully for evidence of overdose. Disopyramide phosphate commonly exhibits side effects of dry mouth, constipation, urinary retention, and other cholinergic blocking actions because of its structural similarity to anticholinergic drugs.

Disopyramide
(Norpace)

Lidocaine Hydrochloride, USP. Lidocaine hydrochloride, 2-(diethylamino)-2',6'-acetoxylicide monohydrochloride (Xylocaine), was conceived as a derivative of gramine (3-dimethylaminomethylindole) and introduced as a local anesthetic. It is now being used intravenously as a standard parenteral agent for suppression of arrhythmias associated with acute myocardial infarction and cardiac surgery. It is the drug of choice for the parenteral treatment of premature ventricular contractions.

Lidocaine hydrochloride is a class IB antiarrhythmic agent with a different effect on the electrophysiological properties of myocardial cells from that of procainamide and quinidine. It binds with equal affinity to the active (A) and inactive (I) Na^+ ion channels. It depresses diastolic depolarization and automaticity in the Purkinje fiber network and increases the functional refractory period relative to action potential duration, as do procainamide and quinidine. It differs from the latter two drugs, however, in that it does not decrease, and may even enhance, conduction velocity and increases membrane responsiveness to stimulation. There are fewer data available on the subcellular mechanisms responsible for the antiarrhythmic actions of lidocaine than on the more established drug quinidine. It has been proposed that lidocaine has little effect on membrane cation exchange of the atria. Sodium ion entrance into ventricular cells during excitation is not influenced by lidocaine because it does not alter conduction velocity in this area. Lidocaine hydrochloride does depress Na^+ influx during diastole, as do all other antiarrhythmic drugs, to diminish automaticity in myocardial tissue. It also alters membrane responsiveness in Purkinje fibers, allowing increased conduction velocity and ample membrane potential at the time of excitation.³¹

Lidocaine hydrochloride administration is limited to the parenteral route and is usually given intravenously, though adequate plasma levels are achieved after intramuscular in-

jections. Lidocaine hydrochloride is not bound to any extent to plasma proteins and is concentrated in the tissues. It is metabolized rapidly by the liver (Fig. 19-12). The first step is deethylation with the formation of monoethylglycinexylidide, followed by hydrolysis of the amide.³² Metabolism is rapid, the half-life of a single injection ranging from 15 to 30 minutes. Lidocaine hydrochloride is a popular drug because of its rapid action and its relative freedom from toxic effects on the heart, especially in the absence of hepatic disease. Monoethylglycinexylidide, the initial metabolite of lidocaine, is an effective antiarrhythmic agent; its rapid hydrolysis by microsomal amidases, however, prevents its use in humans.

Precautions must be taken so that lidocaine hydrochloride solutions containing epinephrine salts are not used as cardiac depressants. Such solutions are intended only for local anesthesia and are not used intravenously. The aqueous solutions without epinephrine may be autoclaved several times, if necessary.

Phenytoin Sodium, USP. Phenytoin sodium, 5,5-diphenyl-2,4-imidazolidinedione, 5,5-diphenylhydantoin, diphenyl-hydantoin sodium (Dilantin), has been used for decades in the control of grand mal types of epileptic seizure. It is structurally analogous to the barbiturates but does not possess their extensive sedative properties. The compound is available as the sodium salt. Solutions for parenteral administration contain 40% propylene glycol and 10% alcohol to dissolve the sodium salt.

Phenytoin sodium's cardiovascular effects were uncovered during observation of toxic manifestations of the drug in patients being treated for seizure disorders. Phenytoin sodium was found to cause bradycardia, prolong the PR interval, and produce T-wave abnormalities on electrocardiograms. It is a class IB antiarrhythmic agent. Today, phenytoin sodium's greatest clinical use as an antiarrhythmic drug is in the treatment of digitalis-induced arrhythmias.³³ Its action is similar to that of lidocaine. It depresses ventricular automaticity produced by digitalis, without adverse intraventricular conduction. Because it also reverses the prolongation of AV conduction by digitalis, phenytoin sodium is useful in supraventricular tachycardias caused by digitalis intoxication.

Phenytoin sodium is located in high amounts in the body tissues, especially fat and liver, leading to large gradients

Figure 19-12 ■ Metabolism of lidocaine.

between the drug in tissues and the plasma concentrations. It is metabolized in the liver.

Mexiletine Hydrochloride. Mexiletine hydrochloride, 1-methyl-2-(2,6-xylyloxy)ethylamine hydrochloride (Mexilitil) (pK_a 8.4), is a class IB antiarrhythmic agent that is effective when given either intravenously or orally. It resembles lidocaine in possessing a xylyl moiety but otherwise is different chemically. Mexiletine hydrochloride is an ether and is not subject to the hydrolysis common to the amides lidocaine and tocainide. Its mean half-life on oral administration is approximately 10 hours.

Although not subject to hydrolysis, mexiletine hydrochloride is metabolized by oxidative and reductive processes in the liver. Its metabolites, *p*-hydroxymexiletine and hydroxymethylmexiletine, are not pharmacologically active as antiarrhythmic agents.³⁴

Mexiletine hydrochloride, like class I antiarrhythmic agents, blocks the fast Na^+ channel in cardiac cells. It is especially effective on the Purkinje fibers in the heart. The drug increases the threshold of excitability of myocardial cells by reducing the rate of rise and amplitude of the action potential and decreases automaticity.

Mexiletine hydrochloride is used for long-term oral prophylaxis of ventricular tachycardia. The drug is given in 200- to 400-mg doses every 8 hours.

Tocainide Hydrochloride. Tocainide hydrochloride, 2-amino-2',6'-propionoxyxylylide hydrochloride (Tonocard) (pK_a 7.7), is an analogue of lidocaine. It is orally active and has electrophysiological properties like those of lidocaine.³⁵ Total body clearance of tocainide hydrochloride is only 166 mL/min, suggesting that hepatic clearance is not large. Because of low hepatic clearance, the hepatic extraction ratio must be small; therefore, tocainide hydrochloride is unlikely to be subject to a substantial first-pass effect. The drug differs from lidocaine, in that it lacks two ethyl groups, which provides tocainide hydrochloride some protection from first-pass hepatic elimination after oral ingestion. Tocainide hydrochloride is hydrolyzed in a manner similar to that of lidocaine. None of its metabolites is active.

Tocainide hydrochloride is classed as a IB antiarrhythmic agent and used orally to prevent or treat ventricular ectopy and tachycardia. The drug is given in 400- to 600-mg doses every 8 hours.

Flecainide Acetate. Flecainide acetate, *N*-(2-piperidinylmethyl)-2,5-bis (2,2,2-trifluoroethoxy)benzamide monoacetate (Tambocor), is a class IC antiarrhythmic drug with local anesthetic activity; it is a chemical derivative of benzamide. The drug undergoes biotransformation, forming a meta-O-dealkylated compound, whose antiarrhythmic properties are half as potent as those of the parent drug, and a meta-O-dealkylated lactam of flecainide with little pharmacological activity.³⁶ Flecainide acetate is given orally to suppress chronic ventricular ectopy and ventricular tachycardia. It has some limitations because of CNS side effects.

Moricizine. Moricizine, ethyl 10-(3-morpholinopropionyl)phenothiazine-2-carbamate (Ethmozine), is a phenothiazine derivative used for the treatment of malignant ventricular arrhythmias. It is categorized as a class IC antiarrhythmic agent, blocking the Na^+ channel with 1:1 stoichiometry. The drug has higher affinity for the inactivated state than the activated or resting states. It appears to bind to a site on the external side of the Na^+ channel membrane.³⁷ It has been used to suppress life-threatening ventricular arrhythmias.

Propafenone. Propafenone, 2-[2'-hydroxy-3-(propylamino)propoxy]-3-phenylpropionone (Rythmol), a class IC antiarrhythmic drug, contains a chiral center and is marketed as the racemic mixture. Therapy with the racemic mixture of propafenone produces effects that can be attributed to both (*S*) and (*R*) enantiomers. Although (*R*) and (*S*) enantiomers exert similar Na^+ channel-blocking effects, the (*S*) enantiomer also produces a β -adrenergic blockade. As a result, the (*S*) enantiomer is reported to be 40-fold more potent than the (*R*) enantiomer as an antiarrhythmic agent.³⁸ The enantiomers also display stereoselective disposition characteristics. The (*R*) enantiomer is cleared more quickly. Hepatic metabolism is polymorphic and determined genet-

cally. Ten percent of Caucasians have a reduced capacity to hydroxylate the drug to form 5-hydroxypropafenone. This polymorphic metabolism accounts for the interindividual variability in the relationships between dose and concentration and, thus, variability in the pharmacodynamic effects of the drug. The 5-hydroxy metabolites of both enantiomers are as potent as the parent compound in blocking Na^+ channels. Propafenone also depresses the slow inward current of Ca^{2+} ions. This drug has been used for acute termination or long-term suppression of ventricular arrhythmias. It is bound in excess of 95% to α_1 -acid glycoprotein in the plasma. It is absorbed effectively, but bioavailability is estimated to be less than 20% because of first-pass metabolism. Less than 1% is eliminated as unchanged drug. Therapy with propafenone may produce effects that can be attributed to both (*S*) and (*R*) enantiomers. Thus, the effects may be modulated because of an enantiomer–enantiomer interaction when patients are treated with the racemate.³⁹

Propafenone
(Rythmol)

CLASS II ANTIARRHYTHMICS

Class II antiarrhythmics are discussed under the heading, Adrenergic System Inhibitors.

CLASS III ANTIARRHYTHMICS

Amiodarone. Amiodarone, 2-butyl-3-benzofuranyl-4-[2-diethylamino)ethoxy]-3,5-diiodophenyl ketone (Cordarone), was introduced as an antianginal agent. It has very pronounced class III action and is especially effective in maintaining sinus rhythm in patients who have been treated by direct current shock for atrial fibrillation.⁴⁰ Like class III antiarrhythmic drugs, amiodarone lengthens the effective refractory period by prolonging the action potential duration in all myocardial tissues. Amiodarone is eliminated very slowly from the body, with a half-life of about 25 to 30 days after oral doses.⁴¹ Although the drug has a broad spectrum of antiarrhythmic activity, its main limitation is a slow onset of action. Drug action may not be initiated for several days, and the peak effect may not be obtained for several weeks.

Amiodarone has adverse effects involving many different organ systems. It also inhibits metabolism of drugs cleared by oxidative microsomal enzymes. It contains iodine in its molecular structure and, as a result, has an effect on thyroid hormones. Hypothyroidism occurs in up to 11% of patients receiving amiodarone.⁴² The principal effect is the inhibition of peripheral conversion of T_4 to T_3 . Serum reverse T_3 (rT_3) is increased as a function of the dose as well as the length of amiodarone therapy. As a result, rT_3 levels have been used as a guide for judging adequacy of amiodarone therapy and predicting toxicity.⁴³

Amiodarone
(Cordarone)

Bretylum Tosylate. Bretylum tosylate, (*o*-bromophenyl)ethyl dimethylammonium *p*-toluenesulfonate (Bretlyol), is an extremely bitter, white, crystalline powder. The chemical is freely soluble in water and alcohol. Bretylum tosylate is an adrenergic neuronal blocking agent that accumulates selectively in the neurons and displaces norepinephrine. Because of this property, bretylum was used initially, under the trade name of Darenthin, as an antihypertensive agent. It caused postural decrease in arterial pressure.⁴³ This use was discontinued because of the rapid development of tolerance, erratic oral absorption of the quaternary ammonium compound, and persistent pain in the parotid gland on prolonged therapy. Currently, bretylum is reserved for use in ventricular arrhythmias that are resistant to other therapy. Bretylum does not suppress phase 4 depolarization, a common action of other antiarrhythmic agents. It prolongs the effective refractory period relative to the action potential duration but does not affect conduction time and is categorized as a class III antiarrhythmic agent. Because bretylum does not have properties similar to those of the other antiarrhythmic agents, it has been suggested that its action is due to its adrenergic neuronal blocking properties; the antiarrhythmic properties of the drug, however, are not affected by administration of reserpine. Bretylum is also a local anesthetic, but it has not been possible to demonstrate such an effect on atria of experimental animals, except at very high concentrations.⁴⁴ Therefore, the precise mechanism of the antiarrhythmic action of bretylum remains to be resolved.

Bretylum
(Bretlyol)

Dofetilide. Dofetilide, *N*-[4-(3-[[2-(4-methanesulfonyl)aminophenyl]ethyl]methylamino]propoxy)phenyl]methanesulfonamide (Tikosyn), acts by blocking the cardiac ion channel carrying the rapid component of the delayed rectifier potassium currents (I_{Kr}) and is used to terminate supraventricular arrhythmias, prevent the recurrence of atrial fibrillation, and treat life-threatening ventricular arrhythmias. Unlike sotalol and ibutilide, which are also methanesulfonamides, it has no effect on adrenergic receptors or sodium channels, respectively. Dofetilide has high specificity for the delayed rectifier potassium currents.⁴⁵

Ibutilide. Ibutilide, *N*-[4-[4-(ethylheptylamino)-1-hydroxybutyl]phenyl]methanesulfonamide (Corvert), a class III antiarrhythmic belonging to the methanesulfonamide class of agents, is indicated for rapid conversion of atrial fibrillation or atrial flutter to normal sinus rhythm. Unlike dofetilide, it is not highly specific for the delayed rectifier potassium currents (I_{kr}) and does have some affinity for sodium channels.

Sotalol. Sotalol, 4-[1-hydroxy-2-(isopropylamino)ethyl]methanesulfonamide (Betapace), is a relatively new antiarrhythmic drug, characterized most often as a class III agent, and although it has effects that are related to the class II agents, it is not therapeutically considered a class II antiarrhythmic. It contains a chiral center and is marketed as the racemic mixture. Because of its enantiomers, its mechanism of action spans two of the antiarrhythmic drug classes. The *l*(-) enantiomer has both β -blocking (class II) and potassium channel-blocking (class III) activity. The *d*(+) enantiomer has class III properties similar to those of the *l*(-) isomer, but its affinity for the β -adrenergic receptor is 30 to 60 times lower. The sotalol enantiomers produce different effects on the heart. Class III action of *d*-sotalol in the sinus node is associated with slowing of sinus heart rate, whereas β -adrenergic blockade contributes to the decrease in heart rate observed with *l*- or *d,l*-sotalol. Sotalol is not metabolized, nor is it bound significantly to proteins. Elimination occurs by renal excretion, with more than 80% of the drug eliminated unchanged. Sotalol is characteristic of class III antiarrhythmic drugs, in that it prolongs the duration of the action potential and, thus, increases the effective refractory period of

myocardial tissue. It is distinguished from the other class III drugs (amiodarone and bretylium) because of its β -adrenergic receptor-blocking action.

Azimilide. Azimilide, *E*-1-[[[5-(4-chlorophenyl)-2-furanyl]methylene]amino]-3-[4-(4-methyl-1-piperazinyl)butyl]-2,4-imidazolidinedione, is a class III agent that significantly blocks the delayed rectifier potassium current, I_{ks}, including the I_{kr} component. Its ability to block multichannels may be due to a lack of the methane sulfonamide group that is common to other class III agents, which selectively block the I_{kr} potassium current. It is believed that blocking both I_{kr} and I_{ks} potassium currents yields consistent class III antiarrhythmic effects at any heart rate.⁴⁶

CLASS IV ANTIARRHYTHMICS

Verapamil and Diltiazem. Both verapamil and diltiazem block the slow inward Ca²⁺ currents (voltage-sensitive channel) in cardiac fibers. This slows down AV conduction and the sinus rate. These drugs are used in controlling atrial and paroxysmal tachycardias and are categorized as class IV antiarrhythmic agents according to the Vaughan Williams classification.²⁰ (A more detailed description of calcium channel blockers is given above.)

ANTIHYPERTENSIVE AGENTS

Hypertension is a consequence of many diseases. Hemodynamically, blood pressure is a function of the amount of

blood pumped by the heart and the ease with which the blood flows through the peripheral vasculature (i.e., resistance to blood flow by peripheral blood vessels). Diseases of components of the central and peripheral nervous systems, which regulate blood pressure and abnormalities of the hormonal system, and diseases of the kidney and peripheral vascular network, which affect blood volume, can create a hypertensive state in humans. Hypertension is generally defined as mild when the diastolic pressure is between 90 and 104 mm Hg, moderate when it is 105 to 114 mm Hg, and severe when it is above 115 mm Hg. It is estimated that about 15% of the adult population in the United States (about 40 million) are hypertensive.

Primary (essential) hypertension is the most common form of hypertension. Although advances have been made in the identification and control of primary hypertension, the etiology of this form of hypertension has not yet been resolved. **Renal hypertension** can be created by experimentally causing renal artery stenosis in animals. Renal artery stenosis also may occur in pathological conditions of the kidney, such as nephritis, renal artery thrombosis, renal artery infarctions, or other conditions that restrict blood flow through the renal artery. Hypertension also may originate from pathological states in the CNS, such as malignancies. Tumors in the adrenal medulla that cause release of large amounts of catecholamines create a hypertensive condition known as **pheochromocytoma**. Excessive secretion of aldosterone by the adrenal cortex, often because of adenomas, also produces hypertensive disorders.

Arterial blood pressure is regulated by several physiological factors, such as heart rate, stroke volume, peripheral vascular network resistance, blood vessel elasticity, blood volume, and viscosity of blood. Endogenous chemicals also play an important part in the regulation of arterial blood pressure. The peripheral vascular system is influenced greatly by the sympathetic-parasympathetic balance of the

autonomic nervous system, the control of which originates in the CNS. Enhanced adrenergic activity is a principal contributor to primary (essential) hypertension.

Therapy using antihypertensive agents evolved rapidly between 1950 and 1960. During that time, a number of drugs for the treatment and control of hypertensive disease were discovered. Despite the many years of experience, treatment remains empiric because the etiology of the principal form of hypertension, primary hypertension, is unknown. The first drugs used to produce symptomatic relief of hypertension were α -adrenergic blocking agents. These drugs had limitations because their duration of action was far too short and side effects precluded long-term therapy. Contemporary therapy of primary hypertension uses one of several drug classes as the first course. These drugs may be diuretics to reduce blood volume, inhibitors of the renin-angiotensin system (ACE inhibitors), and agents that reduce peripheral vascular resistance (e.g., calcium channel blockers, vasodilators, and sympathetic nervous system depressants). The antihypertensive drug classes discussed in this section include ACE inhibitors, sympathetic nervous system depressants, and vasodilators acting on smooth muscle. Calcium channel blockers and other vasodilators are included in previous discussions in this chapter. Diuretics are discussed in Chapter 18.

The Renin-Angiotensin System and Hypertension

The renin-angiotensin system is a hormonal system that plays a central role in the control of sodium excretion and body fluid volume. It interacts closely with the sympathetic nervous system and aldosterone secretion in the regulation of blood pressure. Figure 19-13 shows the relationship of the component parts of the renin-angiotensin system and their main physiological effects.

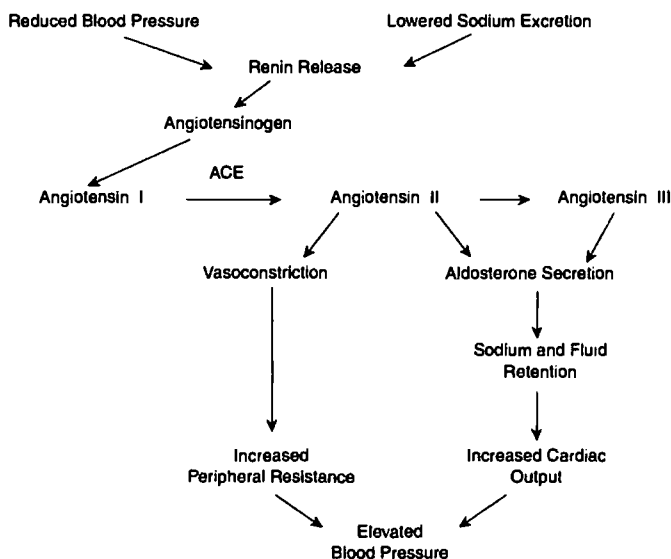

Figure 19-13 ■ Renin-angiotensin system of blood pressure control

Figure 19-14 ■ Biochemistry of the renin-angiotensin system: formation of angiotensins from angiotensinogen.

The relationship between the renin-angiotensin system and blood pressure in humans has been known since before the beginning of the 20th century. Tigerstedt and Bergman⁴⁷ demonstrated in 1898 that when injected in a host, kidney extract produced a potent vasopressor response. The substance was named *renin*. Many years later, this substance was shown to require a cofactor to produce vasoconstriction.⁴⁸ Eventually, in 1939, this hypertensive substance was isolated, identified as a decapeptide, and later called *angiotensin*. This cofactor existed as an inactive precursor, angiotensinogen. Later studies revealed that angiotensin existed in two forms, the biologically inactive decapeptide angiotensin I and the active octapeptide angiotensin II.⁴⁹

The precursor of angiotensin, angiotensinogen, is a glycoprotein of molecular weight (MW) 58,000 to 61,000, synthesized primarily in the liver and brought into the circulatory system. Renin, an aspartyl protease (MW 35,000 to 40,000), whose primary source is the kidney, cleaves the Leu-Val bond from the aspartic acid end of the angiotensinogen polypeptide molecule to release the decapeptide angiotensin I (Fig. 19-14). The biochemical conversion continues with the cleavage of a dipeptide (His-Leu) from the carboxyl terminal of angiotensin I by ACE to form the octapeptide angiotensin II, a potent vasoconstrictor. Angiotensin III is formed by removal of the N-terminal aspartate residue of angiotensin II, a reaction catalyzed by glutamyl aminopeptidase. In contrast to angiotensin II, angiotensin III has a less potent but significant regulatory effect on sodium excretion by the renal tubules.

The regulatory action of the renin-angiotensin system in controlling sodium and potassium balance and arterial blood pressure is modified by vasodilators called *kinins*. Proteolytic enzymes that circulate in the plasma form kinins. Kallikrein is activated in plasma by noxious influences to act on

a kinin, kallidin, which is converted to bradykinin by tissue enzymes. Bradykinin enhances release of the prostaglandins PGE₂ and PGI₂ within certain tissues to produce a vasodilatory effect (Fig. 19-15). Bradykinin is converted to inactive products by ACE and other carboxypeptidases. Although ACE causes activation of angiotensin and inactivation of bradykinin, actions that appear to be opposite, the balance of the system seems to favor vasoconstriction.

ACE is a membrane-bound enzyme anchored to the cell membrane through a single transmembrane domain located near the carboxy-terminal extremity. The enzyme is a zinc-containing glycoprotein with a MW about 130,000. It is a nonspecific peptidyl dipeptide hydrolase, widely distributed in mammalian tissues, that cleaves dipeptides from the carboxy terminus of a number of endogenous peptides. The minimum structural requirement for binding and cleavage of a substrate by ACE is that it be a tripeptide with a free carboxylate group. A general exception is that this enzyme does not cleave peptides with a penultimate prolyl residue. This accounts for the biological stability of angiotensin II. The important binding points at the active site of ACE are a cationic site to attract a carboxylate ion and a zinc ion that can polarize a carbonyl group of an amide function to make it more susceptible to hydrolysis. In the active site, there is a nucleophilic attack of the amide carbonyl by the γ-carboxyl.

Figure 19-15 ■ Bradykinin formation and action

Figure 19-16 ■ Model showing cleavage of the histidine-phenylalanine residue of angiotensin I by ACE to form the octapeptide antiotensin II and the dipeptide residue of histidine and leucine.

group of a glutamic acid residue to cause hydrolysis of the peptide. Figure 19-16 shows a hypothetical model of the hydrolysis of angiotensin I by the active site of ACE. ACE exists in more than one form. Somatic ACE that regulates blood pressure, found in most tissues, differs from the isoenzyme ACE found in the testis. Somatic ACE, in contrast to testicular ACE, contains two binding domains. The principal active site for hydrolysis is the domain located in the C-terminal half of somatic ACE.³¹

RENIN-ANGIOTENSIN SYSTEM INHIBITORS

Captopril. Captopril, 1-[(2*S*)-3-mercapto-2-methyl-1-oxopropionyl]proline (Capoten), blocks the conversion of angiotensin I to angiotensin II by inhibiting the converting enzyme. The rational development of captopril as an inhibitor of ACE was based on the hypothesis that ACE and carboxypeptidase A functioned by similar mechanisms. It was noted that *D*-2-benzylsuccinic acid⁵⁰ was a potent inhibitor of carboxypeptidase A but not ACE. By use of this small molecule as a prototype, captopril was designed with a carboxyl group on a proline and a thiol group was introduced to enhance the binding to the zinc ion of ACE. The important

binding points at the active site of ACE are thought to be an arginine residue, which provides a cationic site that attracts a carboxylate ion, and a zinc ion, which can polarize a carbonyl group of an amide function to make it more susceptible to hydrolysis. Hydrophobic pockets lie between these groups in the active site, as does a functional group that forms a hydrogen bond with an amide carbonyl. Figure 19-17 shows the hypothetical binding of captopril in the active site of ACE.

Lisinopril. Lisinopril, 1-[*N*²-[*S*-1-carboxy-3-phenylpropyl]-L-lysyl]-L-proline dihydrate (Prinivil, Zestril), is a ly-

Figure 19-17 ■ Accommodation of captopril to the active site of ACE.

sine derivative of enalaprilat, the active metabolite of enalapril. Like all ACE inhibitors, it is an active site-directed inhibitor of the enzyme, with the zinc ion used in an effective binding interaction at a stoichiometric ratio of 1:1. The pharmacological effects of lisinopril are similar to those of captopril and enalapril.

ACE INHIBITOR PRODRUGS

Many new ACE inhibitors became available for the treatment of hypertension following the clinical effectiveness of enalapril. Enalapril is a non-thiol-containing ACE inhibitor devoid of the side effects of rash and loss of the sense of taste characteristic of the thiol-containing compound captopril. With the exception of the phosphorus-containing fosinopril, these antihypertensive agents have a 2-(*S*)-amino-phenylbutyric acid ethyl ester moiety differing only in the substituents on the amino group. They have the common property of acting as prodrugs, being converted to the active enzyme inhibitor following absorption and metabolism by liver and intestinal enzymes. These drugs (Fig. 19-18), like the prototypical drug captopril, are used in the treatment of mild-to-moderate hypertension, either alone or in conjunction with diuretics or calcium channel blockers. Table 19-5 compares some of their properties.

Enalapril Maleate. Enalapril maleate, 1-[*N*[(*S*)-1-carboxy-3-phenylpropyl]-L-alanyl]-L-proline 1'-ethyl ester maleate (Vasotec), is a long-acting ACE inhibitor. It requires activation by hydrolysis of its ethyl ester to form the diacid enalaprilat. Enalapril is devoid of the side effects of rash

and loss of taste seen with captopril. These side effects are similar to those of the mercapto-containing drug penicillamine. The absence of the thiol group in enalapril maleate may free it from these side effects. The half-life is 11 hours.

Benazepril Hydrochloride. Benazepril hydrochloride (3*S*)-3-[[[(1*S*)-1-carboxy-3-phenylpropyl]amino]-2,3,4,5-tetrahydro-2-oxo-1*H*-1-benzazepine-1-acetic acid 3-ethyl ester hydrochloride (Lotensin), is metabolized rapidly to the active diacid benazeprilat. As with the ACE prodrugs, no mutagenicity has been found, even though these drugs cross the placenta.

Quinapril Hydrochloride. Quinapril hydrochloride (*S*)-[[(*S*)-*N*[(*S*)-21-carboxy-3-phenylpropyl]alanyl]-1,2,3,4-tetrahydro-3-isoquinolinecarboxylic acid 1-ethyl ester hydrochloride (Acuretic), forms the diacid quinaprilate in the body. It is more potent than captopril and equipotent to the active form of enalapril.

Figure 19-18 ■ ACE inhibitor prodrugs.

TABLE 19-5 ACE-Inhibitor Prodrugs

Prodrug	Metabolite	Metabolite Protein Binding (%)	Metabolite Plasma $t_{1/2}$ (hours)	Mode of Excretion
Benazepril	Benazeprilat	95	10–11	Renal
Enalapril	Enalaprilat	50–60	11.0	Renal
Fosinopril	Fosinoprilat	97	11.5	Renal/fecal
Quinapril	Quinaprilat	97	3.0	Renal/fecal
Ramipril	Ramiprilat	56	13–17	Renal/fecal

Quinapril
(Accupril)

Ramipril. Ramipril, (2*S*, 3*aS*, 6*aS*)-1-[(*S*)-*N*-(*S*)-1-carboxy-3-phenylpropyl]alanyl]octahydrocyclopenta[*b*]pyrrole-2-carboxylic acid 1-ethyl ester (Altace), is hydrolyzed to ramiprilat, its active diacid form, faster than enalapril is hydrolyzed to its active diacid form. Peak serum concentrations from a single oral dose are achieved between 1.5 and 3.0 hours. The ramiprilate formed completely suppresses ACE activity for up to 12 hours, with 80% inhibition of the enzyme still observed after 24 hours.

Ramipril
(Altace)

Fosinopril Sodium. Fosinopril sodium, (4*S*)-4-cyclohexyl-1-[[[(*RS*)-1-hydroxy-2-methylpropoxy](4-phenyl-butyl)phosphinyl]acetyl]-L-proline sodium salt (Monopril), is a phosphorus-containing ACE inhibitor. It is inactive but serves as a prodrug, being completely hydrolyzed by intestinal and liver enzymes to the active diacid fosinoprilat.

Fosinopril
(Monopril)

Trandolapril. Trandolapril, 1-[2-(1-ethoxycarbonyl-3-phenylpropylamino)propionyl]octahydroindole-2-carboxylic acid (Mavik), is an indole-containing ACE inhibitor that is structurally related to most of the agents discussed above. Enalapril is very similar to trandolapril, with the primary difference occurring in the heterocyclic systems. The

pyrrolidine of enalapril has been replaced with an octahydroindole system. Much like enalaprilate, trandolapril must be hydrolyzed to tranolaprilate, which is the bioactive species.

Trandolapril
(Mavik)

ANGIOTENSIN ANTAGONISTS

Administration of a competitive antagonist can inhibit angiotensin II to produce a vasodilatory effect. Since the substrate for this receptor is an octapeptide, much of the earlier work was performed by using various peptide systems. One such agent, saralasin, is an octapeptide that differs from angiotensin by two amino acids. This agent's use was limited because it had some partial agonistic properties. Nevertheless, it served as a lead in the development of other agents that are useful in antagonizing the angiotensin II receptor. The most significant lead in the development of this class came from a series of imidazole-5-acetic acid derivatives that attenuated pressor response to angiotensin II in test animals. Molecular modeling revealed that the imidazole-5-acetic acid could be exploited to more closely mimic the pharmacophore of angiotensin II. The first successful agent to be developed through this method is losartan. Later, four other agents were introduced into the U. S. market. These tend to be biphenyl-methyl derivatives that possess certain acidic moieties, which can interact with various positions on the receptor, much like the substrate, angiotensin II. Since the late 1980s, this particular class has received a great deal of attention. In the early 1990s, the receptor for angiotensin II was found to exist as four isozymes, AT₁, AT₂, AT₃, and AT₄, with AT₁ being responsible for smooth muscle contraction, sympathetic pressor mechanisms, and aldosterone release.

ANGIOTENSIN II BLOCKERS

Losartan. Losartan, 2-butyl-4-chloro-1-[*p*-(*o*-1*H*-tetrazol-5-yl-phenyl)benzyl]imidazole-5-methanol monopotassium salt (Cozarr), was the first nonpeptide imidazole to be introduced as an orally active angiotensin II antagonist with high specificity for AT₁. When administered to patients, it undergoes extensive first-pass metabolism, with the 5-methanol being oxidized to a carboxylic acid. This metabolism is mediated by CYP 2C9 and 3A4 isozymes. The 5-methanol metabolite is approximately 15 times more potent than the parent hydroxyl compound. Since the parent hydroxyl compound has affinity for the AT₁ receptor, strictly speaking, it is not a prodrug.

Candesartan. Candesartan, (+)-1-[[[(cyclohexyloxy)carbonyl]-oxy]ethyl 2-ethoxy-1-[[2'-(1*H*-tetrazol-5-yl)]-1'-biphenyl]-4-yl]methyl]-1*H*-benzimidazole-7-carboxylate

ite (Atacand), like losartan, possesses the acidic tetrazole system, which most likely plays a role in binding to the angiotensin II receptor similarly to the acidic groups of angiotensin II. Also, the imidazole system has been replaced with a benzimidazole possessing an ester at position 7. This ester must be hydrolyzed to the free acid. Fortunately, this conversion takes place fairly easily because of the carbonate in the ester side chain. This facilitates hydrolysis of the ester so much that conversion to the free acid takes place during absorption from the gastrointestinal tract.

Irbesartan. Irbesartan, 2-butyl-3-[[2'-(1*H*-tetrazol-5-yl)[1,1'-biphenyl]-4-yl]methyl[1,3-diazaspiro[4,4]non-1-en-4-one (Avapro), like losartan, possesses the acidic tetrazole system, which most likely plays a role, similar to the acidic groups of angiotensin II, in binding to the angiotensin II receptor. In addition, the biphenyl system that serves to separate the tetrazole from the aliphatic nitrogen is still present. A major difference in this agent is that it does not possess the acidic side chain. Even so, irbesartan has good affinity for the angiotensin II receptor because of hydrogen bonding with the carbonyl moiety of the amide system. Also, this particular agent does not require metabolic activation as candesartan does.

Telmisartan. Telmisartan, 4'-[(1,4'-dimethyl-2'-propyl[2,6'-bi-1*H*-benzimidazol]-1'-yl)methyl]-[1,1'-biphenyl]-2-carboxylic acid (Micardis), does not appear to bear any structural relationship to this class, but there is actually a great deal of overlap in the chemical architecture with other agents. The first, and most significant, difference is the replacement of the acidic tetrazole system with a simple carboxylic acid. This acid, like the tetrazole, plays a role in receptor binding. The second difference is the lack of a carboxylic acid near the imidazole nitrogen that also contributes to receptor binding. As with irbesartan, however, there is not a need for this group to be acidic but, rather, to be one that participates in receptor binding. The second imidazole ring, much like a purine base in DNA, can hydrogen bond with the angiotensin II receptor.

Valsartan. Valsartan, *N*-(1-oxopentyl)-*N*-[[2'-(1*H*-tetrazol-5-yl)[1,1'-biphenyl]-4-yl]methyl-L-valine (Diovan), like losartan, possesses the acidic tetrazole system, which most likely plays a role, similar to that of the acidic groups of angiotensin II, in binding to the angiotensin II receptor. In addition, the biphenyl system that serves to separate the tetrazole from the aliphatic nitrogen is still present. In addition, there is a carboxylic acid side chain in the valine moiety that also serves to bind to the angiotensin II receptor.

ADRENERGIC SYSTEM INHIBITORS

Drugs that reduce blood pressure by depressing the activity of the sympathetic nervous system have been used as effective agents in the treatment of hypertension. This can be accomplished in several ways: (a) depleting the stores of neurotransmitter, (b) reducing the number of impulses trav-

eling in sympathetic nerves, (c) antagonizing the actions of the neurotransmitter on the effector cells, and (d) inhibiting neurotransmitter release.

AGENTS DEPLETING NEUROTRANSMITTER STORES

Folk remedies prepared from species of *Rauwolfia*, a plant genus belonging to the Apocynaceae family, were reported as early as 1563. The root of the species *R. serpentina* has been used for centuries as an antidote to stings and bites of insects, to reduce fever, as a stimulant to uterine contractions, for insomnia, and particularly for the treatment of insanity. Its use in hypertension was recorded in the Indian literature in 1918, but not until 1949 did hypotensive properties of *Rauwolfia* spp. appear in the Western literature.⁵² *Rauwolfia* preparations were introduced in psychiatry for the treatment of schizophrenia in the early 1950s, following confirmation of the folk remedy reports on their use in mentally deranged patients. By the end of the 1960s, however, the drug had been replaced by more efficacious neurotropic agents. Reserpine and its preparations remain useful in the control of mild essential hypertension.

The effects of reserpine do not correlate well with tissue levels of the drug. The pharmacological effects of reserpine were still present in animals when it could no longer be detected in the brain.⁵³ Reserpine depletes catecholamines and serotonin from central and peripheral neurons by interfering with the uptake of these amines from the cytosol into the vesicles and granules.^{54,55} As a consequence, norepinephrine cannot be stored intraneuronally in adrenergic neurons, and much of the norepinephrine in the cytosol is metabolized by monoamine oxidase (Fig. 19-19). The binding of reserpine to the storage vesicle membrane is firm, and as a result, the storage granule is destroyed, reducing the ability of the nerve to concentrate and store norepinephrine. Since reserpine acts on both central and peripheral adrenergic neurons, its antihypertensive effects may result from neurotransmitter depletion from both of these sites.

Chemical investigations of the active components of *R. serpentina* roots have yielded several alkaloids (e.g., ajmaline, ajmalicine, ajmalinine, serpentine, and serpentinine).

Figure 19-19 • Action of reserpine at adrenergic nerve ending.

Reserpine, which is the major active constituent of *Rauwolfia*,⁵⁶ was isolated in 1952 and is a much weaker base than the alkaloids just mentioned. Reserpinoid alkaloids are yohimbine-like bases that have an additional functional group on C-18. Only three naturally occurring alkaloids possess reserpine-like activity strong enough for use in treating hypertension: reserpine, deserpidine, and rescinnamine.

Reserpine is absorbed rapidly after oral administration. Fat tissue accumulates reserpine slowly, with a maximal level reached between 4 and 6 hours. After 24 hours, small amounts of reserpine are found in the liver and fat, but none is found in the brain or other tissues. Reserpine is metabolized by the liver and intestine to methyl reserpate and 3,4,5-trimethoxybenzoic acid.

Powdered *Rauwolfia Serpentina*, USP. *Rauwolfia* (Raudixin, Rauserpal, Rauval) is the powdered whole root of *R. serpentina* (Benth). It is a light tan to light brown powder, sparingly soluble in alcohol and only slightly soluble in water. It contains the total alkaloids, of which reserpine accounts for about 50% of the total activity. Orally, a dosage of 200 to 300 mg is roughly equivalent to 500 μ g of reserpine. It is used in the treatment of mild or moderate hypertension or in combination with other hypotensive agents in severe hypertension.

Reserpine, USP. Reserpine (Serpasil, Reserpoid, Rau-Sed, Sandril) is a white to light yellow, crystalline alkaloid practically insoluble in water, obtained from various species of *Rauwolfia*. In common with other compounds with an indole nucleus, it is susceptible to decomposition by light and oxidation, especially when in solution. In the dry state, discoloration occurs rapidly when reserpine is exposed to light, but the loss in potency is usually small. In solution, reserpine may break down with no appreciable color change when exposed to light, especially in clear glass containers; thus, color change cannot be used as an index of the amount of decomposition.

Reserpine is effective orally and parenterally for the treatment of hypertension. After a single intravenous dose, the onset of antihypertensive action usually begins in about 1 hour. After intramuscular injection, the maximum effect occurs within approximately 4 hours and lasts about 10 hours. When it is given orally, the maximum effect occurs within about 2 weeks and may persist up to 4 weeks after the final dose. When used in conjunction with other hypotensive drugs in the treatment of severe hypertension, the daily dose varies from 100 to 250 μ g.

Guanethidine and Related Compounds. Guanethidine has been classified traditionally as an adrenergic blocking agent because it can prevent the release of norepinephrine from postganglionic neurons in response to adrenergic stimulation. Guanethidine and other compounds discussed in this section have other actions on catecholamine metabolism and can cause significant depletion of these amines in adrenergic neurons. They do not interfere with release of epinephrine from the adrenal medulla.

Guanethidine Monosulfate, USP. Guanethidine monosulfate, [2-(hexahydro-1 (2*H*)-azocinyl)ethyl]guanidine sulfate (Ismelin sulfate), is a white, crystalline material that is very soluble in water. It was one of a series of guanidine compounds prepared in the search for potent antitrypanosomal agents. There is an absence of CNS effects, such as depression, because the drug is highly polar and does not easily cross the blood-brain barrier. Guanethidine monosulfate produces a gradual, prolonged fall in blood pressure. Usually, 2 to 7 days of therapy are required before the peak effect is reached, and usually, this peak effect is maintained for 3 or 4 days. Then, if the drug is discontinued, the blood pressure returns to pretreatment levels over a period of 1 to 3 weeks. Because of this slow onset and prolonged duration of action, only a single daily dose is needed.

Guanethidine monosulfate is metabolized by microsomal enzymes to 2-(6-carboxyhexylamino)ethylguanidine and guanethidine *N*-oxide (Fig. 19-20). Both metabolites have very weak antihypertensive properties. Guanethidine mono-

sulfate is taken up by the amine pump located on the neuronal membrane and retained in the nerve, displacing norepinephrine from its storage sites in the neuronal granules. The displaced norepinephrine is metabolized to homovanillic acid by mitochondrial monoamine oxidase, depleting the nerve ending of the neurotransmitter. The usefulness of guanethidine monosulfate also resides in the fact that once it is taken up by the nerve, it produces a sympathetic blockade by inhibiting release of norepinephrine that would occur on neuronal membrane response to stimulation²⁸ by the nerve action potential. Guanethidine monosulfate stored in the granules is released by the nerve action potential but has very low intrinsic activity for the adrenergic receptors on the postjunctional membrane. Moderate doses for a prolonged period or large doses may produce undesirable side effects by causing neuromuscular blockade and adrenergic nerve conduction blockade.

Guanadrel Sulfate. Guanadrel sulfate, (1,4-dioxaspiro[4.5]dec-2-ylmethyl)guanidine sulfate (Hylorel), is similar to guanethidine monosulfate in the manner in which it reduces elevated blood pressure. It acts as a postganglionic adrenergic blocking agent by displacing norepinephrine in adrenergic neuron storage granules, thereby preventing release of the endogenous neurotransmitter on nerve stimulation. Guanadrel sulfate has a much shorter half-life (10 hours) than guanethidine monosulfate, whose half-life is measured in days. In the stepped-care approach to hypertension, guanadrel sulfate is usually a step 2 agent.

SELECTIVE α -ADRENERGIC ANTAGONISTS

The principal clinical use of α -adrenergic antagonists is in the treatment of catecholamine-dependent hypertension. Classic drugs such as phentolamine and phenoxybenzamine are nonspecific blocking agents of both α_1 and α_2 receptors on the presynaptic membrane of the adrenergic neuron. Specific antagonists of α_1 receptors are effective antihypertensive agents by blocking the vasoconstricting effect on smooth muscle and not interfering with the activation of α_2 receptors

Figure 19-20 ■ Metabolism of guanethidine monosulfate.

on the adrenergic neuron, which when activated inhibit further release of norepinephrine.

Prazosin Hydrochloride. The antihypertensive effects of prazosin hydrochloride, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(2-furoyl)piperazine monohydrochloride (Minipress), are due to peripheral vasodilation as a result of its blockade of α_1 -adrenergic receptors. In ligand-binding studies, prazosin hydrochloride has 5,000-fold greater affinity for α_1 receptors than for some α_2 -adrenergic receptors.⁵⁷

Prazosin
(Minipress)

Prazosin hydrochloride is readily absorbed, and plasma concentrations reach a peak about 3 hours after administration. Plasma half-life is between 2 and 3 hours. Prazosin hydrochloride is highly bound to plasma protein; it does not cause adverse reactions, however, with drugs that might be displaced from their protein-binding sites (e.g., cardiac glycosides). It may cause severe orthostatic hypertension because of its α -adrenergic blocking action, which prevents the reflex venous constriction that is activated when an individual sits up from a prone position.

Terazosin Hydrochloride. Terazosin hydrochloride, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(tetrahydro-2-furoyl)piperazine monohydrochloride (Hytrin), is a structural congener of prazosin hydrochloride. It possesses similar selective properties of specifically inhibiting α_1 -adrenergic receptors. The drug is slightly less potent than prazosin hydrochloride. Terazosin hydrochloride has a half-life of approximately 12 hours, which is much longer than that of prazosin. This lends itself to a once-daily dose to control hypertension in many patients.

Terazosin
(Hytrin)

Doxazosin
(Cardura)

Doxazosin. Doxazosin, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(1,4-benzodioxan-2-ylcarbonyl)piperazine (Cardura), is a quinazoline compound that selectively inhibits the α_1 subtype of α -adrenergic receptors. This agent is very useful in the management of hypertension associated with pheochromocytoma.

CENTRALLY ACTING ADRENERGIC DRUGS

The use of agents that directly affect the peripheral component of the sympathetic nervous system represents an important approach to the treatment of hypertension. A second approach to modifying sympathetic influence on the cardiovascular system is through inhibition or reduction of CNS control of blood pressure. Several widely used medications act by stimulating α_2 receptors, which in the CNS reduces sympathetic outflow to the cardiovascular system and produces a hypotensive effect.

Methyldopate Hydrochloride, USP. Methyldopate hydrochloride, 1-3-(3,4-dihydroxyphenyl)-2-methylalanine ethyl ester hydrochloride (Aldomet ester hydrochloride), α -methyldopa, lowers blood pressure by inhibiting the outflow of sympathetic vasoconstrictor impulses from the brain. Early studies had suggested that the hypotensive action of α -methyldopa was due to the peripheral properties of the drug as a decarboxylase inhibitor or a false transmitter.

The current hypothesis concerning the hypotensive activity of methyldopa involves the CNS as the site of action.⁵⁸ Methyldopa, on conversion to α -methylnorepinephrine, acts on α_2 -adrenergic receptors to inhibit the release of norepinephrine, resulting in decreased sympathetic outflow from the CNS and activation of parasympathetic outflow.

Methyldopa is used as a step 2 agent and is recommended for patients with high blood pressure who are not responsive to diuretic therapy alone. Methyldopa, suitable for oral use, is a zwitterion and is not soluble enough for parenteral use. The problem was solved by making the ester, leaving the amine free to form the water-soluble hydrochloride salt. It is supplied as a stable, buffered solution, protected with antioxidants and chelating agents.

Clonidine Hydrochloride. Clonidine hydrochloride, 2-[(2,6-dichlorophenyl)imino]imidazolidine monohydrochloride (Catapres), was the first antihypertensive known to act on the CNS. It was synthesized in 1962 as a derivative of the known α -sympathomimetic drugs naphazoline and tolazoline, potential nasal vasoconstrictors, but instead it proved to be effective in the treatment of mild-to-severe hypertension.

Clonidine hydrochloride acts by both peripheral and central mechanisms in the body to affect blood pressure. It stimulates the peripheral α -adrenergic receptors to produce vasoconstriction, resulting in a brief period of hypertension. Clonidine hydrochloride acts centrally to inhibit the sympathetic tone and cause hypotension that is of much longer duration than the initial hypertensive effect. Administration of clonidine hydrochloride thus produces a biphasic change in blood pressure, beginning with a brief hypertensive effect and followed by a hypotensive effect that persists for about 4 hours. This biphasic response is altered by dose only: Larger doses produce a greater hypertensive effect and delay the onset of the hypotensive properties of the drug. Clonidine hydrochloride acts on α_2 adrenoreceptors located in the hindbrain to produce its hypotensive action. Clonidine hydrochloride also acts centrally to cause bradycardia and to reduce plasma levels of renin. Sensitization of baroreceptor pathways in the CNS appears to be responsible for the bradycardia transmitted by way of the vagus nerve. The central mechanism that results in decreased plasma renin is not known, however. The hypotensive properties of clonidine in animals can be blocked by applying α -adrenergic blocking agents directly to the brain.⁵⁹

Clonidine hydrochloride has advantages over antihypertensive drugs such as guanethidine monosulfate and prazosin hydrochloride, in that it seldom produces orthostatic hypotensive side effects. It does, however, have some sedative properties that are undesirable; it also may cause constipation and dryness of the mouth.

Clonidine hydrochloride is distributed throughout the body, with the highest concentrations found in the organs of elimination: kidney, gut, and liver. Brain concentrations are low but higher than plasma concentrations. The high concentration in the gut is due to an enterohepatic cycle in which clonidine hydrochloride is secreted into the bile in rather high concentrations. The half-life in humans is about 20 hours. Clonidine hydrochloride is metabolized by the body to form two major metabolites, *p*-hydroxycyclonidine and its glucuronide. *p*-Hydroxycyclonidine does not cross the blood-brain barrier and has no hypotensive effect in humans.

Clonidine
(Catapres)

Guanabenz Acetate. Guanabenz acetate, [(2,6-dichlorobenzylidene)amino]guanidine monoacetate (Wytensin), is a central α_2 -adrenergic agonist that reduces the release of

norepinephrine from the neuron when stimulated. The effect of the drug results in decreased sympathetic tone in the heart, kidneys, and peripheral blood vessels. The drug does not produce orthostatic hypotension.

Guanabenz
(Wytensin)

Guanfacine Hydrochloride. Guanfacine hydrochloride, *N*-(aminoiminomethyl)-2,6-dichlorobenzacetamide (Tenex), is structurally related to clonidine hydrochloride and guanabenz acetate and shares many of their pharmacological properties. The drug has a longer duration of action than either clonidine hydrochloride or guanabenz acetate. It lasts up to 24 hours. It also requires much longer (8 to 12 hours) for a peak effect to occur after the drug is administered.

Guanfacine
(Tenex)

VASODILATORY DRUGS ACTING ON SMOOTH MUSCLE

Reduction of arterial smooth muscle tone may occur by many mechanisms, such as reduction in sympathetic tone, stimulation of β -adrenergic receptors, or even direct action on the vasculature without interference from the autonomic innervation. Drugs acting on the arteriolar smooth muscle also increase sympathetic reflex activity, causing an increase in heart rate and cardiac output and stimulating renin release, which increases sodium retention and plasma volume. As a result, it is common to coadminister saluretics and β -adrenergic blocking drugs with these agents.

Antihypertensive agents that produce vasodilation of smooth muscle can be divided into two categories: direct-acting and indirect-acting vasodilators. Indirect-acting vasodilators may be distinguished from direct-acting vasodilators, in that they produce their effect by interfering with the vasoconstrictor stimuli and their primary site of action is not necessarily the vascular smooth muscle itself. Indirect-acting vasodilators include sympatholytic drugs, such as reserpine; α -adrenergic antagonists, such as prazosin hydrochloride; ACE inhibitors; and angiotensin II receptor antagonists, such as saralysin. Direct-acting vasodilators include hydralazine hydrochloride, sodium nitroprusside, potassium channel openers, and calcium channel-blocking agents.⁶⁰

Hydralazine Hydrochloride, USP. Hydralazine hydrochloride, 1-hydrazinophthalazine monohydrochloride (Apresoline hydrochloride), originated from the work of a chemist⁶⁰ attempting to produce some unusual chemical

Figure 19-21 ■ Metabolism of hydralazine hydrochloride

compounds and from the observation⁶¹ that this compound had antihypertensive properties. It occurs as yellow crystals and is soluble in water to the extent of about 3%. A 2% aqueous solution has a pH of 3.5 to 4.5.

Hydralazine hydrochloride is useful in the treatment of moderate-to-severe hypertension. It is often used in conjunction with less potent antihypertensive agents because side effects occur frequently when it is used alone in adequate doses. In combinations, it can be used in lower and safer doses. Its action appears to be centered on the smooth muscle of the vascular walls, with a decrease in peripheral resistance to blood flow. This results in increased blood flow through the peripheral blood vessels. It also has the unique property of increasing renal blood flow, an important consideration in patients with renal insufficiency.

Hydralazine hydrochloride acts on vascular smooth muscle to cause relaxation. Its mechanism of action is unclear. It interferes with Ca^{2+} entry and Ca^{2+} release from intracellular stores and reportedly causes activation of guanylate cyclase, resulting in increased levels of cGMP. All of these biochemical events can cause vasodilation.

Absorption of hydralazine hydrochloride taken orally is rapid and nearly complete. The maximal hypotensive effect is demonstrable within 1 hour. The drug is excreted rapidly by the kidneys, and within 24 hours, 75% of the total amount administered appears in the urine as metabolites or unchanged drug. Hydralazine hydrochloride undergoes benzylic oxidation, glucuronide formation, and N-acetylation by the microsomal enzymes in the tissues (Fig. 19-21). Acetylation appears to be a major determinant of the rate of hepatic removal of the drug from the blood and, therefore, of systemic availability.⁶² Rapid acetylation results in a highly hepatic extraction ratio from blood and greater first-pass elimination.

Hydralazine
(Apresoline)

Hydralazine hydrochloride is more effective clinically when coadministered with drugs that antagonize adrenergic transmission (e.g., β -adrenergic antagonists, reserpine, guanethidine monosulfate, methyldopa, and clonidine hydrochloride). When given with diuretics, it is useful in the treatment of CHF.

Sodium Nitroprusside, USP. Sodium nitroprusside, sodium nitroferricyanide, disodium pentacyanonitrosylferate(2) $\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}]$ (Nipride, Nitropress), is one of the most potent blood pressure-lowering drugs. Its use is limited to hypertensive emergencies because of its short duration of action. The effectiveness of sodium nitroprusside as an antihypertensive has been known since 1928, but not until 1955 was its efficacy as a drug established.⁶³ The drug differs from other vasodilators, in that vasodilation occurs in both venous and arterial vascular beds. Sodium nitroprusside is a reddish-brown water-soluble powder that is decomposed by light when in solution. The hypotensive effect of the chemical is due to the formation of NO in situ (look under the heading, Nitrovasodilators), elevating cellular levels of cGMP. Sodium nitroprusside is metabolized by the liver, yielding thiocyanate. Because thiocyanate is excreted by the kidneys, patients with impaired renal function may suffer thiocyanate toxicity.

Sodium Nitroprusside
(Nipride)
(Nitropress)

POTASSIUM CHANNEL AGONISTS

The two agents that can be classified in this category are diazoxide and minoxidil. These drugs are also called *potassium channel openers*. These agents activate ATP-sensitive potassium channels, which leads to a decrease of intracellular Ca^{2+} and reduces the excitability of smooth muscle. The primary action of these drugs is to open potassium channels in the plasma membrane of vascular smooth muscle. As efflux of potassium from the cell follows, resulting in hyperpolarization of the membrane, which produces an inhibitory

influence on membrane excitation and subsequent vasodilation.

Diazoxide, USP. Diazoxide is used as the sodium salt of 7-chloro-3-methyl-2*H*-1,2,4-benzothiadiazine 1,1-dioxide (Hyperstat IV). Diazoxide lowers peripheral vascular resistance, increases cardiac output, and does not compromise renal blood flow.

This is a des-sulfamoyl analogue of the benzothiazine diuretics and has a close structural similarity to chlorothiazide. It was developed intentionally to increase the antihypertensive action of the thiazides and to minimize the diuretic effect.

It is used by intravenous injection as a rapidly acting antihypertensive agent for emergency reduction of blood pressure in hospitalized patients with accelerated or malignant hypertension. Over 90% is bound to serum protein, and caution is needed when it is used in conjunction with other protein-bound drugs that may be displaced by diazoxide. The injection is given rapidly by the intravenous route to ensure maximal effect. The initial dose is usually 1 mg/kg body weight, with a second dose given if the first injection does not lower blood pressure satisfactorily within 30 minutes. Further doses may be given at 4- to 24-hour intervals if needed. Oral antihypertensive therapy is begun as soon as possible.

The injection has a pH of about 11.5, which is necessary to convert the drug to its soluble sodium salt. There is no significant chemical decomposition after storage at room temperature for 2 years. When the solution is exposed to light, it darkens.

Diazoxide
(Hyperstat)

Minoxidil, USP. Minoxidil, 2,4-diamino-6-piperidinopyrimidine-3-oxide (Loniten), was developed as a result of steric replacement of a triaminotriazine moiety by triaminopyrimidine. The triaminotriazines were initially observed to be potent vasodilators in cats and dogs following their formation of *N*-oxides in these animals. The triazines were inactive in humans because of their inability to form *N*-oxide metabolites; this led to the discovery of minoxidil. Minoxidil is the only direct-acting vasodilator that requires metabolic activation to produce its antihypertensive effect (Fig. 19-22). It is converted to minoxidil sulfate in the liver by a sulfotransferase enzyme.⁶⁴

The antihypertensive properties of minoxidil are similar to those of hydralazine hydrochloride, in that minoxidil can decrease arteriolar vascular resistance. Minoxidil exerts its vasodilatory action by a direct effect on arteriolar smooth muscle and appears to have no effect on the CNS or on the autonomic nervous system in animals.⁶⁵ The serum half-life is 4.5 hours, and the antihypertensive effect may last up to 24 hours.

Figure 19-22 ■ Activation of minoxidil

Minoxidil is used for severe hypertension that is difficult to control with other antihypertensive agents. The drug has some of the characteristic side effects of direct vasodilatory drugs. It causes sodium and water retention and may require coadministration of a diuretic. Minoxidil also causes reflex tachycardia, which can be controlled by use of a β -adrenergic blocking agent.

Minoxidil topical solution is used to treat alopecia androgenetica (male pattern baldness). Although the mechanism is not clearly understood, topical minoxidil is believed to increase cutaneous blood flow, which may stimulate hair growth. The stimulation of hair growth is attributed to vasodilation in the vicinity of application of the drug, resulting in better nourishment of the local hair follicles.

Minoxidil
(Loniten)

POSITIVE INOTROPIC AGENTS

Agents that successfully increase the force of contraction of the heart may be particularly useful in the treatment of CHF. In CHF, the heart cannot maintain sufficient blood flow to various organs to provide oxygen-rich blood. Agents that increase the force of contraction allow greater amounts of blood to be distributed throughout the body and, in turn, reduce the symptoms associated with CHF. Most of the positive inotropic agents exhibit their effects on the force of contraction by modifying the coupling mechanism involved in the myocardial contractile process.

Digitalis glycosides, a mixture of products isolated from foxglove, *Digitalis* spp., were first used as a heart medication as early as 1500 BC when in the *Ebers Papyrus* the ancient Egyptians reported their success in using these products. Throughout history these plant extracts have also been used as arrow poisons, emetics, and diuretics. The dichotomy of the poisonous effects and the beneficial heart properties is still evident today. Cardiac glycosides are still used today in the treatment of CHF and atrial fibrillation, with careful attention paid to monitoring the toxicity these agents possess.

The cardiac glycosides include two distinct classes of compounds—the cardenolides and the bufadienolides. These differ in the substitutions at the C-17 position, where the cardenolides possess an unsaturated butyrolactone ring, while the bufadienolides have an α -pyrone ring. Pharmacologically, both have similar properties and are found in many of the same natural sources, including plant and toad species. By far, the most important sources include *Digitalis purpurea* and *D. lanata*. In 1785, William Withering published "An Account of the Foxglove and Its Medical Uses: With Practical Remarks on Dropsy and Other Diseases," in which he describes the beneficial use of foxglove in dropsy (edema), which often exists in CHF.

Even with recent advances in synthetic organic chemistry coupled with the use of combinatorial chemistry, no new therapeutics have displaced the cardiac glycosides. Furthermore, the perennial use of these agents over many centuries is even more remarkable when one considers the useful life of a "blockbuster" drug in today's marketplace. This remarkable fact is based, quite simply, on the unique ability of nature to produce extraordinarily bioactive substances, which characteristically possess both a lipophilic portion in the steroidal ring and a hydrophilic moiety in the glycosidic rings. The therapeutic use of these agents depends largely on a balance between the different solubility characteristics of the steroid structure, and the type and number of sugar units attached to it. Although the fundamental pharmacological properties reside with the steroidal nucleus, the sugars play a critical role in the biological effects elicited, since they increase the water solubility of the lipid system, making them more available for translocation in an aqueous environment and, at the same time, allowing transportation across fatty sites. These properties uniquely balance each other and allow successful translocation to the receptive sites in the body. Ultimately, the lipophilic steroid also plays a specific role in the agent's onset and duration of action. As the steroidal rings are modified with polar groups (e.g., hydroxyls), the onset increases and the duration of action decreases. The sugar residues are substituted on C-3 of the steroid and generally are digitoxose, glucose, rhamnose, or cymarose.

The cardiac glycosides elicit their effects through inhibition of the Na^+/K^+ -ATPase pump. Inhibition of this pump increases the intracellular Na^+ concentration, which affects $\text{Na}^+/\text{Ca}^{2+}$ exchange. This increases intracellular concentrations of Ca^{2+} , which is available to activate the contractile proteins actin and myosin, thereby enhancing the force of contraction. Also, it is suggested that these agents have other compensatory mechanisms including baroreceptor sensitivity, which result in improved conditions for patients suffering from CHF.

Digoxin. Digoxin (Lanoxin) is a purified digitalis preparation from *Digitalis lanata* and represents the most widely used digitalis glycoside. This wide use is primarily due to its fast onset and short half-life. Position 3 of the steroid is substituted with three digitoxose residues that, when removed, provide a genin or aglycone steroid that is still capable of receptor binding but with altered pharmacokinetics.

Digitalis. Digitalis (Crystodigin) is isolated from *D. lanata* and *D. purpurea*, among other *Digitalis* spp., and is

the chief active glycoside in digitalis leaf, with 1 mg digitoxin equal to 1 g of digitalis leaf therapy. In patients who miss doses, digitalis is very useful for maintenance therapy because of the longer half-life it provides. The longer duration and increased half-life are due to the lack of the C-12 hydroxy that is present in digoxin. In digoxin, this hydroxy plays two roles: (a) it serves as a site for metabolism, which reduces the compound's half-life; and (b) it gives more hydrophilic character, which results in greater water solubility and ease in renal elimination.

(Lanoxin)

Digitalis
(Crystodigin)

Amrinone. During normal heart function, cAMP performs important roles in regulating intracellular calcium levels.

els. That is, certain calcium channels and storage sites for calcium must be activated by cAMP-dependent protein kinases. Since cAMP plays an indirect role in the contractility process, agents that inhibit its degradation will provide more calcium for cardiac contraction. One phosphodiesterase enzyme that is involved in the hydrolysis of myocardium cAMP is F-III. Amrinone, 5-amino-3,4'-dipyridin-6 1(*H*)-one (Inocor), possesses positive isotropic effects as a result of its ability to inhibit this phosphodiesterase. In 1999, the U. S. Pharmacopoeia (USP) Nomenclature Committee and the United States Adopted Names (USAN) Council approved changing the nonproprietary name and the current official monograph title of amrinone to inamrinone. This change in nomenclature was a result of amrinone being confused with amiodarone because of the similarity of the names. This was reported to cause confusion between the products that led to medication errors, some of which resulted in serious injury or death.

Amrinone
(Inocor)

Milrinone. Milrinone, 1,6-dihydro-2-methyl-6-oxo-3,4'-bipyridine-5-carbonitrile (Primacor), is another dipyridine phosphodiesterase F-III inhibitor that possesses pharmacological properties similar to those of amrinone. The inhibition of the degradation of cAMP results in an increase in the cardiac muscle's force of contraction.

Milrinone
(Primacor)

ANTHYPERLIPIDEMIC AGENTS

The major cause of death in the Western world today is vascular disease, of which the most prevalent form is atherosclerotic heart disease. Although many causative factors of this disease are recognized (e.g., smoking, stress, diet), atherosclerotic disease can be treated through medication or surgery.

Hypertlipidemia is the most prevalent indicator for susceptibility to atherosclerotic heart disease; it is a term used to describe elevated plasma levels of lipids that are usually in the form of lipoproteins. Hypertlipidemia may be caused by

an underlying disease involving the liver, kidney, pancreas, or thyroid, or it may not be attributable to any recognizable disease. In recent years, lipids have been implicated in the development of atherosclerosis in humans. *Atherosclerosis* may be defined as degenerative changes in the intima of medium and large arteries. This degeneration includes the accumulation of lipids, complex carbohydrates, blood, and blood products and is accompanied by the formation of fibrous tissue and calcium deposition on the intima of the blood vessels. These deposits or *plaques* decrease the lumen of the artery, reduce its elasticity, and may create foci for thrombi and subsequent occlusion of the blood vessel.

Lipoprotein Classes

Lipoproteins are macromolecules consisting of lipid substances (cholesterol, triglycerides) noncovalently bound with protein and carbohydrate. These combinations solubilize the lipids and prevent them from forming insoluble aggregates in the plasma. They have a spherical shape and consist of a nonpolar core surrounded by a monolayer of phospholipids whose polar groups are oriented toward the lipid phase of the plasma. Included in the phospholipid monolayer are a small number of cholesterol molecules and proteins termed *apolipoproteins*. The apolipoproteins appear to be able to solubilize lipids for transport in an aqueous surrounding such as plasma (Fig. 19-23).

The various lipoproteins found in plasma can be separated by ultracentrifugal techniques into chylomicrons, very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). These correlate with the electrophoretic separations of the lipoproteins as follows: chylomicrons, pre- β -lipoprotein (VLDL), broad β -lipoprotein (IDL), β -lipoprotein (LDL), and α -lipoprotein (HDL).

Chylomicrons contain 90% triglycerides by weight and originate from exogenous fat from the diet. They are the least dense of the lipoproteins and migrate the least under the

Figure 19-23 ■ Hypothetical model of lipoprotein particle.

influence of an electric current. Chylomicrons are normally absent in plasma after 12 to 24 hours of fasting. The VLDL is composed of about 60% triglycerides, 12% cholesterol, and 18% phospholipids. It originates in the liver from FFAs. Although VLDL can be isolated from plasma, it is catabolized rapidly into IDL, which is degraded further into LDL. Normally, IDL also is catabolized rapidly to LDL, but it is usually not isolated from plasma. The LDL consists of 50% cholesterol and 10% triglycerides. This is the major cholesterol-carrying protein. In normal persons, this lipoprotein accounts for about 65% of the plasma cholesterol and is of major concern in hyperlipidemic disease states. The LDL is formed from the intravascular catabolism of VLDL. The HDL is composed of 25% cholesterol and 50% protein and accounts for about 17% of the total cholesterol in plasma.

Lipoprotein Metabolism

The rate at which cholesterol and triglycerides enter the circulation from the liver and small intestine depends on the supply of the lipid and proteins necessary to form the lipoprotein complexes. Although the protein component must be synthesized, the lipids can be obtained either from de novo biosynthesis in the tissues or from the diet. Reduction of plasma lipids by diet can delay the development of atherosclerosis. Furthermore, the use of drugs that decrease assimilation of lipids into the body plus diet decreases mortality from cardiovascular disease.⁶⁶

Lipid transport mechanisms exist that shuttle cholesterol and triglycerides among the liver, intestine, and other tissues. Normally, plasma lipids, including lipoprotein cholesterol, are cycled into and out of plasma and do not cause extensive accumulation of deposits in the walls of arteries. Genetic factors and changes in hormone levels affect lipid transport by altering enzyme concentrations and apoprotein content, as well as the number and activity of lipoprotein receptors. This complex relationship makes the treatment of all hyperlipoproteinemias by a singular approach difficult, if not impractical.

Lipids are transported by both *exogenous* and *endogenous* pathways. In the exogenous pathway, dietary fat (triglycerides and cholesterol) is incorporated into large lipoprotein particles (chylomicrons), which enter the lymphatic system and are then passed into the plasma. The chylomicrons are acted on by lipoprotein lipase in the adipose tissue capillaries, forming triglycerides and monoglycerides. The FFAs cross the endothelial membrane of the capillary and are incorporated into triglycerides in the tissue for storage as fat or are used for energy by oxidative metabolism. The chylomicron remnant in the capillary reaches the liver and is cleared from the circulation by binding to a receptor that recognizes the apoprotein E and B-48 protein components of the chylomicron remnant.

In the endogenous pathway of lipid transport, lipids are secreted from the liver. These are triglycerides and cholesterol combined with apoprotein B-100 and apoprotein E to form VLDL. The VLDL is acted on by lipoprotein lipase in the capillaries of adipose tissue to generate FFAs and an IDL. Some IDL binds to LDL receptors in the liver and is cleared from plasma by endocytosis. Approximately half of the circulating IDL is converted to LDL in the plasma by additional loss of triglycerides. This LDL has a half-life in

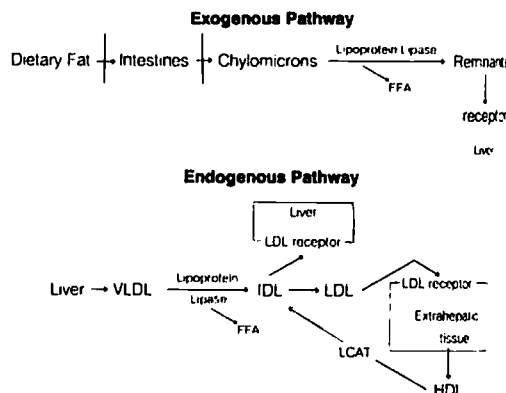

Figure 19-24 ■ Exogenous and endogenous pathways of lipoprotein metabolism.

plasma of about 1.5 days and represents 60 to 70% of the cholesterol in plasma. These LDL particles bind to LDL receptors in extrahepatic tissues and are removed from the plasma. Levels of LDL receptors vary depending on the need of extrahepatic tissues to bind LDL to use cholesterol. The extrahepatic tissue subsequently releases HDL. Free plasma cholesterol can be adsorbed onto HDL and the cholesterol esters formed by the enzyme lecithin-cholesterol acyltransferase (LCAT). These esters are transferred from HDL to VLDL or LDL in plasma to complete the cycle. The pathways for plasma lipoprotein metabolism by the exogenous and endogenous routes are shown in Figure 19-24.

Hyperlipoproteinemias

Lipid disorders are related to problems of lipoprotein metabolism⁶⁷ that create conditions of hyperlipoproteinemia. The hyperlipoproteinemias have been classified into six types, each of which is treated differently (Table 19-6).

The abnormal lipoprotein pattern characteristic of type I is caused by a decrease in the activity of lipoprotein lipase, an enzyme that normally hydrolyzes the triglycerides present in chylomicrons and clears the plasma of this lipoprotein fraction. Because the triglycerides found in chylomicrons come primarily from exogenous sources, this type of hyperlipoproteinemia may be treated by decreasing the intake of dietary fat. There are no drugs at present that can be used to counteract type I hyperlipidemia effectively.

Type II hyperlipoproteinemia has been divided into type IIa and IIb. Type IIa is characterized by elevated levels of LDL (β -lipoproteins) and normal levels of triglycerides. This subtype disorder is very common and may be caused by disturbed catabolism of LDL. Type IIb differs from type IIa, in that this hyperlipidemia has elevated VLDL levels in addition to LDL levels. Type II hyperlipoproteinemia is often clearly familial and frequently inherited as an autosomal dominant abnormality with complete penetrance and expression in infancy. Patients have been treated by using dietary restrictions on cholesterol and saturated fats. This type of hyperlipoproteinemia responds to some form of

TABLE 19-6 Characterization of Hyperlipoproteinemia Types

Hyperlipoproteinemia	Abnormality		Appearance of Plasma ^a	Triglycerides	Total Cholesterol
	Electrophoresis	Ultracentrifuge			
I	Massive chylomicronemia	Clear; creamy layer of chylomicronemia on top	Massively elevated	Slightly to moderately elevated	
IIa	β -Lipoproteins elevated	LDL increased	Clear	Normal	Heavily elevated
IIb	Pre- β -lipoproteins elevated	LDL + VLDL increased	Slightly turbid	Slightly elevated	Heavily elevated
III	Broad β -lipoprotein band	VLDL/LDL of abnormal composition	Slightly turbid to turbid	Elevated	Elevated
IV	Pre- β -lipoproteins elevated	VLDL increased	Turbid	Moderately to heavily elevated	Normal to elevated
V	Pre- β -lipoproteins elevated; chylomicronemia	VLDL increased; chylomicronemia	Turbid; on top, chylomicronemia	Massively elevated	Slightly elevated

Adapted from Witte, E. C.: *Prog. Med. Chem.* 11:199, 1975.

^aAfter having been kept standing at 4° C for 25 hours.

chemotherapy. The combined therapy may bring LDL levels back to normal.

Type III is a rare disorder characterized by a broad band of β -lipoprotein. Like type II, it is also familial. Patients respond favorably to diet and drug therapy.

In type IV hyperlipoproteinemia, levels of VLDL are elevated. Because this type of lipoprotein is rich in triglycerides, plasma triglyceride levels are elevated. The metabolic defect that causes type IV is still unknown; this form of hyperlipidemia, however, responds to diet and drug therapy.

Type V hyperlipoproteinemia has high levels of chylomicrons and VLDL, resulting in high levels of plasma triglycerides. The biochemical defect of type V hyperlipoproteinemia is not understood. Clearance of dietary fat is impaired, and reduction of dietary fat is indicated along with drug therapy.

Clofibrate, USP. Clofibrate, ethyl 2-(*p*-chlorophenoxy)-2-methylpropionate (Atromid-S), is a stable, colorless to pale yellow liquid with a faint odor and a characteristic taste. It is soluble in organic solvents but insoluble in water.

Clofibrate is prepared by a Williamson synthesis, condensing *p*-chlorophenol with ethyl α -bromoisobutyrate, or by the interaction of a mixture of acetone, *p*-chlorophenol, and chloroform in the presence of excess potassium hydroxide. The acid obtained by either of these methods is esterified to give clofibrate. Both acid and ester are active; the latter, however, is preferred for medicinal use. Clofibrate is hydrolyzed rapidly to 2-*p*-chlorophenoxy-2-methylpropionic acid by esterases in vivo and, bound to serum albumin, circulates in blood. The acid has been investigated as a hypolipemic agent. It is absorbed more slowly and to a smaller extent than is the ester. The aluminum salt of the acid gives even lower blood levels than *p*-chlorophenoxy-2-methylpropionic acid.⁶⁸

Clofibrate is the drug of choice in the treatment of type III hyperlipoproteinemias and may also be useful, to a lesser extent, in types IIb and IV hyperlipoproteinemias. The drug is not effective in types I and IIa.

Clofibrate can lower plasma concentrations of both triglycerides and cholesterol, but it has a more consistent clinical effect on triglycerides. It also affects lipoprotein plasma

levels by enhancing removal of triglycerides from the circulation and causes reduction of VLDL by stimulating lipoprotein lipase to increase the catabolism of this lipoprotein to LDL.⁶⁹ Clofibrate lowers triglyceride levels in the serum much more than cholesterol levels and decreases levels of FFAs and phospholipids. The lowering of cholesterol levels may result from more than one mechanism. Clofibrate inhibits the incorporation of acetate into the synthesis of cholesterol, between the acetate and mevalonate step, by inhibiting *sn*-glyceryl-3-phosphate acyltransferase. Clofibrate also regulates cholesterol synthesis in the liver by inhibiting microsomal reduction of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA), catalyzed by HMG-CoA reductase. Clofibrate may lower plasma lipids by means other than impairment of cholesterol biosynthesis, such as increasing excretion through the biliary tract.

Clofibrate is tolerated well by most patients; the most common side effects are nausea and, to a smaller extent, other gastrointestinal distress. The dosage of anticoagulants, if used in conjunction with this drug, should be reduced by one third to one half, depending on the individual response, so that the prothrombin time may be kept within the desired limits.

Clofibrate
(Atromid)

Gemfibrozil. Gemfibrozil, 5-(2,5-dimethylphenoxy)-2,2-dimethylpentanoic acid (Lopid), is a congener of clofibrate that was used first in the treatment of hyperlipoproteinemia in the mid-1970s. Its mechanism of action and use are similar to those of clofibrate. Gemfibrozil reduces plasma levels of VLDL triglycerides and stimulates clearance of VLDL from plasma. The drug has little effect on cholesterol plasma levels but does cause an increase of HDL.

Gemfibrozil is absorbed quickly from the gut and excreted

unchanged in the urine. The drug has a plasma half-life of 1.5 hours, but reduction of plasma VLDL concentration takes between 2 and 5 days to become evident. The peak effect of its hypolipidemic action may take up to 4 weeks to become manifest.

Gemfibrozil
(Lopid)

Fenofibrate. Fenofibrate, 2-[4-(4-chlorobenzoyl)phenoxy]-2-methylpropanoic acid 1-methylethyl ester (Tricor), has structural features represented in clofibrate. The primary difference involves the second aromatic ring. This imparts a greater lipophilic character than exists in clofibrate, resulting in a much more potent hypocholesterolemic and triglyceride-lowering agent. Also, this structural modification results in a lower dose requirement than with clofibrate or gemfibrozil.

Fenofibrate
(Tricor)

Dextrothyroxine Sodium, USP. Dextrothyroxine sodium, *O*-(4-hydroxy-3,5-diiodophenyl)-3,5-diiodo-L-tyrosine monosodium salt hydrate, sodium D-3,3',5,5'-tetraiodothyronine (Choloxin), occurs as a light yellow to buff powder. It is stable in dry air but discolors on exposure to light; hence, it should be stored in light-resistant containers. It is very slightly soluble in water, slightly soluble in alcohol, and insoluble in acetone, chloroform, and ether.

The hormones secreted by the thyroid gland have marked hypocholesterolemic activity along with their other well-known actions. The finding that not all active thyroid principles possessed the same degree of physiological actions led to a search for congeners that would cause a decrease in serum cholesterol levels without other effects such as angina pectoris, palpitation, and congestive failure. D-Thyroxine resulted from this search. At the dosage required, however, L-thyroxine contamination must be minimal; otherwise, it will exert its characteristic actions. One route to optically pure (at least 99% pure) D-thyroxine is the use of an L-amino acid oxidase from snake venom, which acts only on the L isomer and makes separation possible.

The mechanism of action of D-thyroxine appears to be stimulation of oxidative catabolism of cholesterol in the liver through stimulation of 7- α -cholesterol hydroxylase, the rate-limiting enzyme in the conversion of cholesterol to bile acids. The bile acids are conjugated with glycine or taurine and excreted by the biliary route into the feces. Although thyroxine does not inhibit cholesterol biosynthesis, it increases the number of LDL receptors, enhancing removal of LDL from plasma.

Dextrothyroxine
(Choloxin)

Use of thyroxine in the treatment of hyperlipidemias is not without adverse effects. The drug increases the frequency and severity of anginal attacks and may cause cardiac arrhythmias.

D-Thyroxine potentiates the action of anticoagulants such as warfarin or dicumarol; thus, the dosage of the anticoagulants used concurrently should be reduced by one third and then, if necessary, further modified to maintain the prothrombin time within the desired limits. Also, it may increase the dosage requirements for insulin or oral hypoglycemic agents if used concurrently with them.

Cholestyramine Resin, USP. Cholestyramine (Cuemid, Questran) is the chloride form of a strongly basic anion-exchange resin. It is a styrene copolymer with divinylbenzene with quaternary ammonium functional groups. After oral ingestion, cholestyramine resin remains in the gastrointestinal tract, where it readily exchanges chloride ions for bile acids in the small intestine, to be excreted as bile salts in the feces. Cholestyramine resin is also useful in lowering plasma lipids. The reduction in the amounts of reabsorbed bile acids results in increased catabolism of cholesterol in bile acids in the liver. The decreased concentration of bile acids returning to the liver lowers the feedback inhibition by bile acids of 7- α -hydroxylase, the rate-limiting enzyme in the conversion of cholesterol to bile acids, increasing the breakdown of hepatic cholesterol. Although biosynthesis of cholesterol is increased, it appears that the rate of catabolism is greater, resulting in a net decrease in plasma cholesterol levels by affecting LDL clearance. The increase of LDL receptors in the liver that occurs when its content of cholesterol is lowered augments this biochemical event.

Cholestyramine resin does not bind with drugs that are neutral or with amine salts; acidic drugs (in the anion form) could be bound, however. For example, in animal tests, absorption of aspirin given concurrently with the resin was depressed only moderately during the first 30 minutes.

Cholestyramine Resin
(Cholybar)
(Questran)

Cholestyramine resin is the drug of choice for type IIa hyperlipoproteinemia. When used in conjunction with a controlled diet, it reduces β -lipoproteins. The drug is an insoluble polymer and, thus, probably one of the safest because it is not absorbed from the gastrointestinal tract to cause systemic toxic effects.

Colestipol Hydrochloride. Colestipol (Colestid) is a high-molecular-weight, insoluble, granular copolymer of tetraethylenepentamine and epichlorohydrin. It functions as an anion-exchange, resin-sequestering agent in a manner similar to that of cholestyramine resin. Colestipol hydrochloride reduces cholesterol levels without affecting triglycerides and seems to be especially effective in the treatment of type II hyperlipoproteinemias.

Colestipol
(Colestid)

Colesevelam. Colesevelam (Welchol) is one of the more recent additions to the class of bile acid-sequestering agents. Its structure is rather novel, and at first glance, it appears to look like the previous examples of cholestyramine and colestipol. It does not possess the chloride ions, however, and, strictly speaking, is not an anion-exchange resin. This compound has good selectivity for both the trihydroxy and dihydroxy bile acids. The selectivity for these hydroxylated derivatives lends some insight into the reduced side effects colesevelam possesses, compared with cholestyramine and colestipol. Unlike the older agents, colesevelam does not have a high incidence of causing constipation. This results from the compound's ability to "pick up" water because of its affinity for hydroxyl system (i.e., hydrogen bonding with either the bile acid or water). In turn, this yields softer, gel-like materials that are easier to excrete.

Colesevelam
(Welchol)

Nicotinic Acid. Nicotinic acid, 3-pyridinecarboxylic acid (Niacin), is effective in the treatment of all types of hyperlipoproteinemia except type I, at doses above those given as a vitamin supplement. The drug reduces VLDL

synthesis and, subsequently, its plasma products, IDL and LDL. Plasma triglyceride levels are reduced because of the decreased VLDL production. Cholesterol levels are lowered, in turn, because of the decreased rate of LDL formation from VLDL. Although niacin is the drug of choice for type II hyperlipoproteinemias, its use is limited because of the vasodilating side effects. Flushing occurs in practically all patients but generally subsides when the drug is discontinued.

The hypolipidemic effects of niacin may be due to its ability to inhibit lipolysis (i.e., prevent the release of FFAs and glycerol from fatty tissues). As a consequence, there is a reduced reserve of FFA in the liver and diminution of lipoprotein biosynthesis, which reduces the production of VLDL. The decreased formation of lipoproteins leads to a pool of unused cholesterol normally incorporated in VLDL. This excess cholesterol is then excreted through the biliary tract.

Niacin (nicotinic acid) may be administered as aluminum nicotinate (Nicalax). This is a complex of aluminum hydroxy nicotinate and niacin. The aluminum salt is hydrolyzed to aluminum hydroxide and niacin in the stomach. The aluminum salt seems to have no advantage over the free acid. Hepatic reaction appears more prevalent than with niacin.

Nicotinic acid has been esterified to prolong its hypolipidemic effect. Pentaerythritol tetranicotinate has been more effective experimentally than niacin in reducing cholesterol levels in rabbits. Sorbitol and myo-inositol hexanicotinate polyesters have been used in the treatment of patients with atherosclerosis obliterans.

The usual maintenance dose of niacin is 3 to 6 g/day given in three divided doses. The drug is usually given at meal-times to reduce the gastric irritation that often accompanies large doses.

Nicotinic Acid
(Niacin)

β -Sitosterol. Sitosterol is a plant sterol, whose structure is identical with that of cholesterol, except for the substituted ethyl group on C-24 of its side chain. Although the mechanism of its hypolipidemic effect is not clearly understood, it is suspected that the drug inhibits the absorption of dietary cholesterol from the gastrointestinal tract. Sitosterols are absorbed poorly from the mucosal lining and appear to compete with cholesterol for absorption sites in the intestine.

β -Sitosterol

Probucol, USP. Probucol, 4,4'-[(1-methylethylidene)-bis(thio)]bis[2,6-bis(1,1-dimethylethyl)phenol], DH-581 (Lorelco), is a chemical agent that was developed for the plastics and rubber industry in the 1960s. The probucol molecule has two tertiary butylphenol groups linked by a dithio-propylidene bridge, giving it a high lipophilic character with strong antioxidant properties. In humans, it causes reduction of both liver and serum cholesterol levels, but it does not alter plasma triglycerides. It reduces LDL and (to a lesser extent) HDL levels by a unique mechanism that is still not clearly delineated. The reduction of HDL may be due to the ability of probucol to inhibit the synthesis of apoprotein A-1, a major protein component of HDL.⁷⁰ It is effective at reducing levels of LDL and is used in hyperlipoproteinemias characterized by elevated LDL levels.

Probucol
(Lorelco)

HMG-CoA Reductase Inhibitors

Drugs in this class of hypolipidemic agents inhibit the enzyme HMG-CoA reductase, responsible for the conversion of HMG-CoA to mevalonate in the synthetic pathway for the synthesis of cholesterol (Fig. 19-25). HMG-CoA reductase is the rate-limiting catalyst for the irreversible conversion of HMG-CoA to mevalonic acid in the synthesis of cholesterol. The activity of HMG-CoA reductase is also under feedback regulation. When cholesterol is available in sufficient amounts for body needs, the enzyme activity of HMG-CoA reductase is suppressed.

Elevated plasma cholesterol levels have been correlated with an increase in cardiovascular disease. Of the plasma lipoproteins, the LDL fraction contains the most cholesterol. The source of cholesterol in humans is either the diet or de novo synthesis with the reduction of HMG-CoA by HMG-CoA reductase as the rate-limiting step. Ingested cholesterol as the free alcohol or ester is taken up after intestinal absorption and transported to the liver and other body organs through the exogenous pathway (Fig. 19-25). The LDL delivers cholesterol to peripheral cells. This process occurs after binding of LDL to specific LDL receptors located on

the surface of cell membranes. After binding and endocytosis of the receptor and LDL, lysosomal degradation of this complex in the cell makes cholesterol available for use in cellular membrane synthesis. It is generally accepted that total plasma cholesterol is lowered most effectively by reducing LDL levels. Therefore, the population of LDL receptors is an important component of clearing the plasma of cholesterol. HMG-CoA reductase inhibitors contribute to this by directly blocking the active site of the enzyme. This action has a twofold effect on cholesterol plasma levels; it causes a decrease in de novo cholesterol synthesis and an increase in hepatic LDL receptors. These HMG-CoA reductase inhibitors are effective hypocholesteremic agents in patients with familial hypercholesteremia.

Three drugs, lovastatin, simvastatin, and pravastatin, comprise the list of approved HMG-CoA reductase inhibitors for the treatment of hyperlipidemia in patients. The three drugs have structures similar to the substrate, HMG-CoA, of the enzyme HMG-CoA reductase. Lovastatin and simvastatin are lactones and prodrugs, activated by hydrolysis in the liver to their respective β -hydroxy acids. Pravastatin, in contrast, is administered as the sodium salt of the β -hydroxy acid.

Lovastatin. Lovastatin, 2-methylbutanoic acid 1,2,3,7,8,8a-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2H-pyran-2-yl)ethyl]-1-naphthalenyl ester, mevinolin, MK-803 (Mevacor) (formerly called mevinolin), is a potent inhibitor of HMG-CoA. The drug was obtained originally from the fermentation products of the fungi *Aspergillus terreus* and *Monascus ruber*. Lovastatin was one of two original HMG-CoA reductase inhibitors. The other drug, mevastatin (formerly called compactin), was isolated from cultures of *Penicillium citrium citrinum*. Mevastatin was withdrawn from clinical trials because it altered intestinal morphology in dogs. This effect was not observed with lovastatin. For inhibitory effects on HMG-CoA reductase, the lactone ring must be hydrolyzed to the open-ring heptanoic acid.

Lovastatin
(Mevacor)

Figure 19-25 ■ HMG-CoA reductase reaction.

Simvastatin. Simvastatin, 2,2-dimethyl butanoic acid, 1,2,3,7,8,8a-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2-pyran-2-yl)ethyl]-1-naphthalenyl ester (Zocor), is an analogue of lovastatin. These two drugs have many similar properties. Both drugs, in the prodrug form, reach the liver unchanged after oral administration, where they undergo extensive metabolism to a number of opening hydroxy acids, including the active β -hydroxy acids. They are also highly bound to plasma proteins. These actions make the bioavailability of simvastatin rather poor but better than that of lovastatin, which has been estimated to be 5%.

Pravastatin. Pravastatin, sodium 1,2,6,7,8,8a-hexahydro- β , δ ,6-trihydroxy-2-methyl-8-(2-methyl-1-oxobutoxy)-1-naphthaleneheptanoate (Pravachol), is the most rapid-acting of the three HMG-CoA reductase inhibitor drugs, reaching a peak concentration in about 1 hour. The sodium salt of the β -hydroxy acid is more hydrophilic than the lactone form of the other two agents, which may explain this property. In addition, the open form of the lactone ring contributes to a more hydrophilic agent, which, in turn, results in less CNS penetration. This explains, in part, why pravastatin has fewer CNS side effects than the more lipophilic lactone ester of this class of agents. Absorption of pravastatin following oral administration can be inhibited by resins such as cholestyramine because of the presence of the carboxylic acid function on the drug. The lactone forms of lovastatin and simvastatin are less affected by cholestyramine.

Fluvastatin. Fluvastatin, [$R^*,S^*-(E)$]-(\pm)-7-[3-(4-fluorophenyl)-1-(1-methylethyl)-1H-indol-2-yl]-3,5-dihydroxy-6-heptenoic acid monosodium salt (Lescol), is very similar to pravastatin. It possesses a heptanoic acid side chain that is superimposable over the lactone ring found in lovastatin and simvastatin. It is this side chain that is recognized by HMG-CoA reductase. Also, much like pravastatin, the CNS side effects of this lipid-lowering agent are much

lower than those of the agents that possess a lactone ring as part of their architectural design.

Atorvastatin. Atorvastatin, [$R^*(R^*,R^*)$]-2-(4-fluorophenyl)-b,d-dihydroxy-5-(1-methylethyl)-3-phenyl-4 [(phenylamino)carbonyl]-1H-pyrrole-1-heptanoic acid (Lipitor), also possesses the heptanoic acid side chain, which is critical for inhibition of HMG-CoA reductase. Although the side chain is less lipophilic than the lactone form, the high amount of lipophilic substitution causes this agent to have a slightly higher level of CNS penetration than pravastatin, resulting in a slight increase in CNS side effects. Even so, its CNS profile is much lower than that of lovastatin.

Cerivastatin. Cerivastatin (Baycol) is one of the newer agents in this class of cholesterol-lowering agents. It carries, however, a higher incidence of rhabdomyolysis and, as a result, was voluntarily withdrawn from the market by its manufacturer in 2001.

ANTICOAGULANTS

A theory of blood clotting introduced in 1905 was based on the existence of four factors: thromboplastin (thrombokinase), prothrombin, fibrinogen, and ionized calcium. The clotting sequence proposed was that when tissue damage occurred, thromboplastin entered the blood from the platelets

TABLE 19-7 Roman Numerical Nomenclature of Blood-Clotting Factors and Some Common Synonyms

Factor	Synonyms
I	Fibrinogen
II	Prothrombin
III	Thromboplastin, tissue factor
IV	Calcium
V	Proaccelerin, accelerator globulin, labile factor
VI	(This number is not now used)
VII	Proconvertin, stable factor, autoprothrombin I, SPCA
VIII	Antihemophilic factor, antihemophilic globulin, platelet cofactor I, antihemophilic factor A
IX	Plasma thromboplastin component (PTC), Christmas factor, platelet cofactor II, autoprothrombin II, antihemophilic factor B
X	Stuart-Power factor, Stuart factor, autoprothrombin III
XI	Plasma thromboplastin antecedent (PTA), antihemophilic factor C
XII	Hageman factor
XIII	Fibrin-stabilizing factor, fibrinase, Laki-Lorand factor

and reacted with prothrombin in the presence of calcium to form thrombin. Thrombin then reacted with fibrinogen to form insoluble fibrin, which enmeshed red blood cells to create a clot. The concept remained unchallenged for almost 50 years, but it has now been modified to accommodate the discovery of numerous additional factors that enter into the clotting mechanism (Table 19-7).

Mechanism of Blood Coagulation

The fluid nature of blood can be attributed to the flat cells (endothelial) that maintain a nonthrombogenic environment in the blood vessels. This is a result of at least four phenomena: (a) the maintenance of a transmural negative electric charge that prevents adhesion between platelets; (b) the release of a plasmatogen activator, which activates the fibrinolytic pathway; (c) the release of thrombomodulin, a cofactor that activates protein C, a coagulation factor inhibitor; and (d) the release of PGI₂, a potent inhibitor of platelet aggregation.

The process of blood coagulation (Fig. 19-26) involves a series of steps that occur in a cascade and terminate in the formation of a fibrin clot. Blood coagulation occurs by activation of either an intrinsic pathway, a relatively slow process of clot formation, or an extrinsic pathway, which has a much faster rate of fibrin formation. Both pathways merge into a common pathway for the conversion of prothrombin to thrombin and subsequent transformation of fibrinogen to the insoluble strands of fibrin. Lysis of intravascular clots occurs through a plasminogen-plasmin system, which consists of plasminogen, plasmin, urokinase, kallikrein, plasminogen activators, and some undefined inhibitors.

The *intrinsic* pathway refers to the system for coagulation that occurs from the interaction of factors circulating in the blood. It is activated when blood comes into contact with a

Figure 19-26 ■ Scheme of blood coagulation and fibrinolysis. *, a vitamin K-dependent factor; †, inhibition by heparin and antithrombin III.

damaged vessel wall or a foreign substance. Each of the plasma coagulation factors (Table 19-7), with the exception of factor III (tissue thromboplastin), circulates as an inactive proenzyme. Except for fibrinogen, which precipitates as fibrin, these factors are usually activated by enzymatic removal of a small peptide in the cascade of reactions that make up the clotting sequence (Fig. 19-26). The *extrinsic* clotting system refers to the mechanism by which thrombin is generated in plasma after the addition of tissue extracts. When various tissues, such as brain or lung (containing thromboplastin), are added to blood, a complex between thromboplastin and factor VII in the presence of calcium ions activates factor X, bypassing the time-consuming steps of the intrinsic pathway that form factor X.

The intrinsic and extrinsic pathways interact *in vivo*. Small amounts of thrombin formed early after stimulation of the extrinsic pathway accelerate clotting by the intrinsic pathway by activating factor VIII. Thrombin also speeds up the clotting rate by activating factor V, located in the common pathway. Thrombin then converts the soluble protein fibrinogen into a soluble fibrin gel by acting on Gly-Arg bonds to remove small fibrinopeptides from the N terminus, enabling the remaining fibrinogen molecule to polymerize. It also activates factor XIII, which stabilizes the fibrin gel in the presence of calcium by cross-linking between the chains of the fibrin monomer through intermolecular γ -glutamyl-lysine bridges to form an insoluble mass.

Anticoagulant Mechanisms

In the milieu of biochemicals being formed to facilitate the clotting of blood, the coagulation cascade *in vivo* is con-

trolled by a balance of inhibitors in the plasma to prevent all of the blood in the body from solidifying. Thrombin plays a pivotal role in blood coagulation. It cleaves fibrinogen, a reaction that initiates formation of the fibrin gel, which constitutes the framework of the blood clot. As mentioned above, it activates the cofactors factor V and factor VIII to accelerate the coagulation process. Intact endothelial cells express a receptor, thrombomodulin, for thrombin. When thrombin is bound to thrombomodulin, it does not have coagulant activity, which thus prevents clot formation beyond damaged areas and onto intact endothelium. In this bound state, however, thrombin does activate protein C, which then inactivates two cofactors and impedes blood clotting. Thrombin also activates factor XIII, leading to cross-linking of the fibrin gel. The activity of thrombin is regulated by its inactivation by plasma protein inhibitors: α_1 -proteinase inhibitor, α_2 -macroglobulin, antithrombin (antithrombin III), and heparin cofactor II. These belong to a family of proteins called *serpins*, an acronym for *serine protease inhibitors*.

Antithrombin III, an α_2 -globin, neutralizes thrombin and the serine proteases in the coagulation cascade—Xa, IXa, XIa, and XIIa. Although antithrombin III is a slow-acting inhibitor, it becomes a rapid-acting inhibitor of thrombin in the presence of heparin. Heparin is a naturally occurring anticoagulant that requires antithrombin III (see above) for its biological property of preventing blood clot formation. It binds at the lysine site of the antithrombin III molecule, causing a change in the conformation of antithrombin III and increasing its anticoagulant properties. Heparin can then dissociate from antithrombin III to bind to another antithrombin III molecule. An additional system, which controls unwanted coagulation, involves protein C, a vitamin K-dependent zymogen in the plasma. Protein C is converted to a serine protease when thrombin and factor Xa, formed in the blood in the coagulation cascade, interact with thrombomodulin. The now-activated protein C inhibits factors V and VIII and, in so doing, blocks further production of thrombin. Protein C also enhances fibrinolysis by causing release of the tissue plasminogen activator.

The biosynthesis of prothrombin (factor II) depends on an adequate supply of vitamin K. A deficiency of vitamin K results in the formation of a defective prothrombin molecule. The defective prothrombin is antigenically similar to normal prothrombin but has reduced calcium-binding ability and no biological activity. In the presence of calcium ions, normal prothrombin adheres to the surface of phospholipid vesicles and greatly increases the activity of the clotting mechanism. The defect in the abnormal prothrombin is in the NH_2 -terminal portion, in which the second carboxyl residue has not been added to the γ -carbon atom of some glutamic acid residues on the prothrombin molecule to form γ -carboxyglutamic acid.⁷¹ Administration of vitamin K antagonists decreases synthesis of a biologically active prothrombin molecule and increases the clotting time of blood in humans.⁷²

Vitamin K is critical to the formation of clotting factors VII, IX, and X. These factors are glycoproteins that have γ -carboxyglutamic acid residues at the N-terminal end of the peptide chain. The enzyme involved in forming an active prothrombin is a vitamin K-dependent carboxylase located in the microsomal fraction of liver cells. It has been sug-

gested that vitamin K drives the carboxylase reaction by abstracting a proton from the relatively unreactive methylene carbon of the glutamyl residue, forming a 2,3-epoxide. Oral anticoagulants interfere with the γ -carboxylation of glutamic acid residues by preventing the reduction of vitamin K to its hydroquinone form (Fig. 19-27).

Hemophilia A, a blood disease characterized by a deficiency of coagulation factor VIII, is the most common inherited blood coagulation disorder. Treatment of this disease over the past 25 years has depended on the concentration of the antihemophilic factor (factor VIII) by cryoprecipitation and immunoaffinity chromatography separation technology. The impact of this therapy has been diminished by the presence of viruses that cause the acquired immunodeficiency syndrome (AIDS) and other less tragic viral diseases in humans. Recombinant antihemophilic factor preparations have been produced since 1989 with use of mammalian cells genetically altered to secrete human factor VIII. Kogenate and Helixate are recombinant preparations, obtained from genetically altering baby hamster kidney cells that contain high concentrations of factor VIII. Recombinant factor VIIa, an active factor in the extrinsic pathway, now in phase III clinical trials (Novo Seven), has been used to treat patients with hemophilia A factor VII deficiency. Hemophilia B, another genetic blood disorder, which constitutes about 20% of hemophilia cases, is caused by a deficiency of factor IX and has been treated from cryoprecipitated fractions obtained from plasma. Monoclonal antibody technology has produced an essentially pure, carrier-free preparation of native factor IX (Mononine). Recombinant technology has solved the problem of limited supply and viral contamination of these critical blood factors.

Platelet Aggregation and Inhibitors

Blood platelets play a pivotal role in hemostasis and thrombus formation. Actually, they have two roles in the cessation of bleeding: a hemostatic function, in which platelets, through their mass, cause physical occlusion of openings in blood vessels, and a thromboplastic function, in which the chemical constituents of the platelets take part in the blood coagulation mechanism. The circulatory system is self-sealing because of the clotting properties of blood. The pathological formation of clots within the circulatory system, however, creates a potentially serious clinical situation that must be dealt with through the use of anticoagulants.

Platelets do not adhere to intact endothelial cells. They do become affixed to subendothelial tissues, which have been exposed by injury, to cause hemostasis. Platelets bind to collagen in the vessel wall and trigger other platelets to adhere to them. This adhesiveness is accompanied by a change in shape of the platelets and may be caused by mobilization of calcium bound to the platelet membrane. The growth of the platelet mass depends on the adenosine diphosphate (ADP) released by the first few adhering cells and enhances the aggregation process. A secondary phase (phase II) immediately follows, with additional platelet aggregation. In this secondary phase, the platelets undergo a secretory process during which enzymes such as cathepsin and acid hydrolases, along with fibrinogen, are released from α granules in the platelets and ADP, ATP, serotonin, and calcium are released from dense bodies in the platelets. The dense bodies

Figure 19-27 ■ Mechanism of action of vitamin K and sites of action of warfarin.

are likened to the storage granules associated with adrenergic neurons. Increased levels of cAMP inhibit platelet aggregation. cAMP activates specific dependent kinases, which form protein-phosphate complexes that chelate calcium ions. The reduced levels of calcium inhibit aggregation (Fig. 19-28). Inhibitors of platelet aggregation can increase cAMP levels by either stimulating adenylate cyclase or inhibiting phosphodiesterase.⁷² Substances such as glucagon, adenosine, and isoproterenol increase cAMP levels and inhibit platelet aggregation. Drugs such as theophylline, aminophylline, dipyridamole, papaverine, and adenosine inhibit phosphodiesterase and aggregation of platelets. Epinephrine, collagen, and serotonin inhibit adenylate cyclase and stimulate platelet aggregation.⁷³ The role of platelets in arterial thrombosis is

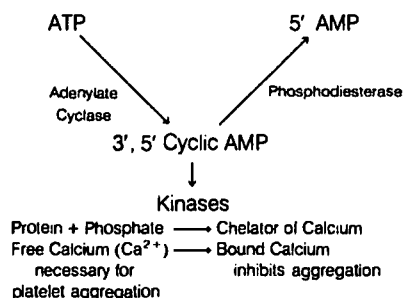

Figure 19-28 ■ Role of adenosine 3',5'-cyclic monophosphate (cAMP) in inhibition of platelet aggregation.

similar to that in hemostasis. The factors contributing to venous thrombosis are circulatory stasis, excessive generation of thrombin formation of fibrin, and, to a lesser extent than in the artery, platelet aggregation.

Aspirin, sulfinpyrazone, and indomethacin have an inhibitory effect on platelet aggregation. They inhibit cyclooxygenase, the enzyme that controls the formation of prostaglandin endoperoxides and increases the tendency for platelets to aggregate.⁷⁴ Aspirin also inhibits the platelet-release reaction. Dipyridamole inhibits adenosine deaminase and adenosine uptake by platelets. As a result, the increased plasma concentrations of adenosine inhibit ADP-induced aggregation of platelets.

Among the many pharmacological actions of prostaglandins is the ability of some to stimulate or inhibit the aggregation of platelets and alter the clotting time of blood. Prostaglandins are synthesized from 20-carbon polyunsaturated fatty acids containing from three to five double bonds. These fatty acids are present in the phospholipids of cell membranes of all mammalian tissues. The main precursor of prostaglandins is arachidonic acid. Arachidonic acid is released from membrane phospholipids by the enzyme phospholipase A_2 . Once released, arachidonic acid is metabolized by cyclooxygenase synthetase to form unstable cyclic endoperoxides, PGG_2 and PGH_2 , which subsequently are transformed into PGI_2 and thromboxane A_2 (TXA_2). The conversion to TXA_2 is aided by the enzyme thromboxane synthetase. The formation of PGI_2 can occur nonenzymatically. Blood platelets convert arachidonic acid to TXA_2 , whereas PGI_2 is formed mainly by the vascular endothelium.

Both PGI_2 and TXA_2 are unstable at physiological pH and temperatures. Their half-lives are 2 to 3 minutes.

PGI_2 inhibits platelet aggregation by stimulating adenylate cyclase to increase cAMP levels in the platelets. PGI_2 is also a vasodilator and, as a result, has potent hypotensive properties when given intravenously or by intra-arterial administration. TXA_2 induces platelet aggregation. Together with PGI_2 , TXA_2 plays a role in the maintenance of vascular homeostasis. In addition to being a platelet aggregator, TXA_2 is a potent vasoconstrictor.

Retardation of clotting is important in blood transfusions, to avoid thrombosis after surgery or from other causes, to prevent recurrent thrombosis in phlebitis and pulmonary embolism, and to lessen the propagation of clots in the coronary arteries. This retardation may be accomplished by agents that inactivate thrombin (heparin) or substances that prevent the formation of prothrombin in the liver (the coumarin derivatives and the phenylindanedione derivatives).

Although heparin is a useful anticoagulant, it has limited applications. Many of the anticoagulants in use today were developed following the discovery of dicumarol, an anticoagulant present in spoiled sweet clover. These compounds are orally effective, but there is a lag period of 18 to 36 hours before they increase the clotting time significantly. Heparin, in contrast, produces an immediate anticoagulant effect after intravenous injection. A major disadvantage of heparin is that the only effective therapeutic route is parenteral.

Dicumarol and related compounds are not vitamin K antagonists in the classic sense. They appear to act by interfering with the function of vitamin K in the liver cells, which are the sites of synthesis of the clotting factors, including prothrombin. This lengthens the clotting time by decreasing the amount of biologically active prothrombin in the blood.

The discovery that dicumarol and related compounds were potent reversible competitors of vitamin K coagulant-promoting properties (although at high levels dicumarol is not reversed by vitamin K) led to the development of anti-vitamin K compounds such as phenindione, which was designed in part according to metabolite-antimetabolite concepts. The active compounds of the phenylindanedione series are characterized by a phenyl, a substituted phenyl, or a diphenylacetyl group in the 2 position. Another requirement for activity is a keto group in the 1 and 3 positions, one of which may form the enol tautomer. A second substituent, other than hydrogen, at the 2 position prevents this keto-enol tautomerism, and the resulting compounds are ineffective as anticoagulants.

PRODUCTS

Protamine Sulfate, USP. Protamine sulfate has an anticoagulant effect, but if used in the proper amount, it counteracts the action of heparin and is used as an antidote for the latter in cases of overdosage. It is administered intravenously in a dose that depends on the circumstances.

Dicumarol, USP. Dicumarol, 3,3'-methylenebis[4-hydroxycoumarin], is a white or creamy white crystalline powder with a faint, pleasant odor and a slightly bitter taste. It is practically insoluble in water or alcohol, slightly soluble in chloroform, and dissolved readily by solutions of fixed

alkalies. The effects after administration require 12 to 72 hours to develop and persist for 24 to 96 hours after discontinuance.

Dicumarol

Dicumarol is used alone or as an adjunct to heparin in the prophylaxis and treatment of intravascular clotting. It is used in postoperative thrombophlebitis, pulmonary embolus, acute embolic and thrombotic occlusion of peripheral arteries, and recurrent idiopathic thrombophlebitis. It has no effect on an already-formed embolus but may prevent further intravascular clotting. Because the outcome of acute coronary thrombosis depends largely on extension of the clot and formation of mural thrombi in the heart chambers, with subsequent embolization, dicumarol has been used in this condition. It has also been administered to arrest impending gangrene after frostbite. The dose, after determination of the prothrombin clotting time, is 25 to 200 mg, depending on the size and the condition of the patient. The drug is given orally in the form of capsules or tablets. On the second day and thereafter, it may be given in amounts sufficient to maintain the prothrombin clotting time at about 30 seconds. If hemorrhages should occur, a dosage of 50 to 100 mg of menadione sodium bisulfite is injected, supplemented by a blood transfusion.

Warfarin Sodium, USP. Warfarin sodium, 3-(α -acetylbenzyl)-4-hydroxycoumarin sodium salt (Coumadin, Panwarfin), is a white, odorless, crystalline powder, with a slightly bitter taste; it is slightly soluble in chloroform and soluble in alcohol or water. A 1% solution has a pH of 7.2 to 8.5.

By virtue of its great potency, warfarin sodium at first was considered unsafe for use in humans and was used very effectively as a rodenticide, especially against rats. At the proper dosage level, however, it can be used in humans, especially by the intravenous route.

Warfarin Sodium
(Coumadin)

Warfarin Potassium, USP. Warfarin potassium, 3-(α -acetylbenzyl)-4-hydroxycoumarin potassium salt (Athrombin-K), is readily absorbed after oral administration,

and a therapeutic hypoprothrombinemia is produced within 12 to 24 hours after administration of 40 to 60 mg. This salt is therapeutically interchangeable with warfarin sodium.

Anisindione, USP. Anisindione, 2-(*p*-methoxyphenyl)-1,3-indandione, 2-(*p*-anisyl)-1,3-indandione (Miradon), is a *p*-methoxy congener of phenindione. It is a white, crystalline powder, slightly soluble in water, tasteless, and absorbed well after oral administration.

Anisindione
(Miradon)

In instances when the urine may be alkaline, an orange color may be detected. This is due to metabolic products of anisindione and is not hematuria.

SYNTHETIC HYPOGLYCEMIC AGENTS

The discovery that certain organic compounds will lower the blood sugar level is not recent. In 1918, guanidine was shown to lower the blood sugar level. The discovery that certain trypanosomes need much glucose and will die in its absence was followed by the discovery that galegine lowered the blood sugar level and was weakly trypanocidal. This led to the development of several very active trypanocidal agents, such as the bisamidines, diisothioureas, bisguanidines, and others. Synthalin (trypanocidal at 1:250 million) and pentamidine are outstanding examples of very active trypanocidal agents. Synthalin lowers the blood sugar level in normal, depancreatized, and completely alloxanized animals. This may be due to reduced oxidative activity of mitochondria, resulting from inhibition of the mechanisms that simultaneously promote phosphorylation of ADP and stimulate oxidation by nicotinamide adenine dinucleotide (NAD) in the citric acid cycle. Hydroxystilbamidine isethionate, USP, is used as an antiprotozoan agent.

Galegine

Pentamidine

Synthalin

In 1942, *p*-aminobenzenesulfonamidoisopropylthiadiazole (an antibacterial sulfonamide) was found to produce hypoglycemia. These results stimulated research for the development of synthetic hypoglycemic agents, several of which are in use today.

Sulfonylureas became widely available in 1955 for the treatment of non-ketosis-prone mild diabetes and are still the drugs of choice. A second class of compounds, the biguanides, in the form of a single drug, phenformin, has been used since 1957. Phenformin was withdrawn from the U.S. market, however, because it causes lactic acidosis, from which fatalities have been reported.

Phenformin

Sulfonylureas

The sulfonylureas may be represented by the following general structure:

These are urea derivatives with an arylsulfonyl group in the 1 position and an aliphatic group at the 3 position. The aliphatic group, R', confers lipophilic properties to the molecule. Maximal activity results when R' consists of three to six carbon atoms, as in chlorpropamide, tolbutamide, and acetohexamide. Aryl groups at R' generally give toxic compounds. The R group on the aromatic ring primarily influences the duration of action of the compound. Tolbutamide disappears quite rapidly from the bloodstream by being metabolized to the inactive carboxy compound, which is excreted rapidly. Chlorpropamide, however, is metabolized more slowly and persists in the blood much longer.

The mechanism of action of the sulfonylureas is to stimulate the release of insulin from the functioning β cells of the intact pancreas. In the absence of the pancreas, they have no significant effect on blood glucose. The sulfonylureas may have other actions, such as inhibition of secretion of glucagon and action at postreceptor intracellular sites to increase insulin activity.

For a time, tolbutamide, chlorpropamide, and acetohexamide were the only oral hypoglycemic agents. Subsequently, a second generation of these drugs became available. Although they did not present a new method of lowering blood glucose levels, they were more potent than the existing drugs. Glipizide and glyburide are the second-generation oral hypoglycemic agents.

Whether they are first- or second-generation oral hypogly-

cemic drugs, this group of agents remains a valuable adjunct to therapy in adult-onset diabetes patients. Accordingly, the sulfonylureas are not indicated in juvenile-onset diabetes.

Tolbutamide, USP. Tolbutamide, 1-butyl-3-(*p*-tolylsulfonyl)urea (Orinase), occurs as a white, crystalline powder that is insoluble in water and soluble in alcohol or aqueous alkali. It is stable in air.

Tolbutamide
(Orinase)

Tolbutamide is absorbed rapidly in responsive diabetic patients. The blood sugar level reaches a minimum after 5 to 8 hours. It is oxidized rapidly *in vivo* to 1-butyl-3-(*p*-carboxyphenyl)sulfonylurea, which is inactive. The metabolite is freely soluble at urinary pH; if the urine is strongly acidified, however, as in the use of sulfosalicylic acid as a protein precipitant, a white precipitate of the free acid may be formed.

Tolbutamide should be used only when the diabetic patient is an adult or shows adult-onset diabetes, and the patient should adhere to dietary restrictions.

Tolbutamide Sodium, USP. Tolbutamide sodium, 1-butyl-3-(*p*-tolylsulfonyl)urea monosodium salt (Orinase Diagnostic), is a white, crystalline powder, freely soluble in water, soluble in alcohol and chloroform, and very slightly soluble in ether.

Tolbutamide Sodium

This water-soluble salt of tolbutamide is used intravenously for the diagnosis of mild diabetes mellitus and of functioning pancreatic islet cell adenomas. The sterile dry powder is dissolved in sterile water for injection to make a clear solution, which then should be administered within 1

hour. The main route of breakdown is to butylamine and sodium *p*-toluene sulfonamide.

Chlorpropamide, USP. Chlorpropamide, 1-[(*p*-chlorophenyl)sulfonyl]-3-propylurea (Diabinese), is a white, crystalline powder, practically insoluble in water, soluble in alcohol, and sparingly soluble in chloroform. It will form water-soluble salts in basic solutions. This drug is more resistant to conversion to inactive metabolites than is tolbutamide and, as a result, has a much longer duration of action. One study showed that about half of the drug is excreted as metabolites, with the principal one being hydroxylated in the 2 position of the propyl side chain.⁷⁵ After control of the blood sugar level, the maintenance dose is usually on a once-a-day schedule.

Chlorpropamide
(Diabinese)

Tolazamide, USP. Tolazamide, 1-(hexahydro-1*H*-azepin-1-yl)-3-(*p*-tolylsulfonyl)urea (Tolinase), is an analogue of tolbutamide and is reported to be effective, in general, under the same circumstances in which tolbutamide is useful. Tolazamide, however, appears to be more potent than tolbutamide and is nearly equal in potency to chlorpropamide. In studies with radioactive tolazamide, investigators found that 85% of an oral dose appeared in the urine as metabolites that were more soluble than tolazamide itself.

Tolazamide
(Tolinase)

Acetohexamide, USP. Acetohexamide, 1-[(*p*-acetylphenyl)sulfonyl]-3-cyclohexylurea (Dymelor), is related chemically and pharmacologically to tolbutamide and chlorpropamide. Like the other sulfonylureas, acetohexamide lowers the blood sugar level, primarily by stimulating the release of endogenous insulin.

Acetohexamide
(Dymelor)

Acetohexamide is metabolized in the liver to a reduced form, the α -hydroxyethyl derivative. This metabolite, the main one in humans, possesses hypoglycemic activity. Acetohexamide is intermediate between tolbutamide and chlor-

propamide in potency and duration of effect on blood sugar levels.

Glipizide. Structurally, glipizide, 1-cyclohexyl-3-[[*p*-[2-(methylpyrazinecarboxamido)ethyl]phenyl]sulfonyl]urea (Glucotrol), is a cyclohexylsulfonamide analogue similar to acetohexamide and glyburide. The drug is absorbed rapidly on oral administration. Its serum half-life is 2 to 4 hours, and it has a hypoglycemic effect that ranges from 12 to 24 hours.

Glyburide. Similar to glipizide, glyburide, 1-[[*p*-[2-(5-chloro-*o*-anisamido)ethyl]phenyl]sulfonyl]-3-cyclohexylurea (DiaBeta, Micronase, Glynase), is a second-generation oral hypoglycemic agent. The drug has a half-life elimination of 10 hours, but its hypoglycemic effect remains for up to 24 hours.

Glipizide. Glipizide, 1-cyclohexyl-3-[[*p*-(2-(5-methylpyrazinecarboxamido)ethyl]phenyl)sulfonyl]urea (Glucotrol), is an off-white, odorless powder with a pK_a of 5.9. It is insoluble in water and alcohols, but soluble in 0.1 N NaOH. Even though on a weight basis it is approximately 100 times more potent than tolbutamide, the maximal hypoglycemic effects of these two agents are similar. It is rapidly absorbed on oral administration, with a serum half-life of 2

to 4 hours, while the hypoglycemic effects range from 12 to 24 hours. Metabolism of glipizide is generally through oxidation of the cyclohexane ring to the *p*-hydroxy and *m*-hydroxy metabolites. A minor metabolite that occurs involves the *N*-acetyl derivative, which results from the acetylation of the primary amine following hydrolysis of the amide system by amidase enzymes.

Glimepiride. Glimepiride, 1-[[*p*-[2-(3-ethyl-4-methyl-2-oxo-3-pyrroline-1-carboxamido)ethyl]phenyl]sulfonyl]-3-(*trans*-4-methylcyclohexyl)urea (Amaryl), is very similar to glipizide with the exception of their heterocyclic rings. Instead of the pyrazine ring found in glipizide, glimepiride contains a pyrrolidine system. It is metabolized primarily through oxidation of the alkyl side chain of the pyrrolidine, with a minor metabolic route involving acetylation of the amine.

Gliclazide. Chemically, gliclazide, 1-(3-azabicyclo[3.3.0]oct-3-yl)-3-*p*-tolylsulphonylurea (Diamicon), is very similar to tolbutamide, with the exception of the bicyclic heterocyclic ring found in gliclazide. The pyrrolidine increases its lipophilicity over that of tolbutamide, which increases its half-life. Even so, the *p*-methyl is susceptible to the same oxidative metabolic fate as observed for tolbutamide, namely, it will be metabolized to a carboxylic acid.

Nonsulfonylureas—Metaglinides

The metaglinides are nonsulfonylurea oral hypoglycemic agents used in the management of type 2 diabetes (non-insulin-dependent diabetes mellitus, NIDDM). These agents tend to have a rapid onset and a short duration of action. Much like the sulfonylureas, these induce insulin release from functioning pancreatic β cells. The mechanism of action for the metaglinides, however, differs from that of the sulfonylureas. The mechanism of action is through binding to specific receptors in the β -cell membrane, leading to the closure of ATP-dependent K^+ channels. The K^+ channel blockade depolarizes the β -cell membrane, which in turn leads to Ca^{2+} influx, increased intracellular Ca^{2+} , and stimulation of insulin secretion. Because of this different mechanism of action from the sulfonylureas, there are two major differences between these seemingly similar classes of agents. The first is that the metaglinides cause much faster insulin production than the sulfonylureas. As a result, the metaglinides should be taken during meals, as the pancreas will produce insulin in a much shorter period. The second difference is that the effects of the metaglinides do not last as long as the effects of the sulfonylureas. The effects of this class appear to last less than 1 hour, while sulfonylureas continue to stimulate insulin production for several hours. One advantage of a short duration of action is that there is less risk of hypoglycemia.

Repaglinide. Repaglinide, (+)-2-ethoxy-4-[N-(3-methyl-1(S)-[2-(1-piperidinyl)phenyl]butyl]carbamoylmethyl]benzoic acid (Prandin), represents a new class of nonsulfonylurea oral hypoglycemic agents. With a fast onset and a short duration of action, the medication should be taken with meals. It is oxidized by CYP 3A4, and the carboxylic acid may be conjugated to inactive compounds. Less than 0.2% is excreted unchanged by the kidney, which may be an advantage for elderly patients who are renally impaired. The most common side effect involves hypoglyce-

mia, resulting in shakiness, headache, cold sweats, anxiety, and changes in mental state.

Nateglinide. Although nateglinide, *N*-(4-isopropylcyclohexanecarbonyl)-D-phenylalanine (Starlix), belongs to the metaglinides, it is a phenylalanine derivative and represents a novel drug in the management of type 2 diabetes.

Thiazolidinediones

The thiazolidinediones represent a novel nonsulfonylurea class of hypoglycemic agents for the treatment of NIDDM. Much like the sulfonylureas, the use of these agents requires a functioning pancreas that can successfully secrete insulin from β cells. Although insulin may be released in normal levels from the cells, peripheral sensitivity to this hormone may be reduced or lacking. The thiazolidinediones are highly selective agonists for the peroxisome proliferator-activated receptor- γ (PPAR γ), which is responsible for improving glycemic control, primarily through the improvement of insulin sensitivity in muscles and adipose tissue. In addition, they inhibit hepatic gluconeogenesis. These agents normalize glucose metabolism and reduce the amount of insulin needed to achieve glycemic control. They are only effective in the presence of insulin.

Rosiglitazone. Rosiglitazone, (\pm)-5-[4-[2-(methyl-2-pyridinylamino)ethoxy]phenyl]methyl]-2,4-thiazolidinedione

(Avandia), is a white to off-white solid with pK_a values of 6.8 and 6.1. Rosiglitazone is readily soluble in ethanol and a buffered aqueous solution with pH of 2.3; solubility decreases with increasing pH in the physiological range. The molecule has a single chiral center and is present as a racemate. Even so, the enantiomers are functionally indistinguishable because of rapid interconversion.

Pioglitazone. Pioglitazone, (\pm) -5-[4-[2-(5-ethyl-2-pyridinyl)ethoxy]phenyl]methyl]-2,4-thiazolidinedione (Actos), is an odorless, white, crystalline powder that must be converted to a salt such as its hydrochloride before it will have any water solubility. Although the molecule contains one chiral center, the compound is used as the racemic mixture. This is primarily due to the *in vivo* interconversion of the two enantiomers. Thus, there are no differences in the pharmacological activity of the two enantiomers.

Bisguanidines

Metformin. Metformin, *N,N*-dimethylimidodicarbonimidic diamide hydrochloride (Glucophage), is a bisguanidine. This class of agents is capable of reducing sugar absorption from the gastrointestinal tract. Also, they can decrease gluconeogenesis while increasing glucose uptake by muscles and fat cells. These effects, in turn, lead to lower blood glucose levels. Unlike the sulfonylureas, these are not hypoglycemic agents but rather can act as antihyperglycemics. This difference in nomenclature is due to the inability of these agents to stimulate the release of insulin from the pancreas. Often, metformin is coadministered with the non-sulfonylureas to improve the efficacy of those agents.

α -Glucosidase Inhibitors

The enzyme α -glucosidase is present in the brush border of the small intestine and is responsible for cleaving dietary carbohydrates and facilitating their absorption into the body. Inhibition of this enzyme allows less dietary carbohydrate to be available for absorption and, in turn, less available in the blood following a meal. The inhibitory properties of these agents are greatest for glycoamylase, followed by sucrase, maltase, and dextranase, respectively. Since these do not enhance insulin secretion when used as monotherapy, hypoglycemia is generally not a concern when using these agents.

Acarbose. Acarbose, *O*-4,6-dideoxy-4-[[[(1*S*,4*R*,5*S*,6*S*)-4,5,6-trihydroxy-3-(hydroxymethyl)-2-cyclohexen-1-yl]amino] α -D-glucopyranosyl-(1,4)-*O*- α -D-glucopyranosyl-(1,4)-D-glucose (Precose), is a naturally occurring oligosaccharide, which is obtained from the microorganism *Actinoplanes utahensis*. It is a white to off-white powder that is soluble in water and has a pK_a of 5.1. As one might expect, its affinity for α -glucosidase is based on it being a polysaccharide that the enzyme attempts to hydrolyze. This allows acarbose to act as a competitive inhibitor, which in turn reduces the intestinal absorption of starch, dextrin, and disaccharides.

Miglitol. Miglitol, 1-(2-hydroxyethyl)-2-(hydroxymethyl)-[2*R*-(2 α ,3 β ,4 α ,5 β)]-piperidine (Glyset), a desoxynojirimycin derivative, is chemically known as 3,4,5-piperidintriol. It is a white to pale-yellow powder that is soluble in water, with a pK_a of 5.9. In chemical structure, this agent is very similar to a sugar, with the heterocyclic nitrogen serving as an isosteric replacement of the sugar oxygen. This feature allows recognition by the α -glucosidase as a sub-

strate. This results in competitive inhibition of the enzyme and delays complex carbohydrate absorption from the gastrointestinal tract.

THYROID HORMONES

Desiccated, defatted thyroid substance has been used for many years as replacement therapy in thyroid gland deficiencies. The efficacy of the whole gland is now known to depend on its thyroglobulin content. This is an iodine-containing globulin. Thyroxine was obtained as a crystalline derivative by Kendall⁷⁶ of the Mayo Clinic in 1915. It showed much the same action as the whole thyroid substance. Later, thyroxine was synthesized by Harington and Barger in England.⁷⁷ Later studies showed that an even more potent iodine-containing hormone existed, which is now known as triiodothyronine. Evidence now indicates that thyroxine may be the storage form of the hormone, whereas triiodothyronine is the circulating form. Another point of view is that in the blood, thyroxine is bound more firmly to the globulin fraction than is triiodothyronine, which can then enter the tissue cells.

Levothyroxine Sodium, USP. Levothyroxine sodium, *O*-(4-hydroxy-3,5-diiodophenyl)-3,5-diiodo-L-tyrosine monosodium salt, hydrate (Synthroid, Letter, Levoxine, Levoid), is the sodium salt of the *levo* isomer of thyroxine, which is an active physiological principle obtained from the thyroid gland of domesticated animals used for food by humans. It is also prepared synthetically. The salt is a light yellow, tasteless, odorless powder. It is hygroscopic but stable in dry air at room temperature. It is soluble in alkali hydroxides, 1:275 in alcohol, and 1:500 in water, to give a pH of about 8.9.

Levothyroxine Sodium
(Synthroid, Letter, Levoxine, Levoid)

Levothyroxine sodium is used in replacement therapy of decreased thyroid function (hypothyroidism). In general, a

dosage of 100 μg of levothyroxine sodium is clinically equivalent to 30 to 60 mg of Thyroid USP.

Liothyronine Sodium, USP. Liothyronine sodium, *O*-(4-hydroxy-3-iodophenyl)-3,5-diiodo-L-tyroxine monosodium salt (Cytamel), is the sodium salt of L-3,3',5-triiodothyronine. It occurs as a light-tan, odorless, crystalline powder, which is slightly soluble in water or alcohol and has a specific rotation of $+18$ to 22° in a mixture of diluted HCl and alcohol.

Liothyronine Sodium
(Cytamel)

Liothyronine sodium occurs *in vivo* together with levothyroxine sodium; it has the same qualitative activities as thyroxine but is more active. It is absorbed readily from the gastrointestinal tract, is cleared rapidly from the bloodstream, and is bound more loosely to plasma proteins than is thyroxine, probably because of the less acidic phenolic hydroxyl group.

Its uses are the same as those of levothyroxine sodium, including treatment of metabolic insufficiency, male infertility, and certain gynecological disorders.

ANTITHYROID DRUGS

Hyperthyroidism (excessive production of thyroid hormones) usually requires surgery, but before surgery the patient must be prepared by preliminary abolition of the hyperthyroidism through the use of antithyroid drugs. Thiourea and related compounds show an antithyroid activity, but they are too toxic for clinical use. The more useful drugs are 2-thiouracil derivatives and a closely related 2-thioimidazole derivative. All of these appear to have a similar mechanism of action (i.e., prevention of the iodination of the precursors of thyroxine and triiodothyronine). The main difference in the compounds lies in their relative toxicities.

Thiourea

2-Thiouracil

These compounds are absorbed well after oral administration and excreted in the urine.

The 2-thiouracils, 4-keto-2-thiopyrimidines, are undoubtedly tautomeric compounds and can be represented as follows:

Some 300 related structures have been evaluated for anti-thyroid activity, but of these, only the 6-alkyl-2-thiouracils and closely related structures possess useful clinical activity. The most serious adverse effect of thiouracil therapy is agranulocytosis.

Propylthiouracil, USP. Propylthiouracil, 6-propyl-2-thiouracil (Propacil), is a stable, white, crystalline powder with a bitter taste. It is slightly soluble in water but readily soluble in alkaline solutions (salt formation).

Propylthiouracil
(Propacil)

This drug is useful in the treatment of hyperthyroidism. There is a delay in appearance of its effects because propylthiouracil does not interfere with the activity of thyroid hormones already formed and stored in the thyroid gland. This lag period may vary from several days to weeks, depending on the condition of the patient. The need for three equally spaced doses during a 24-hour period is often stressed, but evidence now indicates that a single daily dose is as effective as multiple daily doses in the treatment of most hyperthyroid patients.⁷⁸

Methimazole, USP. Methimazole, 1-methylimidazole-2-thiol (Tapazole), occurs as a white to off-white, crystalline powder with a characteristic odor and is freely soluble in water. A 2% aqueous solution has a pH of 6.7 to 6.9. It should be packaged in well-closed, light-resistant containers.

Methimazole
(Tapazole)

Methimazole is indicated in the treatment of hyperthyroidism. It is more potent than propylthiouracil. The side effects are similar to those of propylthiouracil. As with other anti-thyroid drugs, patients using this drug should be under medical supervision. Also, like the other antithyroid drugs, methimazole is most effective if the total daily dose is subdivided and given at 8-hour intervals.

Local Anesthetic Agents

GARETH THOMAS

Local anesthetics are blocking drugs that, when administered locally in the correct concentration, “block” the nerves that carry nerve impulses in local areas of the body. They do not block coarse touch or movement, and the action is reversible. Their method of administration is governed by such properties as toxicity, stability, duration of action, water solubility, membrane permeability, and point of application, while their modes of action (see under heading, Mechanism of Action) depend on their lipid solubility, pK_a , vasodilation, and protein-binding characteristics.

Although given locally, the drug may exert a systemic effect because of transport in the blood from the site of administration to other areas, such as the heart and central nervous system (CNS). These systemic effects, which depend on the concentration of the local anesthetic in the blood, are usually sedation and lightheadedness, but restlessness, nausea, and anxiety may also occur. High plasma concentrations can result in convulsions, chiropidy, and coma with respiratory and cardiac depression.

Local anesthetics are used to alleviate the pain caused by a wide variety of situations. They are used in dentistry, in ophthalmology, in minor surgical operations including endoscopy, and in relieving pain in intractable medical conditions, such as tumors growing in the spine. Local anesthetics are also used topically for the temporary relief of pain from insect bites, burns, and other types of surface wounds. They are particularly effective when they are used on mucous membranes, such as the mouth, vagina, or rectum.

HISTORICAL DEVELOPMENT

The start of the search for ways to relieve pain is lost in the past. People have used religious exorcism, hypnotism, acupuncture, hypothermia, nerve compression, and drugs. Each of these methods has had its periods of popularity, and most are still used in one form or another. The modern development of the use of drugs to induce local anesthesia probably started in the mid-19th century. The earliest recorded use of hypothermia as a local anesthetic, however, is believed to be by Larrey, Napoleon’s chief army surgeon during the retreat from Moscow. He recorded that amputations were carried out in subzero temperatures had a higher patient survival rate than those carried out in warmer conditions. Later in the century, Thompson reported that ether acted as a refrigerant when poured onto the skin. These observations lay dormant until 1848 when Arnott reported that he had used a pig’s bladder filled with crushed ice to alleviate the pain caused by incisions made in the skin. This was followed by Snow’s unsuccessful attempts to find a viable way of using refrigeration as a local anesthetic. Success was

achieved eventually by his protégé Richardson, who replaced the cologne in the then recently introduced Eau-de-Cologne spray with ether. This achieved temperatures that allowed minor surgery to be carried out. Richardson and other workers improved the efficiency of the procedure by using a petroleum distillate, then ethyl bromide, and ultimately ethyl chloride. The success of the Richardson spray inspired Koller to search for a local anesthetic that could be safely applied to the eye.

Koller qualified in medicine in 1882 and went on to specialize in ophthalmology in Vienna. His experience as an eye surgeon made him increasingly aware of the need for a local anesthetic that could be used in the eye. In 1884, while he was collaborating with Freud to study the effect of cocaine on fatigue, a colleague remarked that the drug numbed his tongue. Koller and Gaertner investigated this claim and found that a dilute aqueous solution of cocaine hydrochloride caused local anesthesia of the cornea. Brettauer presented Koller’s results on his behalf at an ophthalmology meeting in Heidelberg in September 1884, since Koller could not afford the train fare from Vienna to Heidelberg. Koller’s paper resulted in the immediate widespread use of cocaine in Europe and the United States. Koller also recommended the use of cocaine as a local anesthetic in ear, nose, and throat operations. At the time, however, little was known about its addictive properties.

In 1885, degradation studies by Camels and Gossin suggested that there were some structural similarities between cocaine and atropine. This led Filehne at the University of Breslau (now Wrocław) in Poland to determine whether atropine had any local anesthetic activity in the eye. Atropine had been isolated from the roots of belladonna in 1831 by Mein, a German apothecary. Filehne found that atropine had little local anesthetic activity and was toxic, causing eye irritation at the doses required for any activity. Earlier, Lossen showed that atropine could be split into tropic acid and a nitrogenous base called *tropine*. Later, in 1880, Ladenburg synthesized a series of physiologically active compounds, which he called *tropines*, by esterifying tropine with a variety of aromatic acids. Filehne investigated these semisynthetic analogues of atropine for local anesthetic activity and found that homatropine (Fig. 20-1a) was less irritating to

Figure 20-1 ■ a. Homatropine. b. Benzoyltropine

Figure 20-2 ■ The incorrect structures proposed for cocaine (a) and tropine (b) by Albert Einhorn and Georg Merling. Structures of methyltriacetone alkamine (c), α -Eucaïne (d), and β -Eucaïne (e).

the eyes and a better local anesthetic than atropine, whereas benzoyltropine (Fig. 20-1b) was a strong local anesthetic but caused too much irritation to be of any clinical use. The identification of a benzoyl group in the structures of the most active atropine analogues and also in cocaine, however, led Filehne to test the activity of the benzoyl derivatives of quinine, cinchonine, hydrocotarnine, and morphine. His results, which were published in 1887, showed that these benzoate esters acted as local anesthetics, but many had unwanted side effects.

By 1888 the toxic and addictive effects of cocaine were beginning to concern the medical world, and many workers were seeking a safe substitute. In 1892, Einhorn,¹ professor of chemistry at the University of Munich, suggested a structure for cocaine (Fig. 20-2a) based on the structure of tropine proposed in 1883 by Merling² at the University of Berlin (Fig. 20-2b). Merling decided, on the basis of these incorrect structures, to synthesize a benzoyl analogue containing only a piperidine ring. He produced a compound whose structure was similar to that of the weakly active methyltriacetone alkamine analogue of atropine (Fig. 20-2c). It was marketed under the name α -Eucaïne (Fig. 20-2d) but was not popular, as it caused a burning sensation when applied to the eyes. It was rapidly replaced by β -Eucaïne (Fig. 20-2e), but this also caused eye irritation.

Einhorn, on realizing Merling's success with the benzoate

derivatives of piperidine, attempted to synthesize active benzoate compounds based on the simpler hexane ring. His syntheses, which were based on the reduction of aromatic benzoate esters, failed, so he decided to have a number of unrelated aromatic benzoate esters tested for local anesthetic activity. Some were found to be active, but more importantly, several of the phenols formed by the hydrolysis of the esters were also found to be active, and in 1896, Einhorn introduced Orthoform (orthocaine) into clinical use. Problems with its production and its side effects led him to introduce Orthoform New in 1897. Einhorn's work was important in that it gave the first indication that a benzoate ester was not essential for local anesthesia.

Although the Orthoforms were relatively successful as topical anesthetics, their poor water solubility made them unsuitable for other medicinal uses. Consequently, Einhorn attempted to improve their water solubility by introducing amine-containing aliphatic side chains. He reasoned that the formation of their amine hydrochlorides would improve water solubility without making the preparation too acidic. One of Einhorn's compounds, Nirvanin, was introduced in 1898. Its activity was low, and it had to be used in high doses, which caused toxic effects.

In 1898, Willstätter determined the correct structures of both atropine and cocaine. He followed this by synthesizing cocaine in 1901.

Einhorn's clinical success with the poorly water soluble Orthoforms resulted in the introduction of ethyl 4-aminobenzoate into clinical use in 1902 under the name Anesthesine. It was later given the approved name of benzocaine. Ritsert had noticed in 1890 that this water-insoluble compound had numbed his tongue and so to improve its water solubility, it had been formulated as the hydrochloride. As aromatic amines are weak bases, however, the resulting solution had proved too acidic, and he had discounted its clinical use.

In 1902, Fourneau in France designed a drug whose structure incorporated functional groups similar to those found in the structure of the cocaine molecule. He did not include the piperidine ring, however, which he considered to be responsible for the toxicity of cocaine. His compound, which he marketed under the name Stovaine, was the first nonirritant local anesthetic that could be given by injection and used as a safe substitute for cocaine. Stovaine was later given the approved name of amylcaine.

Earlier work in 1885 by Corning in the United States had shown that the anesthetic effect of cocaine could be enhanced by the use of tourniquets to keep the drug from being carried away from the site of application. This increased the effectiveness of the drug and allowed lower doses to be used. Applications of the tourniquet technique were limited, however. In 1900, the publication of the observation that adrenal extracts caused blood vessels to contract resulted in Braun demonstrating that mixtures of cocaine and adrenal extracts were more effective than cocaine alone. The isolation of adrenaline, the active component of adrenal extracts, and its subsequent structure determination led Braun in 1904 to design a drug based on the structure of both adrenaline and Einhorn's local anesthetics. It was marketed as Novocaine and was later given the approved name of procaine. Procaine dominated the local anesthetic market for half a century and is still in use today.

In the next 30 or so years after the synthesis of procaine, large numbers of compounds were tested for local anesthetic activity, but none of importance emerged. Miescher, working for Ciba in Switzerland, found, however, that some of

the acetanilide analogues he had synthesized as potential antipyretic agents also exhibited local anesthetic activity. In 1931, his synthetic work led to the production of cinchocaine (Nupercaine), a long-acting local anesthetic that was particularly useful in spinal anesthesia.

At about the same time that cinchocaine was developed, an investigation of the chemical structure of the alkaloid gramine at Stockholm University resulted in Erdtman synthesizing its isomer, isogramine. As luck would have it, Erdtman tasted isogramine and found that his tongue went numb. Realizing its potential, he tested its open-chain precursor and found that it also exhibited local anesthetic activity. For the next 7 years, Erdtman and his student Lofgren synthesized and tested compounds with similar structural characteristics. Their search was rewarded 57 compounds later, by the discovery of lignocaine (Lidocaine, Xylocaine). This drug was marketed in 1948 by Astra in Sweden, and because of its rapidity of action, nonirritant and relatively safe nature, it has become the leading local anesthetic.

In 1957, scientists at AB Bofors replaced the acyclic tertiary amino side chain of lignocaine with a cyclic tertiary amine for no reason other than it produced novel compounds. This irrational approach led to two useful local anesthetics, mepivacaine (Carbocaine) and bupivacaine (Marcain). Bupivacaine was long acting, producing nerve blocks for up to 8 hours.

A large number of active compounds have now been synthesized, but lignocaine, procaine, and many of the pre-1957 compounds are still in current use. In 1974, Hughes isolated and, in 1975,³ determined the structures of the natural pain-

control agents, methionine-enkephalin (met-enkephalin) and leucine-enkephalin (leu-enkephalin). The isolation of these and other peptides with similar activity opened up a possible new structural route to the synthesis of local anesthetic agents that has yet to be fully exploited.

THE NERVOUS SYSTEM

The nervous system consists of sensory and motor components. The sensory component responds to various external stimulations, which it transmits in the form of a nerve impulse to the CNS for interpretation. The motor component of the nervous system carries a signal from the CNS to the appropriate part of the body to elicit the response to the stimulation. One of these responses is the sensation known as pain. Nerve impulses are now known to take the form of an electrical impulse. Experimental evidence suggests that both stimulation and the transmission of a nerve impulse may be blocked by the action of local anesthetic agents.⁴ Consequently, understanding this action requires a knowledge of the structure and action of the nervous system.

The basic building blocks of the nervous system are the *nerve cells* or *neurons*. Associated with the neurons are the *glial cells*. In humans, the complete system contains over 10 billion neurons and about 10 to 15 times that number of glial cells. Extending from the brain, the *command center* of the nervous system, is the cluster of neurons and glial cells that form the spinal cord. The brain together with the spinal cord forms the CNS. Extending outward from the CNS is the peripheral nervous system (PNS). The motor and sensory components of the PNS are subdivided into somatic and vegetative systems. Somatic systems control conscious functions, such as physical movements, while the vegetative systems control unconscious functions. The motor vegetative system is referred to as the *autonomic* or *involuntary nervous system*⁵ and controls body functions such as breathing, digestion, and heart beat.

Neurons receive, conduct, and transmit electrical signals in the form of ionic currents. A typical neuron usually consists of a central cell body from which radiate out a number of thin, branch-like protuberances (Fig. 20-3). These branches are of two types, a single branch known as the

Figure 20-4 ■ Representations of myelinated (a) and unmyelinated (b) axons.

axon, which acts as a conductor of signals from the cell body, and a number of other separate branches known as the *dendrites*, which act as antennae, receiving signals from the axon of other neurons. Both the axons and dendrites of neurons can exhibit an astonishing variety of branching, but axon branching is usually simpler. The terminal branches of the axon end in *synaptic knobs*, which are also known as *terminal buttons* or *axon telodiria*.

The axon arises from a thickened area of the cell body called the *axon hillock*. Its membrane is mainly composed of lipids and proteins and is known as the *axolemma*. Many of the axons of the CNS and PNS are partly covered from near the axon hillock to the synaptic knob by a sheath of *myelin* (myelinated axons), but some axons do not have this type of covering (unmyelinated axons). The myelin sheath of PNS myelinated axons is not continuous but is broken at about 1-mm intervals to expose the axolemma to the extracellular fluid. These exposed areas, which are about 1 μm long, are known as the *nodes of Ranvier*. The distance between the nodes is often referred to as the *internodal distance*.

A segment of the PNS myelin sheath consists of a single glial cell known as a *Schwann cell*, tightly wrapped around the axon so as to form several tightly bound layers of the same cell (Fig. 20-4a). In unmyelinated axons, the Schwann cells simply surround the axon and are not tightly wrapped around it (Fig. 20-4b). The CNS myelinated sheath is a much more complicated structure. In all cases, however, the main function of myelin is to act as an insulating material, electrically insulating the axon from the extracellular fluid.

A nerve consists of myelinated or unmyelinated nerve fibers (Fig. 20-5a). These nerve fibers consist of "chains" of neurons. The junction between adjacent neurons in the chain consists of the synaptic knob of the transmitting neuron separated by a gap of about 30 to 50 nm from either the dendrite, axon hillock, or cell body of the other neuron. This

Figure 20-3 ■ Schematic diagram of a neuron. Representation of the variety of branching found in dendrites.

Figure 20-5 ■ Representations of a section of nerve fiber (a) (reproduced from Thomas, G.: Medicinal Chemistry, An Introduction. Chichester, U. K., John Wiley & Sons, 2000, by permission of John Wiley & Sons, Ltd.) and a cross section of a nerve (b).

gap is known as the *synaptic cleft*, and the whole area where transmission and reception of the impulse from one neuron to the other occur is known as a *synapse*. The nerve fibers are enclosed in different layers of protective tissues (Fig. 20-5b). For example, in a spinal nerve the individual nerve fibers, whether myelinated or unmyelinated, are wrapped in a layer of protective connective tissue known as the *endoneurium*. These endoneurium-coated fibers are grouped in bundles known as *fascicles*. Each fascicle is coated with a layer of connective tissue called the *perineurium*. The complete nerve consists of a number of fascicles embedded in tissue through which run various blood vessels, the whole structure being covered by a layer of connective tissue known as the *epineurium*.

Neurons are excited by electrical, chemical, and mechanical stimuli. They convey the information provided by this stimulation in the form of electrical signals. The precise nature of the information carried depends on the type of neuron, however. For example, a *motor neuron* will convey electrical signals that cause a particular muscle to contract. In all cases, the signals take the form of changes in the electrical potential across the neuronal membranes. In myelinated neurons, a change in the membrane potential in one node of Ranvier will stimulate further changes in an adjacent node and so on; that is, a change in electrical potential at A stimulates a change in electrical potential at B, which in turn initiates a change in the electrical potential at C and so on (Fig. 20-6). The process whereby the change in potential jumps from one node to another is known as *saltatory conduction*. It results in the movement of an electrical impulse that is referred to as either the *nerve impulse* or *action potential* along

Figure 20-6 ■ Representation of the transmission of a nerve impulse along a neuron fiber by saltatory conduction.

the axon. In unmyelinated nerves, the change in potential of one section of the membrane stimulates a change in potential of an immediately adjacent section of the membrane. These nerve impulses are transmitted or conducted along an axon sheathed with myelin at speeds up to 120 m/sec or more, but only up to 10 m/sec in unmyelinated axons. In large neurons, the strength of the nerve impulse is maintained by an automatic amplification system, but many smaller neurons have no such systems.

If the center of an axon is stimulated, the nerve impulse will be transmitted in both directions along that axon (Fig. 20-7). The synapse allows, however, only the transmission of the impulse from the axon to the next neuron, i.e., in only one direction. Consequently, an impulse will only travel in one direction along a nerve fiber.

In most cells, the electrical potential difference between the inner and outer surfaces of the cell membrane is due to the movement of ions across that membrane.³ In all axons, the interior face of the membrane is the negative side of the potential difference, largely because of the excess of anions, such as chloride ions, found in the interior of the neuron. For a cell at rest (i.e., a cell that is not subject to any outside stimulation), this electrical potential is known as the *resting potential* and can vary from -20 to -200 mV, where by convention the extracellular side of the membrane is taken to be 0 volts. The resting potential of neurons is about -70 mV. The *action potential* of the axon is the series of potential changes that occurs when the axon is stimulated. Microelectrodes implanted in the axon (*intracellular recording*) show that stimulation causes an initial depolarization of the membrane by about 20 mV. This is followed by the rapid rise of the membrane's potential to a maximum value of about $+35$ mV. The membrane is then said to be *depolarized*. This is immediately followed by the potential dropping back toward the resting potential (*repolarization*). The repolarization overshoots the resting potential (*hyperpolarization*) before slowly recovering to the resting potential (Fig. 20-8). The rapid rise and fall of the potential is termed the *spike poten-*

Figure 20-7 ■ Stimulation at the center of an axon results in a nerve impulse being transmitted in both directions.

tial, and the point at which it starts, the *firing level* or *threshold* of the axon. No action potential is produced if the stimulus is below the threshold potential. Once the threshold level is reached, however, the action potential will occur regardless of the strength of the stimulus. Furthermore, the amplitude of this action potential is independent of the intensity of the stimulant. The action potential is said to obey the "all-or-nothing" law.

The peripheral nerves of mammals consist of bundles of neurons held together in a fibrous envelope called the *epineurium*. The change in potential for these systems is the sum of the action potentials of all the axons in the system if extracellular recording is attempted. Each axon in the system has a different threshold potential, and so the number of axons firing will initially increase with increased intensity of the stimulus. Eventually, all the axons in the nerve will fire, and at this point, further increases in the intensity of the stimulus will cause no further increase in the size of the action potential. In bundles of mixed nerves, there will be multiple peaks in the action potential profile, however, because the differing types of nerve fiber will have different conduction speeds.

The electrical potential across the lipid membrane of an axon is mainly due to the transport of small inorganic ions, such as Ca^{2+} , Na^+ , K^+ , and Cl^- , across the membrane by active or passive transport. Active transport usually involves the intervention of a carrier protein that physically carries the ion to the other side of the membrane. It can occur against the electrochemical and concentration gradients across the membrane (*uphill*). Passive transport occurs by the diffusion of the ions through water-filled channels (ion channels) formed by the integral proteins of the membrane. The ions move from high concentration to low concentration (*downhill*) at rates on the order of 10^6 or more ions per second, which is 100 times faster than the active transport of ions. Passive transport of the ions is usually in the opposite direction to active transport. For example, Na^+ ions are transported into an axon by passive transport but out of an axon by active transport. Similarly, K^+ ions may be transported

out of an axon by passive transport but into an axon by active transport. A small movement of ions across a membrane can lead to the generation of electric fields that are enormous by macroscopic standards. For example, the transfer of one ion pair per million, the cation leaving and the anion entering the neuron across a membrane, results in an electrical potential of about $150,000 \text{ V cm}^{-1}$.

The highest density of Na^+ ion channels occurs at the nodes of Ranvier.⁶ The myelinated internodal sections of the neuron contain far fewer Na^+ channels. In addition, these internodal regions are electrically insulated and so do not contribute to the action potential. Consequently, the potential produced at the nodes of Ranvier must be strong enough to produce an effect up to 1 mm away.

Ion channels are formed by groups of integral proteins that run from one side of the membrane to the other. The channels are selective, allowing the passage of certain ions but preventing the passage of others. This suggests that parts of the channel must act as a selective filter. Furthermore, some of the channels are not permanently open; changes in the conformation of the proteins that form the channel effectively open and close the channel as though it contained a gate. These *gates* usually open briefly in response to various membrane changes, such as a change in voltage across the membrane (*voltage-gated channels*) or the binding of a ligand to a receptor (*ligand-gated channels*). Over 50 types of gated channel have been discovered.⁷

The axolemma is more permeable to K^+ ions than to Na^+ ions. These ions diffuse out of the neuron through the so-called *potassium leak channels*, whose opening does not appear to require a specific membrane change. The movement of K^+ ions is concentration driven; K^+ ions move from inside the neuron, where the concentration is high, to the extracellular fluid, where the concentration is lower (Fig. 20-9a). This tendency of K^+ ions to leak out of the neuron (*driven by the concentration gradient*) is balanced to some extent by a limited movement of K^+ ions back into the neuron, both by diffusion through K^+ channels and by active transport mechanisms such as the sodium pump. These

Figure 20-8 ■ Changes in electrical potential observed during a nerve impulse.

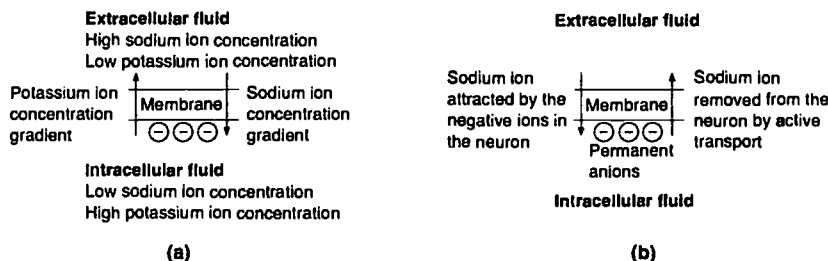

Figure 20-9 ■ a. Movement of Na⁺ and K⁺ ions across a membrane because of differences in concentration. b. Attraction of positive ions into a cell by electrostatic attraction and their removal by active transport

movements of K⁺ result in a potential difference across the membrane, which is a major contributor to the *equilibrium potential* that exists between the opposite faces of a biological membrane in a normal cell at rest with a switched-on sodium pump. Its value for a particular ion when the system is in equilibrium and the cell is at rest may be calculated by using the Nernst equation:

$$V = V_i - V_o = \frac{RT}{zF} \ln \frac{C_o}{C_i} \quad (\text{Eq. 20-1})$$

where V is the equilibrium potential, V_i is the internal potential, V_o is the external potential, C_i is the internal concentration of the ion (mol dm⁻³), C_o is the external concentration of the ion (mol dm⁻³), R is the ideal gas constant, and T is the temperature (°K). F is Faraday's constant (96,487 coulombs), and z is the charge on the ion.

The axolemma of a neuron at rest with a switched-on sodium pump does not allow the free movement of Na⁺ ions, even though it contains channels that are specific for them. If the sodium pump is switched off, however, the concentration of Na⁺ starts to build up in the cell, as the membrane is not completely impermeable to Na⁺. The Na⁺ ions pass into the cell down the concentration gradient through the so-called *sodium ion channels*, aided by an attraction for the anions in the cell. This inward movement of Na⁺ neutralizes the negative charges of some of these anions and so reduces (*depolarizes*) the membrane potential, which allows a greater concentration of K⁺ ions to leave the cell (Fig. 20-9b).

Ca²⁺ ions will also move into a cell, attracted by the anions permanently present inside and will also leak out of cells via *calcium channels*. Similarly, under the appropriate

conditions, Cl⁻ ions move in and out of cells. The movement of both of these ions also contributes to the membrane potential of the cell, which for a cell at rest can vary from -20 to -200 mV. The more permeable a membrane is to a particular ion, the more closely the membrane potential approaches the equilibrium potential for that ion.

The initial depolarization of the neuron (Fig. 20-8) was shown by Hodgkin and Huxley in 1953 to be due to increased movement of Na⁺ into the neuron, which is followed almost immediately by increased movement of K⁺ ions out of the neuron. Consequently, the gated ion channels of neurons are believed to be responsible for the transmittance of the action potentials that carry information to and from the body of the nerve cell. It is thought that the action potential is triggered by a stimulation that causes momentary shift of the membrane potential of a small section of the membrane to a less negative value (*depolarization of the membrane*). This causes the gated Na⁺ channels in this section of the membrane to open, which allows Na⁺ to enter the cell. This process depolarizes the membrane still further, until the action potential reaches a critical value (the *firing threshold*), when it triggers the opening of large numbers of adjacent Na⁺ channels so that Na⁺ ions flood into the axon. This process continues until the membrane potential of this section of membrane reaches about +60 mV, which is the equilibrium potential (V_{Na}) for Na⁺ ions when the cell is at rest (calculated using Eq. 20-1). At this point, all the Na⁺ channels of the membrane should be permanently open. This situation is not reached, however, because each channel has an automatic closing mechanism that operates even though the cell membrane is still depolarized (Fig. 20-10). Once

Figure 20-10 ■ Cycle of conformational changes that occur in a sodium channel.

Figure 20-12 ■ Representation of the mechanism of action of local anesthetics in blocking closed and open sodium channels.

receptor. This is a glycoprotein that consists of five integral proteins. There are about 20,000 per mm^2 of these receptors in the synapse sites of muscle cells. When two acetylcholine molecules bind to the receptor, they cause a change in conformation of the proteins that opens the channel. The channel has a cluster of negatively charged amino acid residues at its entrance, which is thought to prevent the passage of negative ions. Its diameter is about 0.65 nm, so it will allow the passage of positive ions such as Na^+ , K^+ , and Ca^{2+} . In muscle cells, Na^+ ions are the main contributors to the change in membrane potential ($\sim 30,000$ ions per channel per millisecond). Ca^{2+} ions make a small contribution because their extracellular concentration is much lower than that of Na^+ ions, while for K^+ ions, the leakage out almost balances the voltage gradient-driven inward movement.

MECHANISM OF ACTION

Experimental work has shown that the main site of local anesthetic action is on the cell membrane. Local anesthetics do not appear to have any appreciable effect on the intracellular fluid (*axoplasm*). Various theories have been put forward to explain the mechanism of the action.¹⁰ Many of these postulate prevention of conduction and formation of an action potential by either fully or partially blocking the Na⁺ ion channels. Blocking is believed to be achieved either by the drug molecule causing a physical block in the channel, like a cork in a bottle, or by the drug molecule distorting the channel. If enough sodium channels are blocked, there would be no significant changes in membrane potential, the firing potential would not be reached, and conduction of an action potential along the neuron would be prevented. Blocking of conduction would automatically prevent the release of neurotransmitter at the presynaptic site. Increasing the Ca⁺ ion concentration of the extracellular fluid may either enhance or reduce the activity of a local anesthetic by affecting the opening of sodium channels.

Shanes¹¹ suggested in 1958 that local anesthetics acted

by increasing the surface pressure of the cell membrane, which would result in the closure of ion channels. In 1968, Metcalfe and Burgen¹² proposed that the nerve impulse was blocked by the drug increasing disorder of the membrane, which caused distortion of the ion channels. However, based on the work of several research groups (Richie¹⁰ in 1975, Hille¹⁴ in 1980, Strichartz¹⁵ in 1980, and Strichartz and Ritchie¹³ in 1985), it is now believed that the main mechanism of local anesthetic action is associated with the blocking of sodium channels (Fig. 20-12). Strichartz¹⁵ also showed, in 1981, that the receptor for the blocking action appears to be about halfway down the sodium channel. Work by Schneider and Dubois⁹ in 1986 indicated that benzocaine blocks two different types of sodium channel. Their work suggested that these channels have different affinities for the drug and so differing rates of inactivation. Other investigations in 1986 by Moczydlowski et al.⁸ of the blocks imposed by local anesthetic agents indicated that there are at least two sites of action of local anesthetic agents and not one in the interior entrance of the channel, as previously proposed by Hille. Their work also supported the idea of a wide internal entryway into the channel but a constricted external entry. This internal entry was large enough to allow the passage of organic molecules, but the external entry was small enough to prevent the ingress of organic molecules with a single methyl group. It was, however, large enough to permit the entry of divalent cations such as Ca^{2+} and Co^{2+} . The observations made by Moczydlowski et al. were supported by the work of MacIver and Roth¹⁶ (1987) on a single isolated neuron (crayfish stretch receptor), which also suggested the existence of receptor sites that can discriminate between the structures of different anesthetics. These deductions were supported by those of Elliot et al.¹⁷ in 1987, who concluded from their investigation of the inhibition of sodium current in giant squid axon by benzocaine that there were at least two sites for the action of the drug.

It is an important feature of the local anesthetics in clinical use that their structures include tertiary amine groups that coexist in equilibrium with the conjugate acid at physiological pH:

Experimental studies carried out by Narahashi and Frazier¹⁸ in 1971 and Strichartz and Ritchie¹³ in 1985 indicated that the site of action of local anesthetics is only accessible from the interior of the neuron. Consequently, as neutral molecules cross membranes more easily than charged molecules, the drug must cross the membrane in its uncharged form before it can enter and block the ion channel. Once inside the neuron, experimental evidence suggests that the action of the drug is mainly due to its charged form and that its binding to the receptor is voltage dependent.^{18, 19}

Analysis of the work of Strichartz, Hille, and Ritchie has shown that the block caused by many local anesthetic agents depends on the number of channels open; the greater the number open, the greater the block. This suggests that the activity of the local anesthetic agent depends on it entering the channel from inside the neuron ("the hydrophilic pathway"). However, blocks can arise even if the channel is not open. This is explained by the local anesthetic agent entering the channel directly from the membrane ("the hydrophobic pathway"). The relative effects of these two pathways appear to depend on the lipid solubility of the drug, but both appear to contribute to the blocking effect.

Local anesthetic agents are removed from the site of application by the blood flowing through the tissues and mem-

branes in the area of application. Metabolism occurs through a variety of routes in both the plasma and the liver. Ester-type agents such as procaine are either eliminated by hydrolysis in the plasma, catalyzed by plasma esterases, or in the liver, catalyzed by specific liver esterases.

The 4-aminobenzoic acid (PABA) produced in this hydrolysis inhibits the action of sulfonamides. However, the PABA is excreted in the urine, partly in the form of conjugates. The diethylaminoethanol is also excreted in the urine but about 70% is metabolized by the liver. Amide-based local anesthetics may also be hydrolyzed by plasma esterases, but the rate of hydrolysis is usually slower than that for the corresponding ester agents. Consequently, amide local anesthetic agents are more likely to be hydrolyzed in the liver. Amide local anesthetic agents are also metabolized by oxidation and N-alkylation in the liver. For example, lignocaine is metabolized by both hydrolysis and N-dealkylation (Fig. 20-13). The importance of the liver in the metabolism of amide-based local anesthetics means that use of these agents in patients with severe liver damage should be avoided, as any toxic effects of the local anesthetic agent will be increased because of a reduced rate of metabolism.

The delivery of local anesthetic agents to the liver for metabolism appears to be related to their degree of binding to

Figure 20-13 ■ Metabolism of lignocaine.

plasma proteins. Experimental work by Tucker et al. (1970) showed that amide-based local anesthetic agents bind more readily to plasma and tissue proteins than do ester-based agents. The binding of amide-based agents often involves the anesthetic binding to α_1 -acid glycoprotein. This binding is usually significant, ranging from 55 to 95% of the drug. However, many factors influence the concentration of plasma proteins; for example, cancer, smoking and trauma decrease the concentration of plasma proteins, while oral contraceptives increase their concentration. Plasma protein concentration may also be altered in many diseases. Obviously these changes will influence the quantity and rate of delivery of the local anesthetic to the liver, with subsequent changes in the systemic toxicity of the drug.

The elimination of local anesthetics and their metabolites from the liver depends on hepatic blood flow. If this flow is reduced, it can result in an increase in concentration of agents and their metabolites in the body when large doses are administered over long periods. This buildup may result in an increase in the systemic toxicity of the local anesthetic agent.²⁰

ADMINISTRATION

Topical or Surface Anesthesia^{20, 21}

Direct application of a local anesthetic agent to the skin or a mucous membrane blocks the sensory nerve endings. The local anesthetic may be applied in the form of a liquid, spray, cream, ointment, or gel. It appears that the form used is often selected subjectively. For example, in the use of local anesthetic agents as premedication in gastrointestinal endoscopy, the patients preferred sprays, even though the degree of anesthesia was the same for sprays and gargles.

Anesthesia of the mucous membranes of the ear, nose, and throat is usually brought about by use of aqueous solutions of the salts of tetracaine, lignocaine, or cocaine. The vasodilator effect of cocaine reduces bleeding in surgical procedures. However, all local anesthetics are rapidly absorbed through mucous membranes, and so their use may be accompanied by an increased risk of toxic systemic reactions. As a result, dosage must be carefully controlled.

Infiltration Anesthesia

A set dose of the local anesthetic in a suitable solvent system is injected directly into the area of the body that is to be anesthetized. These areas range from the skin to deeper tissues. The most frequently used local anesthetics for infiltration are lignocaine, bupivacaine, and procaine.

The technique produces a good degree of anesthesia in a localized area without disrupting general bodily functions. However, the use of this technique may require large concentrations of anesthetic to bring about the desired degree of anesthesia, with an attendant increase in the risk of toxic systemic reactions.

Field Block Anesthesia

A solution of the local anesthetic is injected subcutaneously at a point adjacent to the area that is to be anesthetized, so

that it blocks the nerve transmissions to that region. Field block anesthesia is brought about by the same drugs used for infiltration anesthesia. However, the technique produces a larger region of anesthesia with a lower dose of the local anesthetic than is required by the infiltration technique.

Regional Nerve Block Anesthesia

Regional nerve block anesthesia is usually brought about by either injection of the anesthetic in a suitable solvent system into the nerve or infiltration of the anesthetic into the tissue surrounding a nerve or plexus supplying the region to be anesthetized. For example, spinal anesthesia may be brought about by injection into the cerebrospinal fluid in the subarachnoid space. Dental anesthesia is brought about by flooding the area around the nerve by injecting the anesthetic into the adjacent tissue. The local anesthetic agent used for a nerve block depends on which nerve is to be blocked, the length of time the anesthesia is required, and the medical condition and physique of the patient. Duration of action is usually prolonged by the use of vasoconstrictors rather than by increasing the dose. This approach reduces the chances of the drug spreading to regions that do not require anesthesia.

Intravenous Regional Anesthesia

Intravenous regional anesthesia is used to anesthetize a large region, such as a limb. The anesthetic is injected into a suitable vein in a limb that has had its blood flow restricted by a tourniquet. The efficiency and safety of the technique depends on preventing arterial flow for the duration of the anesthesia. Lignocaine is frequently used to produce intravenous regional anesthesia, but bupivacaine is not approved for this purpose because of its long duration of action.

Spinal Anesthesia

Spinal anesthesia is carried out by injecting the anesthetic agent into the subarachnoid space in the spinal cord. The anesthetic acts mainly on the nerve fibers and blocks the pain regions of the body served by the sections of the spinal cord affected.

Epidural Anesthesia

The drug is injected into the epidural space between the vertebrae and spinal cord. This numbs the nerves leading to the uterus and the pelvic area and leads to pain relief during labor. Epidural anesthesia may sometimes cause headaches.

FACTORS INFLUENCING THE EFFECTIVENESS OF THE ANESTHETIC ACTION

Susceptibility of the Neuron to Anesthesia

Pain information is carried by the largely unmyelinated C fibers, while sharp pain is transmitted by myelinated A δ fibers. The sensitivity of nerve fibers to local anesthetic appears to vary according to the size, anatomical type, and degree of conductance of the nerve fiber. In general, the

order of onset of local anesthesia with increasing concentration of agent is often small nonmyelinated fibers > small myelinated fibers > large fibers. However, this order is not strictly followed in practice. Some myelinated fibers are blocked with lower concentrations of local anesthetics than some nonmyelinated fibers, while large fibers are often blocked before smaller fibers. Furthermore, in experimental work, the outer fibers in the nerve are affected first, regardless of their nature.

Experimental work by Franz and Perry²² in 1974 supported by the work of Chiu and Ritchie²³ in 1984 suggests that the differential blocking of nerve fibers depends on the length of axon that has to be exposed to the local anesthetic to bring about anesthesia. Shorter nerve fibers have shorter internodal distances and in the early stages of anesthesia are fully exposed to the local anesthetic, with the result that they are more readily blocked than longer fibers. In most patients, the sensation of pain is the first to be lost, followed by temperature and touch.

pH of the Extracellular and Intracellular Fluids

Local anesthetics are normally weak bases ($pK_a \sim 8.5$), which are only slightly soluble in water. Consequently, they are usually marketed as aqueous solutions of their more soluble salts. These solutions are often quite acidic, which makes them less prone to bacterial and fungal contamination. However, an aqueous solution of the salt of a local anesthetic will normally contain between 2 and 15% of the free base in equilibrium with the salt.

Although the drug is mainly transferred through the cell membrane in its free base form, administration of the drug in alkaline solution does not enhance its activity. This is because the structure of the drug is controlled by the pH of the extracellular fluid and not the pH of the dosage form. Once inside the neuron, equilibrium is reestablished. Both the free base and its protonated form are known to be active, but it is not known whether they bind to the same receptor site. However, it does appear that the protonated base plays the major part in anesthetic activity.^{12, 24, 25}

Vasoconstrictors

The anesthetic action of local anesthetics is proportional to the time that the agent is in contact with nerve tissue. As early as 1903, Braun discovered that the addition of adrenaline to solutions of local anesthetics increased and prolonged their action. It is now accepted that the addition of vasoconstrictors such as adrenaline to local anesthetic solutions prolongs and intensifies their action. The agent is confined to its site of action by reducing the rate at which the blood

carries it away. Vasoconstrictors such as adrenaline also reduce the rate of absorption of a drug by allowing the metabolic rate of the local anesthetic to keep pace with the rate at which it is absorbed into the bloodstream. This also reduces systemic toxicity. However, prolonged use of a vasoconstrictor on major arteries may cause irreversible tissue damage and can lead to gangrene.

The main vasoconstrictors in current use with local anesthetics are adrenaline (epinephrine), noradrenaline (norepinephrine), and felypressin. Solutions of local anesthetics often contain either adrenaline or a synthetic analogue such as phenylephrine. The effect of vasoconstrictors depends on the local anesthetic agent used; for example, adrenaline significantly prolongs the action of lignocaine but has less effect with prilocaine. The concentrations of vasoconstrictors are kept as low as possible to reduce the risk of unwanted side effects, such as chest pains, palpitations, and increased heart rate. Local anesthetic preparations containing vasoconstrictors should never be used on digits, since they have no alternative blood supply. Consequently, restriction of blood supply can cause necrosis, a form of enforced cell death. Additionally, preparations containing adrenaline should not normally be used on patients with diseases including poorly controlled diabetes, cardiovascular disease, and thyrotoxicosis. Cocaine is a vasoconstrictor and so probably owes some of its effectiveness to this property.

Neuron Stimulation

The effectiveness of the blocking action of a given concentration of a local anesthetic agent depends on the frequency and extent to which a neuron has been recently stimulated. The greater the frequency of this stimulation, the more effective the local anesthetic agent is in blocking a response.^{14, 26}

RATE OF ONSET AND DURATION OF ANESTHESIA

The time for the onset of action appears to be related to the type of tissue being anesthetized, the method of administration, and the percentage of the local anesthetic agent in its unprotonated form at physiological pH. Since the degree of protonation is indicated by the pK_a value of the drug, local anesthetic agents with a low pK_a value and high lipid solubility usually have a more rapid onset of action than those with higher pK_a values and lower lipid solubility. For example, lignocaine, which is about 35% unprotonated at pH 7.4, usually has a more rapid onset of action than bupivacaine, which is about 8% unprotonated at this pH. The time taken for the

drug to diffuse from its site of application to its site of action will also affect the rate of onset of anesthesia.¹⁰

Reportedly,^{27, 28} the time taken for the onset of anesthesia can be reduced by the use of the hydrogen carbonate form of the drug. This does not increase the toxicity of the local anesthetic agent, but it has been reported to reduce the pain associated with injection and improve the effectiveness of the block in some cases.

The duration of action appears to be related to the lipid solubility of the local anesthetic agent and its ability to bind to protein. As a general rule, the more lipid soluble the drug, the longer the duration of its action. It is difficult, to classify local anesthetics in terms of the duration of anesthesia, however, because although the period of action depends on the dose, the relationship between dose and duration of anesthesia is not clear. In most cases, increasing the dose increases the duration of the anesthesia, but the relationship is not linear. For example, doubling a dose does not necessarily double the time of action.

The dose used clinically is usually determined by factors such as systemic toxicity, potency, and the time for which the anesthesia is required. When long periods of anesthesia are required, it is better to repeat applications rather than use large doses. This keeps dose levels to a minimum, which reduces the level of any possible systemic toxicity.

SECONDARY PHARMACOLOGICAL ACTION

Local anesthetics do not rely on blood circulation to reach their site of action, as they are usually administered at, or close to, their site of action. Systemic side effects arise because the local anesthetic agent is carried away in the blood before it can be fully metabolized. Consequently, the chemical and pharmacological properties of local anesthetics are of major importance in determining not only the effectiveness of the drug but also its systemic side effects.

Local anesthetic agents can affect the function of any organs in which electrical impulse transmission occurs. The nature and the extent of these unwanted side effects depend on the drug used, the concentration of the drug in circulation, the site of application, and the technique used. The secondary effects of local anesthetic agents in these situations are discussed in this section.

Cardiovascular System

Local anesthetic agents usually affect the cardiovascular system by decreasing the force of contraction, electrical excitability, and conduction of the myocardium. A high systemic concentration of local anesthetic is usually necessary, however, before any of these effects are observed. Occasionally, low concentrations administered by infiltration cause cardiovascular collapse and death. The reason for cardiovascular collapse is not known,²⁹ it appears, however, that local anesthetic agents may act as antiarrhythmic agents by blocking the Na^+ , K^+ , and Ca^{2+} channels responsible for the excitation of heart muscle. For example, many workers believe that lignocaine may reduce the possibility of Na^+ channels opening during depolarization. Recovery from this type of block, however, is usually rapid.

Central Nervous System

All amide-based local anesthetics can stimulate the CNS, causing symptoms ranging from restlessness to clonic convulsions. Stimulation may be followed by depression of the CNS and death, usually from respiratory failure. These unwanted side effects appear to be related to the potency of the anesthetic. It is therefore possible to predict these side effects from a knowledge of the drug and its concentration in the bloodstream. Unfortunately, convulsions can occur with little or no warning but can be prevented or stopped by the use of sedatives, such as diazepam or barbiturates, although near-anesthetic doses of the latter are required.

Other types of local anesthetic can stimulate the CNS system but often lead to drowsiness. Individual compounds may cause other unwanted side effects, however. For example, at blood concentrations of $5 \mu\text{g cm}^{-3}$, lignocaine may produce muscle twitching, dysphoria, and euphoria. Both lignocaine and procaine can produce symptoms of sedation, followed by unconsciousness. Cocaine, in common with some other local anesthetic agents, has an effect on mood and behavior.

Blood³⁰⁻³²

Amethocaine (tetracaine), benzocaine, lignocaine, and prilocaine have been reported to induce methemoglobinemia. This is a condition in which the level of methemoglobin in erythrocytes exceeds the normal 1 to 2%. Methemoglobin is hemoglobin that contains iron III instead of iron II and so cannot transport oxygen. Concentrations of about 15% result in the appearance of cyanosis in which the lips take on a purple-blue coloration. High concentrations are rare but are associated with a high mortality rate. It has been suggested that methemoglobinemia may be due to either the presence of an aromatic amine in the local anesthetic or the metabolism of the local anesthetic to an aromatic amine.

Wound Healing

Local anesthetics may interfere with wound healing. This is particularly important in surgery carried out on the hands and feet.

Hypersensitivity

Hypersensitivity to local anesthetics appears to be related to both chemical structure and the method of administration. Allergic reactions occur most frequently with ester-based local anesthetic agents (benzoic acid derivatives). Adverse effects include allergic dermatitis, asthmatic attack, or, in extreme cases, death due to anaphylactic shock. Individuals suffering a hypersensitive reaction from one local anesthetic agent are often sensitive to compounds with a similar structure. For example, patients sensitive to procaine are often also sensitive to amethocaine.

Amide-based local anesthetic agents do not usually produce hypersensitivity reactions, although they may be responsible for other unwanted effects and have been implicated in malignant hyperpyrexia. Families with a history of this disease should only be treated with ester-based local anesthetics.

Patch testing frequently provides adequate warning of hypersensitivity. When Ruzicka et al. (1987) conducted allergy

tests on 104 patients who were known to have had an allergic reaction to benzocaine and procaine, however, the results showed that prick testing did not indicate an allergic reaction and intracutaneous testing rarely gave a hypersensitive reaction. They concluded that contact allergic patients could be injected with local anesthetic agents without a significant risk of a reaction.

Hypotension caused by local anesthetic agents is often unrelated to the type of drug used and can be prevented by premedication with a suitable sedative.³³

STRUCTURE ACTION

A large number of compounds will produce a conduction block. Most of the local anesthetic agents in general use, however, may conveniently be classified into four basic types, namely, those that act by hypothermia, alkaloids, derivatives of benzoic acid and aniline, and miscellaneous compounds. The benzoic acid and aniline group contains most of the local anesthetic agents currently in clinical use.

It is not possible to relate the chemical structures of local anesthetics to their activity because little is known about the structures of the receptors. It is possible, however, to pick out similar structural features between some of the active compounds in common use.

Agents With Hypothermic Action

Local anesthetics that act by reducing the temperature of the area being anesthetized are largely of historical interest. Most of the chemical agents used, however, produce intense cold through rapid evaporation and, hence, an anesthetic action. One of the most effective was ethyl chloride, which is still in use today as a topical local anesthetic. This agent should not be used on mucous membranes or broken skin, however, and prolonged use may cause chemical frostbite.

Alkaloids³⁴

Alkaloids are obtained from plants and trees. The only one in general clinical use is cocaine, which because of its addictive properties is largely restricted to use with the ear, nose, and

throat. Cocaine is of considerable interest, however, because of the active agents that were developed from its structure.

Tetrodotoxin and saxitoxin are naturally occurring local anesthetic agents but are too toxic to be of clinical use. Tetrodotoxin is found in the tissue and organs of fish of the order *Tetraodontiformes*, and saxitoxin is isolated from some marine dinoflagellates. These compounds, which are highly toxic to humans, are structurally different but appear to have the same mechanism of action. They are thought to block the external opening of the Na^+ channel. Interest in these compounds centers on the fact that they could lead to the development of new local anesthetic agents and their use as tools in neurochemical research work and in investigating the molecular nature of action potentials and sodium channels.¹⁰

Benzoic Acid and Aniline Derivatives With Local Anesthetic Activity

Most of the local anesthetic agents in current medical use are of these types (Tables 20-2 and 20-3). The benzoic acid derivatives are esters that were developed from cocaine, while the aniline derivatives are amides developed from isogramine. Both types of derivative have chemical structures that normally have the general format:

Both the ester and N-substituted amide functional groups are bioisosteres (Fig. 20-14), which explains the occurrence of these groups in similar positions in the structures of local anesthetics.

The lipophilic center is usually either a carbocyclic or a heterocyclic ring system, while the hydrophilic center is normally a secondary or a tertiary amine that might or might not be cyclic. Tertiary amines are more useful, since they are less irritating to tissue. The hydrophilic center may be attached to the ester or amide by either a short hydrocarbon chain or oxygen, nitrogen, or sulfur atoms. Most of the local anesthetic agents, in common, however, use a short hydrocarbon chain. The lipophilic center is believed to be largely responsible for the lipid solubility of the local anesthetic agent and its ability to pass through the nonpolar heart of

the cell membrane. Lipid solubility plays an important part in the action of local anesthetics, since their action depends on their ability to penetrate the cell membrane of the axon.

The hydrophilic center provides the local anesthetic agent with some of its water solubility. This is an essential factor in transporting the drug to the membrane and, once inside the cell, to the receptor. The hydrophilic center also allows the drug to penetrate the polar outer face of the cell membrane, enabling the drug to reach the lipid heart of the membrane. It also allows the drug to pass through the inner polar face of the membrane into the cell. The hydrophilic center is also believed to be involved in the binding of the drug to the receptor.

The best local anesthetic action is obtained when the lipophilic and hydrophilic centers are in balance. If the hydrophilic center is the dominant structure, the anesthetic action of the drug is weak, since its membrane penetration is poor. Similarly, if the lipophilic center is the dominant structure, local anesthetic action is again poor. In this case, the agent can penetrate the lipid membrane of the axon, but its solubility in both extracellular and intracellular fluids is poor.

The pK_a values of a local anesthetic agents have been used as a measure of its ionization and, hence, of the lipophilic-to-hydrophilic ratio. At physiological pH, the ratio of ionized to un-ionized molecules in solution may be calculated by using the appropriate form of the Henderson-Hasselbalch equation, which states for weak monobasic acids

$$pK_a = pH + \log \frac{[\text{non-ionized form}]}{[\text{ionized form}]} \quad (\text{Eq. 20-2})$$

and for weak monoacidic bases

$$pK_a = pH + \log \frac{[\text{ionized form}]}{[\text{non-ionized form}]} \quad (\text{Eq. 20-3})$$

Most clinically useful local anesthetics are weak bases that have pK_a values in the range of 7.5 to 9.5. This implies that compounds with pK_a values below 7.5 are not sufficiently ionized at physiological pH to be effective in bringing about anesthesia, even though they can penetrate the axon. In contrast, drugs with pK_a values above 9.5 are almost fully ionized at physiological pH. Consequently, these drugs are less effective because they have difficulty penetrating the cell membrane.

The partition coefficients of structurally similar local anesthetics have been used as a measure of their relative activity. In vivo experiments have shown that with a series of related structures, an increase in activity corresponds to an increase in partition coefficient until maximum activity is

reached. After this point is reached, the activity decreases, even though the partition coefficient increases. Unfortunately, the increase in activity is often accompanied by an increase in toxicity.

A study³⁵ of the homologous series formed by substituting the aryl ring of local anesthetics by alkyl, alkoxy, and alkylamino groups showed that the partition coefficients of the members of a series increased with an increase in the number of methylene groups in the substituent of the series. In general, the maximum activity in a series was achieved for the C_4 to C_6 homologues. Similarly, substitution of the hydrophilic center showed that the partition coefficient increased with the number of carbon atoms, which was also accompanied by an increase in activity. The use of piperidino and pyrrolidino groups as hydrophilic groups gave products with a degree of activity like that obtained with a diethylamino group. The morpholino group, however, gave products with lower activity.³⁶

Local anesthetics are believed to bind to plasma and tissue proteins by van der Waals' forces, dipole-dipole attractions, and electrostatic forces (Fig. 20-15). Local anesthetic activity of benzoic acid-based drugs improves if the aryl lipophilic center has electron-donor substituents but decreases with electron-acceptor substituents. Therefore, it is likely that electron-donor substituents increase the binding of the local anesthetic agent to the receptor, but electron-acceptor substituents reduce this binding. Buchi and Perlia³⁶ suggested that this latter was a consequence of electron acceptors withdrawing electrons from the carbonyl group, which decreases its polarization. This reduces the strength of the carbonyl group's dipole and, consequently, weakens its dipole-dipole attraction with the receptor.

Compounds whose structures contain amide functional groups tend to bind more strongly to receptor sites. For example, Tucker and coworkers (1970) reported that 95% of bupivacaine bound to plasma and tissue proteins, compared with 55% for prilocaine. Tucker and Mather²⁰ (1975) also showed that the more potent and longer-acting agents are more extensively bound to plasma proteins. This is not the only factor affecting potency, however. For example, amide bonds are more resistant to hydrolysis, which will also effect the duration of action.

Miscellaneous Agents

Several different classes of compounds, other than those discussed in the preceding sections, exhibit some local anesthetic activity (Table 20-4). These compounds are usually

TABLE 20-4 Miscellaneous Compounds With Local Anesthetic Activity

Dimethisoquin	
Diperodon	
Dyclonine hydrochloride	$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}-\text{C}_6\text{H}_4-\text{COCH}_2\text{CH}_2-\text{N}(\text{C}_2\text{H}_5)_2 = \text{HCl}$
Euprocain	
Fomocaine	
Myrtecaine	
Phenacaine hydrochloride	$\text{CH}_3\text{CH}_2\text{O}-\text{C}_6\text{H}_4-\text{NHC}(\text{CH}_3)=\text{N}-\text{C}_6\text{H}_4-\text{OCH}_2\text{CH}_3 = \text{HCl}$
Prantoxine hydrochloride	$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{O}-\text{C}_6\text{H}_4-\text{OCH}_2\text{CH}_2\text{CH}_2-\text{N}(\text{C}_2\text{H}_5)_2 = \text{HCl}$

weak bases with distinct hydrophilic and lipophilic regions. In addition, a wide variety of compounds, including benzyl alcohol, phenol, and some antihistamines, also show some local anesthetic activity.

Histamine and Antihistaminic Agents

THOMAS N. RILEY AND JACK DERUITER

Histamine is a β -imidazolyethylamine derivative that is present in essentially all mammalian tissues. The major physiological actions of histamine are centered on the cardiovascular system, nonvascular smooth muscle, exocrine glands, and the adrenal medulla.¹ In a general sense, histamine plays an important role as a "chemical messenger" component of a variety of pathways that have evolved in multicellular organisms, allowing them to communicate efficiently and effectively. The involvement of histamine in the mediation of allergic and hypersensitivity reactions and the regulation of gastric acid secretion has led to the development of important drug classes useful in the treatment of symptoms associated with allergic and gastric hypersecretory disorders.

HISTAMINE

Nomenclature

Histamine, known trivially as 4(5)-(2-aminoethyl)imidazole, structurally is composed of an imidazole heterocycle and ethylamine side chain. The methylene groups of the aminoethyl side chain are designated α and β . The side chain is attached, via the β -CH₂ group, to the 4 position of an imidazole ring. The imidazole N at position 3 is designated the *pros* (π) N, whereas the N at position 1 is termed the *tele* (τ) N. The side chain N is distinguished as N ^{α} .

Ionization and Tautomerism

Histamine is a basic organic compound (N ^{τ} , pK_{a1} = 5.80; N ^{α} , pK_{a2} = 9.40; N ^{π} , pK_{a3} = 14.0) capable of existing as a mixture of different ionic and uncharged tautomeric species (Fig. 21-1).^{2,3} Histamine exists almost exclusively (96.6%)

as the monocationic conjugate species (α NH₃⁺) at physiological pH (7.4). The ratio of the concentrations of the tautomers N ^{τ} -H/N ^{π} -H has been calculated to be 4.2, indicating that in aqueous solution, 80% of the histamine monocation exists as N ^{τ} -H and 20% exists as N ^{π} -H.

Structure-activity relationship studies suggest that the α -NH₃⁺ monocation is important for agonist activity at histamine receptors and that transient existence of the more lipophilic uncharged histamine species may contribute to translocation of cell membranes. Other studies support the proposal that the N ^{τ} -H tautomer of the histamine monocation is the pharmacophoric species at the H₁ receptor, while a 1,3-tautomeric system is important for selective H₂-receptor agonism.

Stereochemistry

Histamine is an achiral molecule; histamine receptors, however, are known to exert high stereoselectivity toward chiral ligands.⁴ Molecular modeling and steric-activity relationship studies of the influence of conformational isomerism on the activity of histamine suggest the importance of *trans-gauche* rotameric structures (Fig. 21-2) in the receptor activities of this substance. Studies with conformationally restricted histamine analogues suggest that while the *trans* rotamer of histamine possesses affinity for both H₁ and H₂ histamine receptors, the *gauche* conformer does not act at H₂ sites.

HISTAMINE LIFE CYCLE

Knowledge of the biodisposition of histamine is important to understanding the involvement of this substance in various pathophysiologies as well as the actions of various ligands that either enhance or block its actions. Each of the steps in the "life cycle" of histamine represents a potential site for pharmacological intervention.

Biosynthesis and Distribution

Histamine is synthesized in cytoplasmic granules of its principal storage cells, mast cells and basophils.⁵ Histamine is formed from the naturally occurring amino acid, *S*-histidine via the catalysis of either the pyridoxal phosphate-dependent enzyme histidine decarboxylase (HDC, EC 4.1.1.22) or aromatic amino acid decarboxylase (Fig. 21-3). Substrate specificity is higher for HDC. HDC inhibitors (HDCIs) re-

Figure 21-1 ■ Histamine tautomers and cations.

Figure 21-2 ■ Histamine rotamers.

clude α -fluoromethyl histidine (FMH) and certain flavonoids, although no HDCIs have proved useful clinically.

Histamine is found in almost all mammalian tissues in concentrations ranging from 1 to more than 100 $\mu\text{g/g}$. This substance is in particularly high concentration in skin, bronchial mucosa, and intestinal mucosa. It is found in higher concentrations in mammalian cerebrospinal fluid than in plasma and other body fluids.

Storage and Release

Most histamine is synthesized and stored in mast cells and basophilic granulocytes.⁶ Protein-complexed histamine is then stored in secretory granules and released by exocytosis in response to a wide variety of immune (antigen and antibody) and nonimmune (bacterial products, xenobiotics, physical effects, and cholinergic effects) stimuli. The release of histamine as one of the mediators of hypersensitivity reactions is initiated by the interaction of an antigen-IgE com-

plex with the membrane of a histamine storage cell. This interaction triggers activation of intracellular phosphokinase C (PKC), leading to accumulation of inositol phosphates, diacylglycerols, and Ca^{2+} . Exocytotic release of histamine follows the degranulation of histamine storage cells. Histamine is released from mast cells in the gastric mucosa by gastrin and acetylcholine. Neurochemical studies also suggest that histamine is stored in selected neuronal tracts in the central nervous system (CNS).

Receptors

Once released, the physiological effects of histamine are mediated by specific cell-surface receptors.⁷ Extensive pharmacological analysis suggests the existence of at least three different histamine receptor subtypes, H_1 , H_2 , and H_3 .

Histamine H_1 receptors have been detected in a wide variety of tissues including mammalian brain; smooth muscle from airways, gastrointestinal (GI) tract, genitourinary system, and the cardiovascular system; adrenal medulla; and endothelial cells and lymphocytes. The structure of the H_1 receptor has been determined and shown to possess several important features that distinguish it from the H_2 receptor.⁸ The H_1 -receptor protein has a molecular mass of 56 kDa. The deduced sequence of the bovine H_1 -receptor protein represents 491 amino acid residues. Structurally, this receptor contains seven hydrophobic transmembrane domains (TMs) characteristic of most G-protein receptors. The third intracellular loop of the receptor is very large (212 amino acids), and the intracellular C-terminal tail is relatively short (17 amino acids). Site-directed mutagenesis studies have provided evidence for the binding domains of H_1 agonists and antagonists. The third (TM3) and fifth (TM5) transmembrane domains of the receptor protein are responsible for binding histamine. Aspartate (107) of the human H_1 receptor is essential for the binding of histamine and H_1 antagonists to the receptor, perhaps by being involved in an $\text{Asp-COO}^- \cdots \text{H}_3\text{N}^+ - \text{R}$ interaction. Asparagine (207) of the TM5 domain is known to interact with the N^{π} -nitrogen of the imidazole ring of histamine, while lysine (200) has been shown to interact with the nucleophilic N^{γ} -nitrogen of the natural ligand. Signal transduction of the H_1 receptor involves the

activation of phospholipase C (PLC), resulting in inositol phosphate accumulation and calcium mobilization in most tissues.

H_2 receptors have been detected in a wide variety of tissues (most notably for therapeutic consideration, myocardial cells and cell membranes of acid-secreting cells [parietal] of the gastric mucosa) and mediate the gastric acid secretory actions of histamine. The H_2 receptor has the general characteristics of a G-protein-coupled receptor, with a molecular mass of 59 kDa and nonessential N-glycosylation sites in the N-terminal region.⁹ The most notable difference between structures of cloned H_1 and H_2 receptors is the much shorter third intracellular loop and longer C-terminal loop of the H_2 -receptor protein. A TM3 aspartate along with an aspartate and threonine residue in TM5 is apparently responsible for binding histamine. The physiological and pharmacological effects of H_2 -receptor ligands are mediated by a stimulatory G_s-protein-coupled receptor, which in turn activates the adenylate cyclase/cyclic adenosine monophosphate (cAMP) intracellular second-messenger system.

The cloning of the human histamine H_3 receptor in 1999 evoked considerable renewed interest in the field of histamine receptors.¹⁰ The H_3 receptor is proposed to function as a neural autoreceptor (presynaptic) serving to modulate histamine synthesis and release in the CNS. Subsequent studies have also located H_3 sites in peripheral tissue, including the gastric mucosa where this receptor may negatively control gastric acid secretion and on the cardiac sympathetic terminals in the myocardium. Although signal transduction mechanisms of the H_3 receptor have not been fully elucidated, increasing evidence suggests that this receptor belongs to the superfamily of G-protein-coupled receptors.¹⁰

A new histamine receptor, the H_4 subtype, was first reported in 2000 and characterized as a 390-amino acid, G_i-coupled protein with 40% identity to the H_3 receptor.¹⁰ This new receptor exhibits a very restricted localization; expression is primarily found in intestinal tissue, spleen, thymus, and immune active cells, such as T cells, neutrophils, and eosinophils, which suggests an important role for H_4 receptors in the regulation of immune function.

Figure 21-3 ■ Histamine biosynthesis.

Figure 21-4 ■ Metabolism of histamine *ALD-DH*, aldehyde dehydrogenase; *PRT* phosphoribosyltransferase.

Termination of Histamine Action

Three principal ways exist to terminate the physiological effects of histamine³:

- **Cellular uptake.** Animal studies have documented the uptake of histamine by many cells. In particular, uptake is a temperature- and, partially, Na^+ -dependent process in rabbit gastric glands, and the histamine is metabolized once in the cell.
- **Desensitization of cells.** Some H_1 receptor-containing tissues exhibit a homogeneous loss of sensitivity to the actions of histamine, perhaps as a result of receptor modification.
- **Metabolism** (Fig. 21.4).¹¹ The most common pathway for terminating histamine action involves enzymatic inactivation.

The enzyme histamine *N*-methyltransferase (HMT; EC 2.1.1.8) is widely distributed among mammalian tissues and

catalyzes the transfer of a methyl group from *S*-adenosyl-L-methionine (SAM) to the ring *tele*-nitrogen of histamine, producing *N*⁷-methylhistamine and *S*-adenosyl-L-homocysteine. Histamine is also subject to oxidative deamination by diamine oxidase (DAO; EC 1.4.3.6), yielding imidazole acetic acid, a physiologically inactive product excreted in the urine. Similarly, *N*⁷-methylhistamine is converted by both DAO and monoamine oxidase (MAO) to *N*-methyl imidazole acetic acid.

Functions of Endogenous Histamine as Related to Pharmacological Intervention

Histamine exhibits a wide variety of both physiological and pathological functions in different tissues and cells. The actions of histamine that are of interest from both a phar-

macological and therapeutic point of view include (a) its important but limited role as a chemical mediator of hypersensitivity reactions, (b) a major role in the regulation of gastric acid secretion, and (c) an emerging role as a neurotransmitter in the CNS.

HISTAMINE H_1 ANTAGONISTS (ANTIHISTAMINIC AGENTS)

The term *antihistamine* historically has referred to drugs that antagonize the actions of histamine at H_1 receptors rather than H_2 receptors. The development of antihistamine drugs began more than five decades ago with the discovery that piperoxan could protect animals from the bronchial spasm induced by histamine.¹² This finding was followed by the synthesis of a number of *N*-phenylethylenediamines with antihistaminic activities superior to those of piperoxan.¹³ Further traditional structure-activity studies in this series, based largely on the principles of isosterism and functional group modification, led to the introduction in the 1940s to 1970s of a variety of H_1 antagonists containing the diarylalkylamine framework.^{14, 15} These H_1 antagonists, referred to now as the *first-generation* or *classical* antihistamines, are related structurally and include a number of aminoalkyl ethers, ethylenediamines, piperazines, propylamines, phenothiazines, and dibenzocycloheptenes. In addition to H_1 -receptor antagonism, these compounds display an array of other pharmacological activities that contribute toward therapeutic applications and adverse reactions. More recently, a number of second-generation or "nonsedating" antihistamines have been developed and introduced.¹⁶ The second-generation agents bear some structural resemblance to the first-generation agents but have been modified to be more specific in action and limited in their distribution profiles.

Mechanism of Action

H_1 antagonists may be defined as drugs that competitively inhibit the action of histamine on tissues containing H_1 receptors. Traditionally, H_1 antagonists have been evaluated in vitro in terms of their ability to inhibit histamine-induced spasms in an isolated strip of guinea pig ileum. Antihistamines may be evaluated in vivo in terms of their ability to protect animals against the lethal effects of histamine administered intravenously or by aerosol.

To distinguish competitive antagonism of histamine from other modes of action, the index pA is applied to in vitro assays. The index pA_2 is defined as the inverse of the logarithm of the molar concentration of the antagonist that reduces the response of a double dose of the agonist to that of a single one. The more potent H_1 antagonists exhibit a pA_2 value significantly higher than 6. Although there are many pitfalls¹⁷ to be avoided in the interpretation of structure-activity relationship (SAR) studies using pA_2 values, the following example illustrates distinguishing competitive antagonism. pA_2 values for pyrilamine (mepyramine) antagonism range from 9.1 to 9.4 with human bronchi and guinea

pig ileum.¹⁵ By contrast, the pA_2 value in guinea pig atria (H_2 receptor) is 5.3. Thus, one may conclude that pyrilamine is a weak, noncompetitive inhibitor of histamine at the atrial receptors and a competitive inhibitor at H_1 receptors. The structural features required for effective interaction with these receptors are discussed below. Some H_1 antagonists also block histamine release. The concentrations required, however, are considerably higher than those required to produce significant histamine receptor blockade. The H_1 antagonists do not block antibody production or antigen-antibody interactions.¹⁸

Structure-Activity Relationships

The H_1 antagonists are now commonly subdivided into two broad groups—the first-generation, or classical, antihistamines and the second-generation, or "nonsedating," antihistamines—based primarily on their general pharmacological profiles.^{16, 19} The differences between these two series are discussed in more detail in the sections that follow. The most detailed published SAR analyses for H_1 antagonists, however, focus on the structural requirements for the first-generation agents.^{14, 15} From these studies, the basic structural requirements for H_1 -receptor antagonism have been identified as those shown in Figure 21-5. In this structure, *Ar* is aryl (including phenyl, substituted phenyl, and heteroaryl groups such as 2-pyridyl); *Ar'* is a second aryl or arylmethyl group; *X* is a connecting atom of O, C, or N; $(CH_2)_n$ represents a carbon chain, usually ethyl; and *NRR'* represents a basic, terminal amine function. The nature of the connecting atom, as well as the diaryl substitution pattern and amine moiety, has been used to subclassify the first-generation antihistamines as indicated in the sections below.

This diaryl substitution pattern is present in both the first- and second-generation antihistamines and is essential for significant H_1 -receptor affinity. Furthermore, several SAR studies suggest that the two aryl moieties must be able to adopt a noncoplanar conformation relative to each other for optimal interaction with the H_1 receptor.²⁰ The two aromatic systems may be linked, as in the tricyclic antihistamines (phenothiazines, dibenzocycloheptanes, and heptenes, etc.), but again they must be noncoplanar for effective receptor interaction. Most H_1 antagonists contain substituents in one of the aryl rings (usually benzene), and these influence antihistamine potency as well as biodisposition, as discussed for individual classes of compounds in the sections below.

In many of the first-generation, or classical, antihistamines, the terminal nitrogen atom is a simple dimethylamino moiety. The amine may also be part of a heterocyclic structure, however, as illustrated by the piperazines, some propylamines (pyrrolidines and piperidines), some phenothiazines, the dibenzocycloheptenes, and the second-generation

Figure 21-5 ■ General antihistamine structure.

antihistamines. In all cases, the amino moiety is basic, with pK_s s ranging from 8.5 to 10, and thus is presumed to be protonated when bound on the receptor. The moiety is also important in the development of stable, solid dosage forms through salt formation.

The carbon chain of typical H_1 antagonists consists of two or three atoms. As a result, the distance between the central point of the diaryl ring system and the terminal nitrogen atom in the extended conformation of these compounds ranges from 5 to 6 angstroms (Å). A similar distance between these key moieties is observed for those antihistamines with less conformational freedom. In some series, branching of the carbon chain results in reduced antihistaminic activity. There are exceptions, however, as evidenced by promethazine, which has greater activity than its nonbranched counterpart. When the carbon adjacent to the terminal nitrogen atom is branched, the possibility of asymmetry exists. Stereoselective H_1 -receptor antagonism is typically not observed, however, when chirality exists at this site.²¹ Also, in compounds with an asymmetrically substituted unsaturated carbon chain (pyrbutamine and triprolidine), one geometric isomer typically displays higher receptor affinity than the other.

The X connecting moiety of typical H_1 antagonists may be a saturated carbon-oxygen moiety or simply a carbon or nitrogen atom. This group, along with the carbon chain, appears to serve primarily as a spacer group for the key pharmacophoric moieties. Many antihistamines containing a carbon atom in the connecting moiety are chiral and exhibit stereoselective receptor binding. For example, in the pheniramine series and carbinoxamine, this atom is chiral, and *in vitro* analyses indicate that enantiomers with the *S* configuration have higher H_1 -receptor affinity.²²

Generally, the first- and second-generation antihistamines are substantially more lipophilic than the endogenous agonist histamine (or the H_2 antagonists).²³ This lipophilicity difference results primarily from the presence of the two aryl rings and the substituted amino moieties and thus may simply reflect the different structural requirements for antagonist versus agonist action at H_1 receptors.

The nature of this connecting moiety and the structural nature of the aryl moieties have been used to classify the antihistamines as indicated in the sections below. Furthermore, variations in the diaryl groups, X connecting moieties, and the nature of substitution in the alkyl side chain or terminal nitrogen among the various drugs account for differences observed in antagonist potency as well as pharmacological, biodisposition, and adverse reaction profiles. The ability of these drugs to display an array of pharmacological activities is largely because they contain the basic pharmacophore required for binding to muscarinic as well as adrenergic and serotonergic receptors. The relationships of antihistamine structure to these overlapping actions (H_1 antagonist, anticholinergic, and local anesthetic) have been analyzed.

General Pharmacological Considerations

The classical antihistamines have been used extensively for the symptomatic treatment (sneezing, rhinorrhea, and itching of eyes, nose, and throat) of allergic rhinitis (hay fever, polli-

nosis), chronic idiopathic urticaria, and a number of other histamine-related diseases. These uses are clearly attributable to their antagonism of the action of histamine at peripheral H_1 receptors. The drugs best relieve the symptoms of allergic diseases at the beginning of the season when pollen counts are low. Although the symptoms of the common cold might be modified by antihistamines, these agents do not prevent or cure colds, nor do they shorten the course of the disease.¹⁹ The antihistamines also are of little or no value in diseases such as systemic anaphylaxis and bronchial asthma, in which autocoids other than histamine are important.¹⁸

A number of the antihistamines, particularly the phenothiazines and aminoalkyl ethers, have antiemetic actions and thus may be useful in the treatment of nausea, vomiting, and motion sickness.^{18, 19} Also, those agents that produce pronounced sedation have application as nonprescription sleeping aids.^{18, 19} Several of the phenothiazines have limited use in Parkinson-like syndromes as a result of their ability to block central muscarinic receptors.^{18, 19} And, a number of antihistamines, including promethazine, pyrilamine, tripeleminamine and diphenhydramine, display local anesthetic activity that may be therapeutically useful.²⁴

As the general pharmacological profiles above suggest, most antihistamines can interact with a variety of neurotransmitter receptors and other biomacromolecular targets. This is most evident among the first-generation agents, many of which function as antagonists at muscarinic receptors and, to a lesser extent, adrenergic, serotonergic, and dopamine receptors.^{16, 18, 19} Although some of these non-target-receptor interactions may have some therapeutic value (as discussed above), more frequently they are manifested as adverse reactions that limit drug use. This is particularly true of the peripheral anticholinergic effects produced by these drugs and of interactions with a number of neurotransmitter systems in the CNS that result in sedation, fatigue, and dizziness.^{16, 18, 19}

The primary objective of antihistamine research over the past 10 to 15 years has centered on developing new drugs with higher selectivity for H_1 receptors and lacking undesirable CNS actions. The pronounced sedative effects of some of the first-generation agents were attributed to the ability of these drugs to penetrate the blood-brain barrier (BBB) because of their lipophilic nature and then block cerebral H_1 receptors and possibly other receptors.¹⁶ Thus research efforts were initiated to design novel antihistamines with reduced ability to penetrate the CNS and decreased affinity for central histamine receptors. These efforts led to the introduction of the second-generation antihistamines, which are nonsedating and have little antagonist activity at other neurotransmitter receptors at therapeutic concentrations. The pharmacological properties of these agents are discussed in more detail below.

Surprisingly little information is available concerning the pharmacokinetic and biodisposition profiles of the first-generation antihistamines.²³ Generally, the compounds are orally active and well absorbed, but oral bioavailability may be limited by first-pass metabolism. The metabolites formed depend on drug structure to a large extent but commonly involve the tertiary amino moiety. This functionality may be

subject to successive oxidative N-dealkylation, deamination, and amino acid conjugation of the resultant acid. The amine group may also undergo N-oxidation, which may be reversible, or direct glucuronide conjugation. First-generation agents with unsubstituted and activated aromatic rings (phenothiazines) may undergo aromatic hydroxylation to yield phenols, which may be eliminated as conjugates.²³ More detailed pharmacokinetic data are available for the second-generation agents and are included in the monographs that follow.

The H₁ antagonists display a variety of significant drug interactions when coadministered with other therapeutic agents. For example, MAO inhibitors prolong and intensify the anticholinergic actions of the antihistamines.^{16, 18, 19, 23} Also, the sedative effects of these agents may potentiate the depressant activity of barbiturates, alcohol, narcotic analgesics, and other depressants. Recently, it was discovered that several of the second-generation antihistamines may produce life-threatening arrhythmias when coadministered with drugs that inhibit their metabolism.^{16, 18} These interactions are discussed in more detail in the sections below.

First-Generation H₁-Antagonist Drug Classes

AMINOALKYL ETHERS (ETHANOLAMINES)

The aminoalkyl ether antihistamines are characterized by the presence of a CHO connecting moiety (X) and a two- or three-carbon atom chain as the linking moiety between the key diaryl and tertiary amino groups (Fig. 21-6). Most compounds in this series are simple *N,N*-dimethylethanamine derivatives and are so classified in a number of texts. Clemastine and diphenylpyraline differ from this basic structural pattern, in that the basic nitrogen moiety and at least part of the carbon chain are part of a heterocyclic ring system and there are three carbon atoms between the oxygen and nitrogen atoms.

The simple diphenyl derivative diphenhydramine was the first clinically useful member of the ethanolamine series and serves as the prototype. Other therapeutically useful derivatives of diphenhydramine have been obtained by *para* substitution of methyl (methyldiphenhydramine), methoxy (medrylamine), chloro (chlorodiphenhydramine), or bromo (bromodiphenhydramine) on one of the phenyl rings. These derivatives reportedly have better therapeutic profiles than diphenhydramine because of reduced adverse effects.²³

Replacement of one of the phenyl rings of the diphenhydramine with a 2-pyridyl group, as in doxylamine and carbi-

noxamine, enhances antihistaminic activity. These compounds display oral antihistaminic activities 40 and 2 times greater, respectively, than diphenhydramine in animals.²¹

As a result of an asymmetrically substituted benzylic carbon, most of the aminoalkyl ethers are optically active. Most studies indicate that the individual enantiomers differ significantly in antihistaminic activity, with activity residing predominantly in the *S* enantiomer.²²

The diaryl tertiary aminoalkyl ether structure that characterizes these compounds also serves as a pharmacophore for muscarinic receptors. As a result, the drugs in this group possess significant anticholinergic activity, which may enhance the H₁-blocking action on exocrine secretions. Drowsiness is a side effect common to the tertiary aminoalkyl ethers, presumably as a result of the ability of these compounds to penetrate the BBB and occupy central H₁ receptors. Although this side effect is exploited in over-the-counter (OTC) sleeping aids, it may interfere with the performance of tasks requiring mental alertness.^{18, 19} The frequency of GI side effects in this series of antihistamines is relatively low, compared with the ethylenediamine antihistamines.^{18, 19}

In spite of their extensive use, pharmacokinetic data on this series of compounds are relatively limited. Most members of this series apparently are extensively metabolized by pathways including N-oxidation and successive oxidative N-dealkylation followed by amino acid conjugation of the resultant acid metabolites.²³

The structures of the aminoalkyl ether derivatives, along with physicochemical properties, basic therapeutic activity data, and dosage form information are provided in the monographs that follow.

Diphenhydramine Hydrochloride, USP. Diphenhydramine hydrochloride, 2-(diphenylmethoxy)-*N,N*-dimethylethanamine hydrochloride (Benadryl), has an oily, lipid-soluble free base available as the bitter-tasting hydrochloric salt, which is a stable, white crystalline powder soluble in water (1:1), alcohol (1:2), and chloroform (1:2). The salt has a pK_a value of 9, and a 1% aqueous solution has a pH of about 5.

In addition to antihistaminic action, diphenhydramine exhibits antidyskinetic, antiemetic, antitussive, and sedative properties. It is used in OTC sleep-aid products. In the usual dose range of 25 to 400 mg, diphenhydramine is not a highly active H₁ antagonist; it has anticholinergic and sedative properties. Conversion to a quaternary ammonium salt does not alter the antihistaminic action greatly but does increase the anticholinergic action.

As an antihistaminic agent, diphenhydramine is recommended in various allergic conditions and, to a lesser extent as an antispasmodic. It is administered either orally or parenterally in the treatment of urticaria, seasonal rhinitis (hay fever), and some dermatoses. The most common side effect is drowsiness, and the concurrent use of alcoholic beverages and other CNS depressants should be avoided.

Usual adult dose: Oral, 25–50 mg; IM or IV, 10–50 mg

Dosage forms: Capsules, elixir, syrup, tablets, injection

Figure 21-6 ■ General structure of the aminoalkyl ethers.

Diphenhydramine Hydrochloride

Dimenhydrinate, USP. The 8-chlorotheophyllinate (theoclate) salt of diphenhydramine, 8-chlorotheophylline 2-[(diphenylmethoxy)-*N,N*-dimethylethylamine compound (Dramamine), is a white crystalline, odorless powder that is slightly soluble in water and freely soluble in alcohol and chloroform.

Dimenhydrinate (see structure below) is recommended for the nausea of motion sickness and for hyperemesis gravidarum (nausea of pregnancy). For the prevention of motion sickness, the dose should be taken at least one-half hour before beginning the trip. The cautions listed for diphenhydramine should be observed.

Usual adult dose: Oral, 50–100 mg/4 hours; IM or IV, 50 mg/4 hours; rectal, 100 mg q.d. or b.i.d.

Dosage forms: Elixir, syrup, tablets, injection, suppositories

Bromodiphenhydramine Hydrochloride, USP. Bromodiphenhydramine hydrochloride, 2-[(4-bromophenyl)-phenylmethoxy]-*N,N*-dimethylethanamine hydrochloride (Ambodryl Hydrochloride), is a white to pale-buff crystalline powder that is freely soluble in water and in alcohol. Relative to diphenhydramine, bromodiphenhydramine is more lipid soluble and was twice as effective in protecting guinea pigs against the lethal effects of histamine aerosols.

Usual adult dose: Oral, 25 mg/4–6 hours

Dosage forms: Capsules and elixir

Dimenhydrinate

Bromodiphenhydramine Hydrochloride

Doxylamine Succinate, USP. The acid succinate salt (bisuccinate) of doxylamine, 2-[α -[2-(dimethylamino)ethoxy]- α -methylbenzyl]pyridine bisuccinate (Decapryn Succinate), is a white to creamy-white powder with a characteristic odor. It is soluble in water (1:1), alcohol (1:2), and chloroform (1:2). A 1% solution has a pH of about 5.

Doxylamine succinate is comparable in potency to diphenhydramine. It is a good nighttime hypnotic, compared with secobarbital.²⁵ Concurrent use of alcohol and other CNS depressants should be avoided.

Usual adult dose: Oral, 12.5–25 mg/4–6 hours

Dosage forms: Syrup and tablets

Doxylamine Succinate

Carbinoxamine Maleate, USP. The oily, lipid-soluble free base of carbinoxamine is available as the bitter bima-
leate salt, (*d,l*)-2-[*p*-chloro- α -[2-(dimethylamino)ethoxy]-

benzyl]pyridine bimaleate (Clistin), a white crystalline powder that is very soluble in water and freely soluble in alcohol and in chloroform. The pH of a 1% solution is between 4.6 and 5.1.

Carbinoxamine is a potent antihistaminic and is available as the racemic mixture. Carbinoxamine differs structurally from chlorpheniramine only in having an oxygen atom separate the asymmetric carbon atom from the aminoethyl side chain. The more active *levo* isomer of carbinoxamine has the (*S*) absolute configuration²⁶ and can be superimposed on the more active *dextro* isomer (*S* configuration²²) of chlorpheniramine.

Usual adult dose: Oral, 4–8 mg t.i.d. or q.i.d.
Dosage forms: Elixir and tablets

Carbinoxamine Maleate

Clemastine Fumarate, USP. Dextrorotatory clemastine, 2-[2-[1-(4-chlorophenyl)-1-phenylethoxy]ethyl]-1-methylpyrrolidine hydrogen fumarate (1:1) (Tavist), has two chiral centers, each of which is of the (*R*) absolute configuration. A comparison of the activities of the antipodes indicates that the asymmetric center close to the side chain nitrogen is of lesser importance to antihistaminic activity.¹⁵

This member of the ethanolamine series is characterized by a long duration of action, with an activity that reaches a maximum in 5 to 7 hours and persists for 10 to 12 hours. It is well absorbed when administered orally, and it is excreted primarily in the urine. The side effects are those usually encountered with this series of antihistamines. Clemastine is closely related to chlorphenoxamine, which is used for its central cholinergic-blocking activity. Therefore, it is not surprising that clemastine has significant antimuscarinic activity.

Usual adult dose: Oral, 1.34 mg b.i.d. or 2.68 mg q.d. to t.i.d.
Dosage forms: Syrup and tablets

Clemastine Fumarate

Diphenylpyraline Hydrochloride, USP. Diphenylpyraline hydrochloride, 4-(diphenylmethoxy)-1-methylpiperidine hydrochloride (Hispril, Diafen) occurs as a white or slightly off-white crystalline powder that is soluble in water or alcohol. Diphenylpyraline is structurally related to diphenhydramine with the aminoalkyl side chain incorporated in a piperidine ring. It is a potent antihistaminic, and the usual dose is 2 mg 3 or 4 times daily. The hydrochloride is available as 5-mg sustained-release capsules.

Usual adult dose: Oral, 5 mg/12 hours
Dosage forms: Extended-release capsules

Diphenylpyraline Hydrochloride

ETHYLENEDIAMINES

The ethylenediamine antihistamines are characterized by the presence of a nitrogen connecting atom (X) and a two-carbon atom chain as the linking moiety between the key diaryl and tertiary amino moieties (Fig. 21-7). All compounds in this series are simple diarylethylenediamines except antazoline, in which the terminal amine and a portion of the carbon chain are included as part of an imidazoline ring system. Because it differs significantly in its pharmacological profile, antazoline is not always classified as an ethylenediamine derivative.

Phenbenzamine was the first clinically useful member of this class and served as the prototype for the development of more effective derivatives. Replacement of the phenyl moiety of phenbenzamine with a 2-pyridyl system yielded tripeleminamine, a significantly more effective histamine receptor blocker.²³ Substitution of a *para* methoxy (pyrilamine or mepyramine), chloro (chloropyramine), or bromo (bromotripeleminamine) further enhances activity.²³ Replacement of the benzyl group of tripeleminamine with a 2-thienylmethyl group provided methapyrilene, and replacement of tripeleminamine's 2-pyridyl group with a pyrimidinyl moiety (along with *p*-methoxy substitution) yielded thonzylamine, both of which function as potent H₁-receptor antagonists.²³

In all of these compounds the aliphatic or terminal amino group is significantly more basic than the nitrogen atom bonded to the diaryl moiety; the nonbonded electrons on the diaryl nitrogen are delocalized by the aromatic ring, and the

Figure 21-7 ■ General structure of the ethylenediamines

resultant reduction in electron density on nitrogen decreases basicity. Thus the aliphatic amino group in the ethylenediamines is sufficiently basic for the formation of pharmaceutically useful salts.

The ethylenediamines were among the first useful antihistamines.²³ They are highly effective H_1 antagonists, but they also display a relatively high frequency of CNS depressant and GI side effects.¹⁹ The anticholinergic and antiemetic actions of these compounds are relatively low, compared with those of most other classical antihistamines. The piperazine- and phenothiazine-type antihistamines also contain the ethylenediamine moiety, but these agents are discussed separately because they exhibit significantly different pharmacological properties.

Relatively little information is available concerning the pharmacokinetics of this series of compounds. Tripeleonnamine is metabolized in humans by N-glucuronidation, N-oxidation, and pyridyl oxidation followed by phenol glucuronidation. It is anticipated that other members of this series are similarly metabolized.²³

The structures of the salt forms of the marketed ethylenediamine antihistamines, along with physicochemical properties, basic therapeutic activity profiles, and dosage form information, are provided in the monographs below.

Tripeleonnamine Citrate, USP. The oily free base of tripeleonnamine citrate, 2-[benzyl]2-(dimethylamino)ethyl]amino]pyridine citrate (1:1), PBZ (Pyribenzamine Citrate), is available as the less bitter monocationic salt, which is a white crystalline powder freely soluble in water and in alcohol. A 1% solution has a pH of 4.25. For oral administration in liquid dose forms, the citrate salt is less bitter and thus more palatable than the hydrochloride. Because of the difference in molecular weights, the doses of the two salts must be equated—30 mg of the citrate salt is equivalent to 20 mg of the hydrochloride salt.

Usual adult dose: Oral, 25–50 mg/4–6 hours
Dosage forms: Elixir

Tripeleonnamine Citrate or HCl

Tripeleonnamine Hydrochloride, USP. Tripeleonnamine hydrochloride is a white crystalline powder that darkens slowly on exposure to light. The salt is soluble in water (1:0.77) and in alcohol (1:6). It has a pK_a of about 9, and a 1% solution has a pH of about 5.5.

Tripeleonnamine, the first ethylenediamine developed in American laboratories, is well absorbed when given orally. On the basis of clinical experience, it appears to be as effective as diphenhydramine and may have the advantage of fewer and less severe side reactions. Drowsiness may occur,

however, and may impair the ability to perform tasks requiring alertness. The concurrent use of alcoholic beverages should be avoided.

Usual adult dose: Oral tablets, 25–50 mg/4–6 hours; extended-release, 100 mg/8–12 hours
Dosage forms: Tablets, extended-release tablets

Pyrilamine Maleate, USP. The oily free base of pyrilamine is available as the acid maleate salt, pyrilamine maleate, 2-[[2-(dimethylamino)ethyl](*p*-methoxybenzyl)amino]pyridine maleate (1:1), mepyramine, which is a white crystalline powder with a faint odor and a bitter, saline taste. The salt is soluble in water (1:0.4) and freely soluble in alcohol. A 10% solution has a pH of approximately 5. At a pH of 7.5 or above, the oily free base begins to precipitate.

Pyrilamine differs structurally from tripeleonnamine by having a methoxy group in the *para* position of the benzyl radical. It differs from its more toxic and less potent precursor phenbenzamine (Antergan) by having a 2-pyridyl group on the nitrogen atom in place of a phenyl group.

Clinically, pyrilamine and tripeleonnamine are considered among the less potent antihistaminics. They are highly potent, however, in antagonizing histamine-induced contractions of guinea pig ileum.¹⁴ Because of the pronounced local anesthetic action, the drug should not be chewed, but taken with food.

Usual adult dose: Oral, 25–50 mg/6–8 hours
Dosage forms: Tablets

Pyrilamine Maleate

Methapyrilene Hydrochloride. The oily free base is available as the bitter-tasting monohydrochloride salt, methapyrilene hydrochloride, 2-[[2-(dimethylamino)ethyl]-2-thienylamino]pyridine monohydrochloride (Histadyl). It is a white crystalline powder that is soluble in water (1:0.5), in alcohol (1:5), and in chloroform (1:3). Its solutions have a pH of about 5.5. It differs structurally from tripeleonnamine in having a 2-thenyl (thiophene-2-methylene) group in place of the benzyl group. The thiophene ring is considered isosteric with the benzene ring, and the isosteres exhibit similar activity. A study of the solid-state conformation of methapyrilene hydrochloride showed that the *trans* conformation is preferred for the two ethylenediamine nitrogen atoms. The Food and Drug Administration declared methapyrilene a potential carcinogen in 1979, and all products containing it have been recalled.

Methapyrilene Hydrochloride

Thonzylamine Hydrochloride. Thonzylamine hydrochloride, 2-[[2-(dimethylamino)ethyl](*p*-methoxybenzyl)amino]pyrimidine hydrochloride, is a white crystalline powder soluble in water (1:1), in alcohol (1:6), and in chloroform (1:4). A 2% aqueous solution has a pH of 5.5. It is similar in activity to triphenylamine but is claimed to be less toxic. The usual dose is 50 mg up to 4 times daily. It is available in certain combination products.

Thonzylamine Hydrochloride

Antazoline Phosphate. Antazoline phosphate, 2-[(*N*-benzylanilino)methyl]-2-imidazoline dihydrogen phosphate, occurs as a bitter, white to off-white crystalline powder that is soluble in water. It has a pK_a of 10.0, and a 2% solution has a pH of about 4.5. Antazoline, like the ethylenediamines, contains an *N*-benzylanilino group linked to a basic nitrogen through a two-carbon chain.

Antazoline is less active than most of the other antihistaminic drugs, but it is characterized by the lack of local irritation. The more soluble phosphate salt is applied topically to the eye in a 0.5% solution. The less soluble hydrochloride is given orally. In addition to its use as an antihistamine, antazoline has more than twice²⁷ the local anesthetic potency of procaine and also exhibits anticholinergic actions.

Antazoline Phosphate

PIPERAZINES (CYCLIZINES)

The piperazines or cyclizines can also be considered ethylenediamine derivatives or cyclic ethylenediamines (cyclizines); in this series, however, the connecting moiety (X) is a CHN group, and the carbon chain, terminal amine functionality, and the nitrogen atom of the connecting group are all part of a piperazine moiety (Fig. 21-8). Both nitrogen atoms in these compounds are aliphatic and thus display comparable basicities. The primary structural differences within this series involve the nature of the *para* aromatic ring substituent (H or Cl) and, more importantly, the nature of the terminal piperazine nitrogen substituent.

The piperazines are moderately potent antihistaminics with a low incidence of drowsiness.^{18, 19, 23} A warning of the possibility of some dulling of mental alertness is advised, however. The activity of the piperazine-type antihistaminics is characterized by a slow onset and long duration of action. These agents exhibit peripheral and central antimuscarinic activity, which may be responsible for the antiemetic and antvertigo effects.^{18, 19} The agents diminish vestibular stimulation and may act on the medullary chemoreceptor trigger zone. Thus as a group, these agents are probably more useful as antiemetics and antinauseants and in the treatment of motion sickness.

Some members of this series have exhibited a strong teratogenic potential, inducing a number of malformations in rats. Norchlorcyclizine, a metabolite of these piperazines, was proposed as responsible for the teratogenic effects of the parent drugs.²⁸

Metabolic studies in this series of compounds have focused primarily on cyclizine and chlorcyclizine, and these compounds undergo similar biotransformation. The primary pathways involve N-oxidation and N-demethylation, and both of these metabolites are devoid of antihistaminic activity.²³

The structures of the marketed salt forms of the piperazine antihistamines, along with physicochemical properties, basic therapeutic activity profiles, and dosage form information, are provided in the monographs below.

Cyclizine Hydrochloride, USP. Cyclizine hydrochloride, 1-(diphenylmethyl)-4-methylpiperazine monohydrochloride (Marezine), occurs as a light-sensitive, white crystalline powder with a bitter taste. It is slightly soluble

Figure 21-8 ■ General structure of the piperazines

in water (1:115), in alcohol (1:115), and in chloroform (1:75). It is used primarily in the prophylaxis and treatment of motion sickness. The lactate salt (Cyclizine Lactate Injection, USP) is used for intramuscular injection because of the limited water solubility of the hydrochloride. The injection should be stored in a cold place because if it is stored at room temperature for several months, a slight yellow tint may develop. This does not indicate a loss in biologic potency.

Usual adult dose: Oral, 50 mg/4–6 hours; IM, 50 mg/4–6 hours
Dosage forms: Tablets (HCl) and injection (lactate)

Cyclizine Hydrochloride or Lactate

Chlorcyclizine Hydrochloride, USP. Chlorcyclizine hydrochloride, 1-(*p*-chloro- α -phenylbenzyl)-4-methylpiperazine monohydrochloride, a light-sensitive, white crystalline powder, is soluble in water (1:2), in alcohol (1:11), and in chloroform (1:4). A 1% solution has a pH between 4.8 and 5.5.

Disubstitution or substitution of halogen in the 2 or 3 position of either of the benzhydryl rings results in a much less potent compound. Chlorcyclizine is indicated in the symptomatic relief of urticaria, hay fever, and certain other allergic conditions.

Chlorcyclizine Hydrochloride

Meclizine Hydrochloride

Figure 21-9 ■ General structure of the propylamines.

Meclizine Hydrochloride, USP. Meclizine hydrochloride, 1-(*p*-chloro- α -phenylbenzyl)-4-(*m*-methylbenzyl)piperazine dihydrochloride monohydrate (Bonine, Antivert), is a tasteless, white or slightly yellowish crystalline powder that is practically insoluble in water (1:1,000). It differs from chlorcyclizine in having an *N*-*m*-methylbenzyl group in place of the *N*-methyl group. Although it is a moderately potent antihistaminic, meclizine is used primarily as an anti-nauseant in the prevention and treatment of motion sickness and in the treatment of nausea and vomiting associated with vertigo and radiation sickness.

Usual adult dose: Oral, 25–50 mg
Dosage forms: Tablets and chewable tablets

Bucizine Hydrochloride, USP. Bucizine hydrochloride, 1-(*p*-*tert*-butylbenzyl)-4-(*p*-chloro- α -phenylbenzyl)piperazine dihydrochloride (Bucladin-S), occurs as a white to slightly yellow crystalline powder that is insoluble in water. The highly lipid-soluble buclizine has CNS depressant, antiemetic, and antihistaminic properties. The salt is available in 50-mg tablets for oral administration. The usual dose is 50 mg 30 minutes before travel and is repeated in 4 to 6 hours as needed.

Usual adult dose: Oral, 50 mg/4–6 hours
Dosage forms: Tablets

PROPYLAMINES (MONOAMINOPROPYL DERIVATIVES)

The propylamine antihistamines are characterized structurally by an sp^3 or sp^2 carbon connecting atom with a carbon chain of two additional carbons linking the key tertiary amino and diaryl pharmacophore moieties (Fig. 21-9). Those propylamines with a saturated carbon connecting moiety are commonly referred to as the *pheniramines*. All of the pheniramines consist of a phenyl and a 2-pyridyl aryl group and a terminal dimethylamino moiety. These compounds differ only in the phenyl substituent at the *para* position—H (phe-

Bucizine Hydrochloride

niramine), Cl (chlorpheniramine), and Br (brompheniramine). The halogenated pheniramines are significantly more potent (20 to 50 times) and have a longer duration of action.²³

All pheniramines are chiral molecules, and the halogen-substituted derivatives have been resolved by crystallization of salts formed with *d*-tartaric acid. Antihistaminic activity resides almost exclusively in the *S* stereoisomers.²²

The propylamines with an unsaturated connecting moiety include the open derivatives pyrrobutamine and triprolidine and the cyclic analogues dimethindene and phenindamine. In the open-chain propylamines, a coplanar aromatic double-bond system appears to be an important factor for antihistaminic activity. The pyrrolidino group of these compounds is the side chain tertiary amine that imparts greatest antihistaminic activity. The conformational rigidity of the unsaturated propylamines has provided a useful model to determine distances between the key diaryl and tertiary pharmacophoric moieties in H_1 -receptor antagonists, a distance of 5 to 6 Å.

The antihistamines in this group are among the most active H_1 antagonists. The agents in this class also produce less sedation than the other classical antihistamines (yet a significant proportion of patients do experience this effect) and have little antiemetic action. They do, however, exhibit significant anticholinergic activity, albeit less than the aminoalkyl ethers and phenothiazines.^{18, 19, 23}

In the propylamine series, the pharmacokinetics of chlorpheniramine have been studied most extensively in humans.²³ Oral bioavailability is relatively low (30 to 50%) and may be limited by first-pass metabolism. The primary metabolites for this compound and other members of this series are the mono- and di-*N*-dealkylation products. Complete oxidation of the terminal amino moiety followed by glycine conjugation has also been reported for brompheniramine. Chlorpheniramine plasma half-lives range from about 12 hours to 28 hours, depending on the route of administration (oral versus IV).²³

The structures of the marketed salt forms of the propylamine antihistamines, along with physicochemical properties, basic therapeutic activity profiles, and dosage form information, are provided in the monographs below.

Pheniramine Maleate. Pheniramine maleate, 2-[α -(2-dimethylaminoethyl)benzyl]pyridine bimalate (Trimeton, Inhiston), is a white crystalline powder, with a faint amine-like odor, that is soluble in water (1:5) and very soluble in alcohol.

This drug is the least potent member of the series and is marketed as the racemate. The usual adult dose is 20 to

40 mg 3 times daily. It is available in certain combination products.

Pheniramine Maleate

Chlorpheniramine Maleate, USP. Chlorpheniramine maleate, (\pm)-2-[*p*-chloro- α -(2-dimethylamino)ethyl]benzylpyridine bimalate (Chlor-Trimeton), is a white crystalline powder that is soluble in water (1:3.4), in alcohol (1:10), and in chloroform (1:10). It has a pK_a of 9.2, and an aqueous solution has a pH between 4 and 5. Chlorination of pheniramine in the *para* position of the phenyl ring increases potency 10-fold with no appreciable change in toxicity. Most of the antihistaminic activity resides with the *dextro* isomer (see dexchlorpheniramine below). The usual dose is 2 to 4 mg 3 or 4 times a day. It has a half-life of 12 to 15 hours.

Usual adult dose: Oral, 4 mg/4–6 hours; extended release, 8–12 mg/8–12 hours; IM, IV, or SC, 5–40 mg

Dosage forms: Extended-release capsules, syrup, tablets, chewable tablets, extended release tablets, injection

Chlorpheniramine Maleate
Dexchlorpheniramine Maleate

Dexchlorpheniramine Maleate, USP. Dexchlorpheniramine (Polaramine) is the dextrorotatory enantiomer of

chlorpheniramine. In vitro and in vivo studies of the enantiomorphs of chlorpheniramine showed that the antihistaminic activity exists predominantly in the *dextro* isomer. As mentioned above, the *dextro* isomer has the (*S*) configuration,²² which is superimposable on the (*S*) configuration of the more active levorotatory enantiomorph of carbinoxamine.

Usual adult dose: Oral, 2 mg t.i.d. or q.i.d.

Dosage forms: Syrup, tablets, extended-release tablets

Brompheniramine Maleate, USP. Brompheniramine maleate, (+)-2-[*p*-bromo- α -(2-(dimethylamino)ethyl)benzyl]pyridine bimalcate (Dimetane), differs from chlorpheniramine by the substitution of a bromine atom for the chlorine atom. Its actions and uses are like those of chlorpheniramine. It has a half-life of 25 hours, which is almost twice that of chlorpheniramine.

Usual adult dose: Oral, 4 mg t.i.d. or q.i.d.; extended-release,

8–12 mg/8–12 hours; IM, IV, or SC, 10 mg/8–12 hours

Dosage forms: Elixir, tablets, extended-release tablets, injection

Brompheniramine Maleate

Dexbrompheniramine Maleate, USP. Like the chlorine congener, the antihistaminic activity of brompheniramine exists predominantly in the *dextro* isomer, dexbrompheniramine maleate (Disomer), and is of comparable potency.

Pyrbutamine Phosphate. Pyrbutamine phosphate, (*E*)-1-[4-(4-chlorophenyl)-3-phenyl-2-butenyl]pyrrolidine diphosphate (Pyronil), occurs as a white crystalline

powder that is soluble to the extent of 10% in warm water. Pyrbutamine was investigated originally as the hydrochloride salt, but the diphosphate was absorbed more readily and completely. Clinical studies indicate that it is long acting, with a comparatively slow onset of action. The feeble antihistaminic properties of several analogues point to the importance of having a planar $\text{ArC}=\text{CH}-\text{CH}_2\text{N}$ unit and a pyrrolidino group as the side chain tertiary amine.¹⁴

Tripolidine Hydrochloride, USP. Tripolidine hydrochloride, (*E*)-2-[3(1-pyrrolidinyl)-1-*p*-tolylpropenyl]pyridine monohydrochloride monohydrate (Actidil), occurs as a white crystalline powder with no more than a slight, but unpleasant, odor. It is soluble in water and in alcohol, and its solutions are alkaline to litmus.

The activity is confined mainly to the geometric isomer in which the pyrrolidinomethyl group is *trans* to the 2-pyridyl group. Pharmacological studies²⁹ confirm the high activity of tripolidine and the superiority of (*E*) over corresponding (*Z*) isomers as H_1 antagonists. At guinea pig ileum sites, the affinity of tripolidine for H_1 receptors was more than 1,000 times the affinity of its (*Z*) partner.

The relative potency of tripolidine is of the same order as that of dexchlorpheniramine. The peak effect occurs about 3.5 hours after oral administration, and the duration of effect is about 12 hours.

Tripolidine Hydrochloride

Phenindamine Tartrate, USP. Phenindamine tartrate, 2,3,4,9-tetrahydro-2-methyl-9-phenyl-1*H*-indeno[2,1-*c*]pyr-

Pyrbutamine Phosphate

idine bitartrate, occurs as a creamy-white powder, usually with a faint odor and sparingly soluble in water (1:40). A 2% aqueous solution has a pH of about 3.5. It is most stable in the pH range of 3.5 to 5.0 and is unstable in solutions of pH 7 or higher. Oxidizing substances or heat may cause isomerization to an inactive form.

Structurally, phenindamine can be regarded as an unsaturated propylamine derivative, in that the rigid ring system contains a distorted, *trans* alkene. Like the other commonly used antihistamines, it may produce drowsiness and sleepiness; it may also cause a mildly stimulating action in some patients and insomnia when taken just before bedtime.³⁰

Usual adult dose: Oral, 25 mg/4–6 hours
Dosage forms: Tablets

Phenindamine Tartrate

Dimethindene Maleate. Dimethindene maleate, (\pm)-2-[1-[2-(2-dimethylamino)ethyl]inden-3-yl]ethylpyridine bimalate (1:1) (Forhistal Maleate), occurs as a white to off-white crystalline powder that has a characteristic odor and is sparingly soluble in water. This potent antihistaminic agent may be considered a derivative of the unsaturated propylamines. The principal side effect is some sedation or drowsiness. The antihistaminic activity resides mainly in the levorotatory isomer.¹⁴

Dimethindene Maleate

PHENOTHIAZINES

Beginning in the mid-1940s, several antihistaminic drugs have been discovered as a result of bridging the aryl units of agents related to the ethylenediamines. The search for effective antimalarials led to the investigation of phenothiazine derivatives in which the bridging entity is sulfur. Subsequent testing found that the phenothiazine class of drugs had not only antihistaminic activity but also a pharmacologi-

Figure 21-10 ■ General structure of the phenothiazines.

cal profile of its own, considerably different from that of the ethylenediamines (Fig. 21-10). Thus began the era of the useful psychotherapeutic agent.^{19, 31}

The phenothiazine derivatives that display therapeutically useful antihistaminic actions contain a two- or three-carbon branched alkyl chain between the ring system and terminal nitrogen atom. This differs significantly from the phenothiazine antipsychotic series in which an unbranched propyl chain is required. The phenothiazines with a three-carbon bridge between nitrogen atoms are more potent *in vitro*. Also, unlike the phenothiazine antipsychotics, the heterocyclic ring of the antihistamines is unsubstituted.²³

The enantiomers of promethazine have been resolved and have similar antihistaminic and other pharmacological properties as described below.³² This is in contrast with results of studies of the pheniramines and carbinoxamine compounds in which the chiral center is closer to the aromatic feature of the molecule. Asymmetry appears to have less influence on antihistaminic activity when the chiral center lies near the positively charged side-chain nitrogen.

Promethazine, the parent member of this series, is moderately potent by present standards, with prolonged action and pronounced sedative side effects. In addition to its antihistaminic action, it is a potent antiemetic, anticholinergic, and sedating agent and significantly potentiates the action of analgesic and sedative drugs.¹⁹ The other members of this series display a similar pharmacological profile and thus may cause drowsiness and impair the ability to perform tasks requiring alertness. Also, concurrent administration of alcoholic beverages and other CNS depressants with the phenothiazines should be avoided.¹⁹ In general, the combination of lengthening of the side chain and substitution of lipophilic groups in the 2 position of the aromatic ring results in compounds with decreased antihistaminic activity and increased psychotherapeutic properties.

Although few pharmacokinetic data are available for the phenothiazine antihistamines, the metabolism of the close structural analogue promethazine has been studied in detail.²³ This compound undergoes mono- and di-N-dealkylation, sulfur oxidation, aromatic oxidation at the 3 position to yield the phenol, and N-oxidation. A number of these metabolites, particularly the phenol, may yield glucuronide conjugates. It is expected that the phenothiazine antihistamines would display similar metabolic profiles.

Promethazine Hydrochloride, USP. Promethazine hydrochloride, (\pm)-10-[2-(dimethylamino)propyl]phenothiazine monohydrochloride (Phenergan), occurs as a white to faint-yellow crystalline powder that is very soluble in water.

in hot absolute alcohol, and in chloroform. Its aqueous solutions are slightly acid to litmus.

Usual adult dose: Oral, 12.5 mg/4–6 hours or 25 mg q.d.; IM or IV, 12.5–25 mg/4–6 hours

Dosage forms: Syrup, tablets, injection, suppositories

Promethazine Hydrochloride

Trimeprazine Tartrate, USP. Trimeprazine tartrate, (\pm)-10-[3-(dimethylamino)-2-methylpropyl]phenothiazine tartrate (Temaril), occurs as a white to off-white crystalline powder that is freely soluble in water and soluble in alcohol. Its antihistaminic action is reported to be from 1.5 to 5 times that of promethazine. Clinical studies have shown it has a pronounced antipruritic action. This action may be unrelated to its histamine-antagonizing properties.

Usual adult dose: Oral, 2.5 mg q.i.d.

Dosage forms: Syrup and tablets

Trimeprazine Tartrate

Methdilazine, USP. Methdilazine, 10-[(1-methyl-3-pyrrolidinyl)methyl]phenothiazine (Tacaryl), occurs as a light-tan crystalline powder that has a characteristic odor and is practically insoluble in water. Methdilazine, as the free base, is used in chewable tablets because its low solubility in water contributes to its tastelessness. Some local anesthesia of the buccal mucosa may be experienced if the tablet is chewed and not swallowed promptly.

Methdilazine Hydrochloride

Methdilazine Hydrochloride, USP. Methdilazine hydrochloride, 10-[(1-methyl-3-pyrrolidinyl)methyl]phenothiazine monohydrochloride (Tacaryl Hydrochloride), also occurs as a light-tan crystalline powder with a slight characteristic odor. The salt is freely soluble in water and in alcohol, however. The activity is like that of methdilazine, and it is administered orally for its antipruritic effect.

DIBENZOCYCLOHEPTENES AND DIBENZOCYCLOHEPTANES

The dibenzocycloheptene and dibenzocycloheptane antihistamines may be regarded as phenothiazine analogues in which the sulfur atom has been replaced by an isosteric vinyl group (cyproheptadine) or a saturated ethyl bridge (azatadine), and the ring nitrogen has been replaced by an sp^2 carbon atom (Fig. 21-11). The two members of this series are closely related in structure; azatadine is an aza (pyridyl) isostere of cyproheptadine in which the 10,11-double bond is reduced. The properties of each agent are detailed in the monographs below.

Cyproheptadine Hydrochloride, USP. Cyproheptadine hydrochloride, 4-(5*H*-dibenzo-[a,d]-cyclohepten-5-ylidene)-1-methylpiperidine hydrochloride sesquihydrate (Periactin), is slightly soluble in water and sparingly soluble in alcohol.

Cyproheptadine possesses both antihistamine and antiserotonin activity and is used as an antipruritic agent. Sedation is the most prominent side effect, and this is usually brief, disappearing after 3 or 4 days of treatment.

Usual adult dose: Oral, 4 mg t.i.d. or q.i.d.

Dosage forms: Syrup and tablets

Cyproheptadine Hydrochloride

Azatadine Maleate, USP. Azatadine maleate, 6,11-dihydro-11-(1-methyl-4-piperidylidene)-5*H*-benzo-[5,6]cyclohepta[1,2-*b*]pyridine maleate (1:2) (Optimine), is a potent, long-acting antihistaminic with antiserotonin activity. In early testing, azatadine exhibited more than 3 times the potency of chlorpheniramine in the isolated guinea pig ileum screen and more than 7 times the oral potency of chlorpheniramine in protection of guinea pigs against a double lethal dose of intravenously administered histamine.¹³ The

Figure 21-11 ■ General structure of the dibenzocycloheptenes and dibenzocycloheptanes.

usual dosage is 1 to 2 mg twice daily. Azatadine is available in 1-mg tablets.

Usual adult dose: Oral, 1–2 mg b.i.d.
Dosage forms: Tablets

Azatadine Maleate

Second-Generation H₁-Antagonist Drug Classes

The second-generation antihistamines are more similar pharmacologically than structurally. As discussed above in this chapter, these compounds were developed as selective H₁-

receptor antagonists with relatively high potency. Most of these compounds also produce prolonged antihistaminic effects as a result of slow dissociation from H₁ receptors and the formation of active metabolites with similar receptor-binding profiles.¹⁶ The second-generation agents have little affinity for muscarinic, adrenergic, or serotonergic receptors and, therefore, display a lower incidence of side effects associated with antagonism at these receptors. Their affinities for these receptors vary somewhat, as indicated in the monographs below. Perhaps most importantly, all of these compounds lack sedating effects at therapeutic concentrations because of poor CNS penetration and, possibly, lowered affinities for central histaminic,¹⁶ cholinergic, and adrenergic receptors. The first members of this antihistamine subclass introduced in the United States included terfenadine (Seldane) and astemizole (Hismanal) (Fig. 21-12). Although these compounds offered several advantages over the classical antihistamines, widespread use revealed a number of therapeutic limitations, most notably the ability to produce life-threatening arrhythmias when used concurrently with drugs that inhibit their metabolism. This drug interaction has been most evident with the imidazole antifungals (ketoconazole, itraconazole, and fluconazole) and the macrolides (erythromycin, clarithromycin), which inhibit the metabolism of terfenadine and astemizole and thus elevate levels of the parent drugs, which are proarrhythmic.¹⁸ As a result of these concerns, both astemizole and terfenadine have been withdrawn from the U. S. market. Subsequent research efforts focused on the development of second-generation antihistamines that maintained the desired receptor-binding profiles of astemizole and terfenadine but were devoid of proarrhythmic toxicity. These efforts led to the introduction of fexofenadine, loratadine, cetirizine, and acrivastine, as described in the monographs below.

Fexofenadine Hydrochloride. Fexofenadine hydrochloride, (±)-4-[1-hydroxy-4-[4-(hydroxydiphenylmethyl)-1-piperinyl]butyl-α,α-dimethylbenzeneacetic acid (Allegra), occurs as a white to off-white crystalline powder that is freely soluble in methanol and ethanol, slightly soluble in chloroform and water, and insoluble in hexane. This compound is marketed as a racemate and exists as a zwitterion in aqueous media at physiological pH.

Fexofenadine is a primary oxidative metabolite of terfenadine. Terfenadine was developed during a search for new butyrophenone antipsychotic drugs as evidenced by the presence of the *N*-phenylbutanol substituent. It also contains a

Fexofenadine Hydrochloride

Figure 21-12 ■ Structures of terfenadine and astemizole.

diphenylmethylpiperidine moiety analogous to that found in the piperazine antihistamines. Terfenadine is a selective, long-acting (>12 hours) H_1 antagonist with little affinity for muscarinic, serotonergic, or adrenergic receptors. The histamine receptor affinity of this compound is believed to be related primarily to the presence of the diphenylmethylpiperidine moiety. The prolonged action results from very slow dissociation from these receptors.¹⁸ The lack of anticholinergic, adrenergic, or serotonergic actions appears to be linked to the presence of the *N*-phenylbutanol substituent. This substituent also limits distribution of terfenadine to the CNS.^{34, 35} Terfenadine undergoes significant first-pass metabolism, with the predominant metabolite being fexofenadine, an active metabolite resulting from methyl group oxidation. When drugs that inhibit this transformation, such as the imidazole antifungals and macrolides, are used concurrently, terfenadine levels may rise to toxic levels, resulting in potentially fatal heart rhythm problems. The observation that fexofenadine displays antihistaminic activity comparable with that of terfenadine but is less cardiotoxic led to its development as an alternative to terfenadine for the relief of the symptoms of seasonal allergies.³⁶

Fexofenadine is a selective peripheral H_1 -receptor blocker that, like terfenadine, produces no clinically significant anticholinergic effects or α_1 -adrenergic receptor blockade at therapeutic doses. No sedative or other CNS effects have been reported for this drug, and animal studies indicate that fexofenadine does not cross the BBB. In vitro studies also suggest that unlike terfenadine, fexofenadine does not block potassium channels in cardiocytes. Furthermore, in drug interaction studies no prolongation of the QTc interval or related heart rhythm abnormalities were detected when fexofenadine was administered concurrently with erythromycin or ketoconazole.^{16, 37}

Fexofenadine is rapidly absorbed after oral administration, producing peak serum concentrations in about 2.5 hours. Fexofenadine is 60 to 70% plasma protein bound.

Unlike its parent drug, only 5% of the total dose of fexofenadine is metabolized. The remainder is excreted in the bile and urine; the mean elimination half-life is about 14 hours.^{16, 37}

Usual adult dose: Oral, 60 mg b.i.d.
Dosage form: Capsules

Loratadine, USP. Loratadine, 4-(8-chloro-5,6-dihydro-11*H*-benzo[5,6]-cyclohepta[1,2-*b*]pyridin-11-ylidene-1-carboxylic acid ethyl ester, is a white to off-white powder not soluble in water but very soluble in acetone, alcohols, and chloroform.

Loratadine is structurally related to the antihistamines azatadine and cyproheptadine. It differs from azatadine, in that a neutral carbamate group has replaced the basic tertiary

widely, and the drug appears to penetrate the CNS poorly. The metabolic fate of acrivastine has not been reported.

Acrivastine

Usual adult dose: Oral, 8 or 60 mg t.i.d. to q.i.d.
Dosage form: Tablets

INHIBITION OF HISTAMINE RELEASE: MAST CELL STABILIZERS

The discovery of the bronchodilating activity of the natural product khellin led to the development of the bis(chromones) as compounds that stabilize mast cells and inhibit the release of histamine and other mediators of inflammation. The first therapeutically significant member of this class was cromolyn sodium.^{30, 44} Further research targeting more effective agents resulted in the introduction of nedocromil, followed more recently by pemirolast and lodoxamide. Generally, the mast cell stabilizers inhibit activation of, and mediator release from, a variety of inflammatory cell types associated with allergy and asthma, including eosinophils, neutrophils, macrophages, mast cells, monocytes, and platelets. In addition to histamine, these drugs inhibit the release of leukotrienes (C4, D4, E4) and prostaglandins. In vitro studies suggest that these drugs indirectly inhibit calcium ion entry into the mast cell and that this action prevents mediator release. In addition to their mediator release, some of these drugs

also inhibit the chemotaxis of eosinophils at the site of application (i.e., ocular tissue). In lung tissue, pretreatment with the mast cell stabilizers cromolyn and nedocromil blocks the immediate and delayed bronchoconstrictive reactions induced by the inhalation of antigens. These drugs also attenuate the bronchospasm associated with exercise, cold air, environmental pollutants, and certain drugs (aspirin). The mast cell stabilizers do not have intrinsic bronchodilator, antihistamine, anticholinergic, vasoconstrictor, or glucocorticoid activity and, when delivered by inhalation at the recommended dose, have no known therapeutic systemic activity. The structures, chemical properties, pharmacological profiles, and dosage data for these agents are provided in the monographs below.

Khellin

Cromolyn Sodium, USP. Cromolyn sodium, disodium 1,3-bis(2-carboxychromon-5-yloxy)-2-hydroxypropane (Intal), is a hygroscopic, white, hydrated crystalline powder that is soluble in water (1:10). It is tasteless at first but leaves a very slightly bitter aftertaste. The pK_a of cromolyn is 2.0. It is available as a solution for a nebulizer, an aerosol spray, a nasal solution, an ophthalmic solution, and an oral concentrate.

Nebulized and aerosol cromolyn is used for prophylactic management of bronchial asthma and prevention of exercise-induced bronchospasm. Cromolyn nasal solution is used for the prevention and treatment of allergic rhinitis, and oral concentrate is used to treat the histaminic symptoms of mastocytosis (diarrhea, flushing, headaches, vomiting, urticaria, abdominal pain, nausea, and itching). In the treatment of asthma, cromolyn efficacy is manifested by decreased severity of clinical symptoms, or need for concomitant therapy, or both. Long-term use is justified if the drug significantly reduces the severity of asthma symptoms; permits a significant reduction in, or elimination of, steroid dosage; or im-

Cromolyn Sodium

proves management of those who have intolerable side effects to sympathomimetic agents or methylxanthines. For cromolyn to be effective, it must be administered at least 30 minutes prior to antigen challenge and administered at regular intervals (see dosing information below). Overuse of cromolyn results in tolerance.

Usual adult dose:

Nebulizer solution, 20 mg inhaled q.i.d.

Aerosol, 2 metered sprays inhaled q.i.d.

Intranasal, 5.2 mg (one metered spray) in each nostril t.i.d. or q.i.d. at regular intervals

Ophthalmic, 1 drop of a 2–4% solution q.i.d. to 6 times daily

Oral, 2 ampules q.i.d. 30 minutes before meals and at bedtime

Nedocromil Sodium, USP. Nedocromil sodium, disodium 9-ethyl-6,9-dihydro-4,6-dioxo-10-propyl-4*H*-pyrano [3,2-*g*]quinoline-2,8-dicarboxylate (Tilade), is available as an aerosol in a metered-dose inhaler.

Nedocromil is structurally related to cromolyn and displays similar, but broader, pharmacological actions. Nedocromil is indicated for maintenance therapy in the management of patients with mild-to-moderate bronchial asthma. It was developed in a search for a compound with a better biological profile than cromolyn, which has limitations in the treatment of certain patients, such as the elderly asthmatic patient and patients with intrinsic asthma. Cromolyn is more effective in stabilizing connective tissue mast cells than mucosal mast cells, and since release of mediators from mast cells in the lung is an important component of inflammation and bronchial hyperactivity in asthmatic patients, an agent with greater effects on mucosal mast cells was desirable. Available data suggest that nedocromil, although having profile of activity like that of cromolyn, is more effective in stabilizing mucosal mast cells.⁴⁵

Nedocromil Disodium

Lodoxamide Tromethamine

The antiasthmatic effects of nedocromil may also involve inhibition of axon reflexes. Axon reflexes may be produced by bradykinin in the presence of damage to the airway epithelium, resulting in release of sensory neuropeptides (substance P, neurokinin A), which can produce bronchoconstriction and edema. Nedocromil is more effective than cromolyn in reversing bradykinin-induced and neurokinin A-induced bronchoconstriction in humans.

Usual adult dose: Intranasal, 14 mg (two inhalations) q.i.d. at regular intervals

Lodoxamide Tromethamine. The only significant structural similarity between lodoxamide and cromolyn and nedocromil is the presence of two acidic groups. Lodoxamide tromethamine, *N,N'*-(2-chloro-5-cyano-*m*-phenylene)dioxamic acid (Alomide), is a white crystalline, water-soluble powder. It is available as a 0.1% solution, with each milliliter containing 1.78 mg of lodoxamide tromethamine equivalent to 1 mg of lodoxamide. The solution contains the preservative benzalkonium chloride (0.007%) as well as mannitol, hydroxypropyl methylcellulose, sodium citrate, citric acid, edetate disodium, tyloxapol, hydrochloric acid and/or sodium hydroxide (to adjust pH), and purified water.

Lodoxamide is indicated in the treatment of the ocular disorders including vernal keratoconjunctivitis, vernal conjunctivitis, and vernal keratitis.⁴⁶ The dose for adults and children older than 2 years of age is 1 to 2 drops in each affected eye 4 times daily for up to 3 months. The most frequently reported ocular adverse experiences were transient burning, stinging, or discomfort on instillation.

Pemirolast Potassium Ophthalmic Solution. Pemirolast can be considered an analogue of one portion of the cromolyn structure in which the carboxyl group has been replaced with an isosteric tetrazole moiety. Pemirolast potassium, 9-methyl-3-(1*H*-tetrazol-5-yl)-4*H*-pyrido [1,2-*α*]pyrimidin-4-one potassium (Alamast), is a yellow, water-soluble powder. The commercial preparation is available as a 0.1% sterile ophthalmic solution for topical administration to the eyes. Each milliliter of this solution contains 1.0 mg of pemirolast potassium, as well as the preservative lauralkonium chloride (0.005%), and glycerin, phosphate buffers, and sodium hydroxide to maintain a solution pH of 8.0. The solution has an osmolality of approximately 240 mOsm/L. The recommended dose is one to two drops instilled into each affected eye 4 times a day. This drug product is for ocular administration only and not for injection or oral use. Pemi-

last solution should be used with caution during pregnancy or while nursing, since its safety has not been studied under these circumstances.⁴⁷

Pemirolast Potassium

RECENT ANTIHISTAMINE DEVELOPMENTS: THE "DUAL-ACTING" ANTIHISTAMINES

Over the past decade there has been considerable interest in the development of novel antihistaminic compounds with dual mechanisms of action including H_1 -receptor antagonism and mast cell stabilization. Currently available drugs that exhibit such dual antihistaminic actions include azelastine and ketotifen. These compounds contain the basic pharmacophore to produce relatively selective histamine H_1 antagonism (diarylalkylamines) as well as inhibition of the release of histamine and other mediators (e.g., leukotrienes and PAF) from mast cells involved in the allergic response. In vitro studies suggest that these compounds also decrease chemotaxis and activation of eosinophils. Azelastine and ketotifen currently are indicated for the treatment of itching of the eye associated with allergic conjunctivitis. Their antiallergy actions occur within minutes after administration and may persist for up to 8 hours. The structures, chemical properties, pharmacological profiles, and dosage data for these agents are provided in the monographs below.

Azelastine Hydrochloride Ophthalmic Solution.

Azelastine hydrochloride, (\pm)-1-(2*H*)-phthalazinone, 4-[(4-chlorophenyl)methyl]-2-(hexahydro-1-methyl-1*H*-azepin-4-yl)-1-(2*H*)-phthalazinone monohydrochloride (Optivar), is a white crystalline powder that is sparingly soluble in water, methanol, and propylene glycol and slightly soluble in ethanol, octanol, and glycerine. The commercial preparation is available as a 0.05% sterile ophthalmic solution for topical administration to the eyes. Each milliliter of azelastine solution contains 0.5 mg azelastine hydrochloride equivalent to 0.457 mg of azelastine base, the preservative benzalkonium chloride (0.125 mg), and inactive ingredients including disodium edetate dihydrate, hydroxypropylmethylcellulose, sorbitol solution, sodium hydroxide, and water for injection. The solution has a pH of approximately 5.0 to 6.5 and an osmolality of approximately 271 to 312 mOsm/L.

Azelastine

The recommended dose of azelastine solution is one drop instilled into each affected eye twice a day. This drug product is for ocular administration only and not for injection or oral use. Absorption of azelastine following ocular administration is relatively low (less than 1 ng/mL). Absorbed drug undergoes extensive oxidative N-demethylation by cytochrome P-450, and the parent drug and metabolite are eliminated primarily in the feces. The most frequently reported adverse reactions are transient eye burning or stinging, headaches, and bitter taste. Azelastine solution should be used with caution during pregnancy or while nursing, since its safety has not been studied under these circumstances.⁴⁸

Ketotifen Fumarate Ophthalmic Solution. Ketotifen fumarate, 4-(1-methyl-4-piperidylidene)-4*H*-benzo[4,5]cyclohepta[1,2-*b*]thiophen-10(9*H*)-one hydrogen fumarate (Zaditor), is a fine crystalline powder. Ketotifen is a ketothiophene isostere analogue of the dibenzocycloheptane antihistamines. The solution contains 0.345 mg of ketotifen fumarate, which is equivalent to 0.25 mg of ketotifen. The solution also contains the preservative benzalkonium chloride (0.01%) as well as glycerol, sodium hydroxide and/or hydrochloric acid (to adjust pH), and purified water. It has a pH of 4.4 to 5.8 and an osmolality of 210 to 300 mOsm/kg.

Ketotifen Fumarate

The recommended dose of ketotifen solution is one drop instilled into each affected eye every 8 to 12 hours. The most frequently reported adverse reactions are conjunctival

injection, headaches, and rhinitis. This drug product is for ocular administration only and not for injection or oral use. Ketotifen solution should be used with caution during pregnancy or while nursing, since its safety has not been studied under these circumstances.⁴⁹

HISTAMINE H₂ ANTAGONISTS

Drugs whose pharmacological action primarily involves antagonism of the action of histamine at its H₂ receptors find therapeutic application in the treatment of acid-peptic disorders ranging from heartburn to peptic ulcer disease, Zollinger-Ellison syndrome, gastroesophageal reflux disease (GERD), acute stress ulcers, and erosions.^{50, 51}

Peptic Acid Secretion

A characteristic feature of the mammalian stomach is its ability to secrete acid as part of its involvement in digesting food for absorption later in the intestine. The presence of

acid and proteolytic pepsin enzymes, whose formation is facilitated by the low gastric pH, is generally assumed to be required for the hydrolysis of proteins and other foods.

The acid secretory unit of the gastric mucosa is the parietal (oxyntic) cell. Parietal cells contain a hydrogen ion pump, a unique H₃O⁺/K⁺-ATPase system that secretes H₃O⁺ in exchange for the uptake of K⁺ ion. Secretion of acid by gastric parietal (oxyntic) cells is regulated by the actions of various mediators at receptors located on the basolateral membrane, including histamine agonism of H₂ receptors (cellular), gastrin activity at G receptors (blood), and acetylcholine (ACh) at M₂ muscarinic receptors (neuronal) (Fig. 21.13).

Peptic Ulcer Disease⁵²

Peptide ulcer disease (PUD) is a group of upper GI tract disorders that result from the erosive action of acid and pepsin. Duodenal ulcer (DU) and gastric ulcer (GU) are the most common forms, although PUD may occur in the esophagus or small intestine. Factors involved in the pathogenesis and

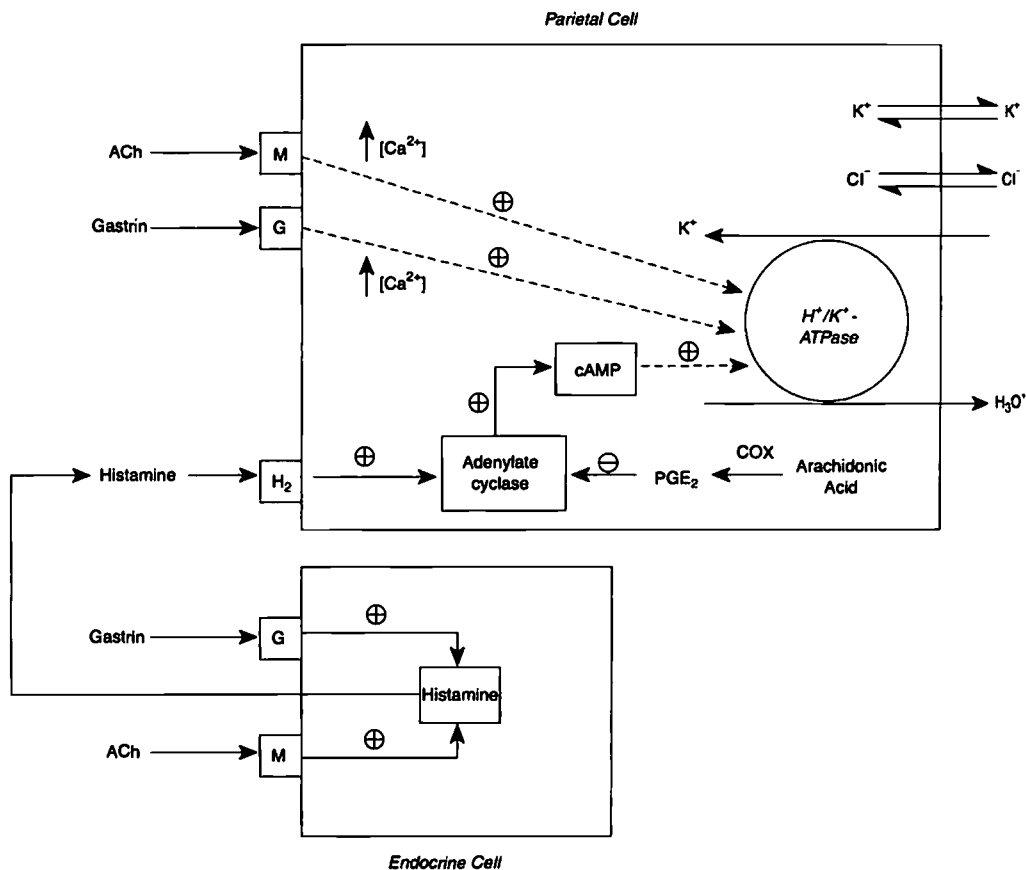

Figure 21-13 ■ Hormonal regulation of acid secretion by parietal cells.

recurrence of PUD include hypersecretion of acid and pepsin and GI infection by *Helicobacter pylori*, a Gram-negative spiral bacterium. *H. pylori* has been found in virtually all patients with DU and approximately 75% of patients with GU. Some risk factors associated with recurrence of PUD include cigarette smoking, chronic use of ulcerogenic drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]), male gender, age, alcohol consumption, emotional stress, and family history.

The goals of PUD therapy are to promote healing, relieve pain, and prevent ulcer complications and recurrences. Medications used to heal or reduce ulcer recurrence include antacids, histamine H_2 -receptor antagonists, protective mucosal barriers, proton pump inhibitors, prostaglandins, and bismuth salt and antibiotic combinations.

Structural Derivation

A review of the characterization and development of histamine H_2 -receptor antagonists reveals a classic medicinal chemistry approach to problem solving.⁵³ Structural evolution of the first discovered, clinically useful H_2 antagonist, cimetidine, is depicted in Figure 21-14. Methylation of the 5 position of the imidazole heterocycle of histamine produces a selective agonist at atrial histamine receptors (H_2). The guanidino analogue of histamine possesses weak antagonist activity to the acid-secretory actions of histamine. Increasing the length of the side chain from two to four carbons, coupled with replacement of the strongly basic guanidino group by the neutral methyl thiourea function, leads to burimamide, the first antagonist to be developed lacking detectable agonist activity in laboratory assays. The

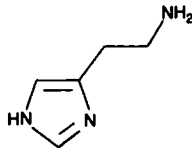

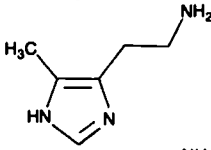

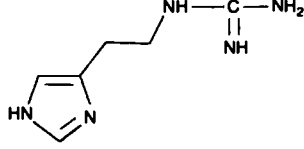

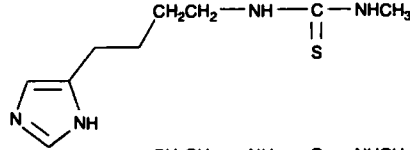

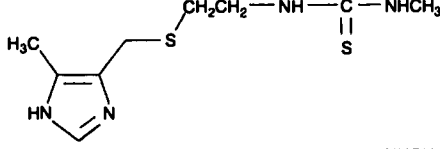

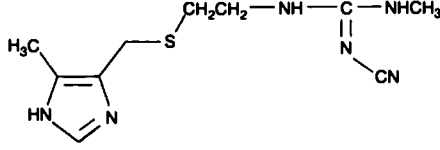

STRUCTURE-ACTIVITY RELATIONSHIP	STRUCTURE
Histamine: $H_1 = H_2$ agonism	
5-Methylhistamine: $H_2 > H_1$ agonism	
N ^G -Guanythistamine: Partial H_2 - receptor agonist (weak antagonist)	
Burimamide: Full H_2 antagonist— low potency, poor oral bioavailability	
Metiamide: Full H_2 antagonist— higher potency, improved oral bioavailability, toxic (thiourea)	
Cimetidine: Full H_2 antagonist— higher potency, high oral bioavailability, low toxicity	

Figure 21-14 ■ Structural derivation of histamine H_2 antagonists.

low potency of burimamide is postulated to be related to its nonbasic, electron-releasing side chain, which favors the nonpharmacophoric N^7 -H imidazole tautomer over the basic, electron-withdrawing side chain in histamine, which predominantly presents the higher-affinity N^7 -H imidazole tautomer to the receptor. Insertion of an electronegative thioether function in the side chain in place of a methylene group favors the N^7 tautomer, and introduction of the 5-methyl group favors H_2 -receptor selectivity and leads to metiamide, a H_2 blocker of higher potency and oral bioavailability than burimamide. Toxicity associated with the thiourea structural feature is eliminated by replacing the thiourea sulfur with a cyano-imino function to produce cimetidine.

Introduction of cimetidine into human medicine revealed an effective gastric antisecretory agent that promotes the healing of duodenal ulcers. Cimetidine is not without a number of limitations, however. Because it is short acting, it requires a frequent-dosing schedule in humans, and in addition, its selectivity is poor. Cimetidine has antiandrogenic activity, which can lead to gynecomastia, and it inhibits the cytochrome P-450 mixed-function oxygenase-metabolizing enzyme system in the liver, an action that potentiates the effects of drugs whose clearance also depends on biotransformation by this system. Cimetidine also causes confusional states in some elderly patients. Subsequent development of additional drugs of this class indicates that a great deal of structural latitude is available in the design of H_2 antagonists (Table 21.1).⁵⁴

Examination of the structural features of H_2 antagonists that came after cimetidine confirms that the imidazole ring of histamine is not required for competitive antagonism of histamine at H_2 receptors. Other heterocycles may be used and may, in fact, enhance both potency and selectivity of H_2 -receptor antagonism. If the imidazole ring is used, however, the N^7 -H tautomer should be the predominant species for maximal H_2 -antagonist activity. The electronic effects of the ring substituents and side-chain structural features determine the tautomerism. Separation of the ring and the nitrogen group with the equivalent of a four-carbon chain appears to be necessary for optimal antagonist activity. The isosteric thioether link is present in the four agents currently marketed in the United States. The terminal nitrogen-con-

taining functionality should be a polar, nonbasic substituent for maximal antagonist activity. Groups that are positively charged at physiological pH appear to confer agonist activity. In general, antagonist activity varies inversely with the hydrophilic character of the nitrogen group. The hydrophilic group, 1,1-diaminonitroethene, found in ranitidine and nizatidine is an exception, however; it is much more active than is predicted by relative solubility effects.

Cimetidine, USP. Cimetidine, N^7 -cyano- N -methyl- N' -(2-[[5-methylimidazol-4-yl)methyl]-thio]ethyl]guanidine (Tagamet), is a colorless crystalline solid that is slightly soluble in water (1.14% at 37°C). The solubility is greatly increased by the addition of dilute acid to protonate the imidazole ring (apparent pK_a of 6.8). At pH 7, aqueous solutions are stable for at least 7 days. Cimetidine is a relatively hydrophilic molecule with an octanol/water partition coefficient of 2.5.

Cimetidine

Cimetidine reduces the hepatic metabolism of drugs biotransformed by the cytochrome P-450 mixed-oxidase system, delaying elimination and increasing serum levels of these drugs. Concomitant therapy of patients with cimetidine and drugs metabolized by hepatic microsomal enzymes, particularly those of low therapeutic ratio or in patients with renal or hepatic impairment, may require dosage adjustment. Table 21.2 provides a compilation of drugs whose combination therapy with cimetidine may increase their pharmacological effects or toxicity. Antacids interfere with cimetidine absorption and should be administered at least 1 hour before or after a cimetidine dose.

Cimetidine has a weak antiandrogenic effect. Gynecomastia may occur in patients treated for 1 month or more.

Cimetidine exhibits high oral bioavailability (60 to 70%) and a plasma half-life of about 2 hours, which is increased

TABLE 21-1 Currently Available H_2 Antagonists

in renal and hepatic impairment and in the elderly. Approximately 30 to 40% of a cimetidine dose is metabolized (S-oxidation, 5-CH₃ hydroxylation), and the parent drug and metabolites are eliminated primarily by renal excretion.

Usual adult oral dose:

Duodenal ulcer: Treatment dose, 800–1,200 mg q.d. to q.i.d. with meals and at bedtime; maintenance dose, 400 mg q.d.
Benign gastric ulcer: 800–1,200 mg q.d. to q.i.d.
Hypersecretory condition: 1,200–2,400 mg q.i.d.
Heartburn: 200 mg (2 OTC tablets) up to twice daily
Usual pediatric dose: Oral, 20–40 mg (base) per kilogram of body weight q.i.d. with meals and at bedtime
Dosage forms: Tablet (200, 300, 400, 800 mg), liquid (300 mg/5 mL), injection (300 mg/2 and 50 mL)

Famotidine, USP. Famotidine, *N'*-(aminosulfonyl)-3-[[[2]-(diaminomethylene)-amino]-4-thiazolyl]methyl]thio]propanimidamide (Pepcid), which uses a thiazole bioisostere of the imidazole heterocycle, is a white to pale-yellow crystalline compound that is very slightly soluble in water and practically insoluble in ethanol.

Famotidine is a competitive inhibitor of histamine H₂ receptors and inhibits basal and nocturnal gastric secretion as well as secretion stimulated by food and pentagastrin. Its current labeling indications are for the short-term treatment of duodenal and benign gastric ulcers, GERD, pathological hypersecretory conditions (e.g., Zollinger-Ellison syndrome), and heartburn (OTC only).

No cases of gynecomastia, increased prolactin levels, or impotence have been reported, even at the higher dosage levels used in patients with pathological hypersecretory conditions. Studies with famotidine in humans, in animal models, and in vitro have shown no significant interference with the disposition of compounds metabolized by the hepatic microsomal enzymes (e.g., cytochrome P-450 system).

Famotidine is incompletely absorbed (40 to 45% bioavail-

ability). The drug is eliminated by renal (65 to 70%) and metabolic (30 to 35%) routes. Famotidine sulfoxide is the only metabolite identified in humans. The effects of food or antacid on the bioavailability of famotidine are not clinically significant.

Usual adult oral dose:

Duodenal ulcer: Treatment dose, 40 mg q.d. to b.i.d. at bedtime; maintenance dose, 20 mg q.d. at bedtime
Benign gastric ulcer: 40 mg q.d.
Hypersecretory condition: 80–640 mg q.i.d.
Heartburn: 10 mg (1 OTC tablet) for relief or 1 hour before a meal for prevention
Dosage forms: Tablet (20 and 40 mg), oral suspension (40 mg/5 mL), injection (10 mg/mL)

Ranitidine, USP. Ranitidine, *N*-[2-[[[5-[dimethylamino]methyl]-2-furanyl]methyl]thio]ethyl]-*N'*-methyl-2-nitro-1,1-ethenediamine (Zantac), is an aminoalkyl furan derivative with pK_a values of 2.7 (side chain) and 8.2 (dimethylamino). It is a white solid. The hydrochloride salt is highly soluble in water.

Bioavailability of an oral dose of ranitidine is about 50 to 60% and is not significantly affected by the presence of food. Some antacids may reduce ranitidine absorption and should not be taken within 1 hour of administration of the H₂-blocker. The plasma half-life of the drug is 2 to 3 hours, and it is excreted along with its metabolites in the urine. Three metabolites, ranitidine *N*-oxide, ranitidine *S*-oxide, and desmethyl ranitidine, have been identified. Ranitidine is only a weak inhibitor of the hepatic cytochrome P-450 mixed-function oxidase system.

In addition to being available in a variety of dosage forms as the hydrochloride salt, ranitidine is also available as a bismuth citrate salt for use with the macrolide antibiotic clarithromycin in treating patients with an active duodenal ulcer.

associated with *H. pylori* infection. Eradication of *H. pylori* reduces the risk of duodenal ulcer recurrence.

Usual adult oral dose:

Duodenal ulcer: Treatment dose, 200–3,000 mg q.d. to b.i.d.; maintenance dose, 150 mg q.d.

Benign gastric ulcer: 300 mg q.d.

Hypersecretory condition: 300–6,000 mg 2 or more times daily

Dosage forms: Tablets (150 and 300 mg of HCl salt), syrup (15 mg/mL as HCl salt), injection (0.5 and 25 mg/mL as HCl salt)

Nizatidine. Nizatidine, *N*-[2-[[[2-[(dimethylamino)methyl]-4-thiazolyl]methyl]thio]ethyl]-*N'*-methyl-2-nitro-1,1-ethenediamine (Axiid), is an off-white to buff crystalline solid that is soluble in water, alcohol, and chloroform. The pK_a s of the drug in water are 2.1 (side chain) and 6.8 (dimethylamino).

Nizatidine has excellent oral bioavailability (>90%). The effects of antacids or food on its bioavailability are not clinically significant. The elimination half-life is 1 to 2 hours. It is excreted primarily in the urine (90%) and mostly as unchanged drug (60%). Metabolites include nizatidine sulfide (6%), *N*-desmethylnizatidine (7%), and nizatidine N_2 -oxide (dinitethylaminomethyl function). Nizatidine has no demonstrable antiandrogenic action or inhibitory effects on cytochrome P-450-linked drug-metabolizing enzyme system.

Usual adult oral dose:

Duodenal ulcer: Treatment dose, 300 mg q.d. to b.i.d.; maintenance dose, 150 mg q.d.

Hypersecretory condition: 150 mg b.i.d.

Dosage forms: Capsules (150 and 300 mg)

Other Antilulcer Therapies

PROTON PUMP INHIBITORS

The final step in acid secretion in the parietal cell is the extrusion ("pumping") of protons. The membrane pump, an H^+/K^+ -ATPase, catalyzes the exchange of hydrogen ions for potassium ions. Inhibition of this proton pump acts beyond the site of action of second messengers (e.g., Ca^{2+} and cAMP) and is independent of the action of secretagogues histamine, gastrin, and acetylcholine. Thus, acid pump inhibitors block basal and stimulated secretion.

In 1972, a group of Swedish medicinal chemists discovered that certain pyridylmethyl benzimidazole sulfides were active proton pump H^+/K^+ -ATPase inhibitors (PPIs).⁵⁵

These compounds were subsequently converted to sulfoxide derivatives, which exhibited highly potent, irreversible inhibition of the proton pump. The benzimidazole PPIs are prodrugs that are rapidly converted to a sulfenamide intermediate in the highly acidic environment of gastric parietal cells. The weakly basic benzimidazole PPIs accumulate in these acidic compartments on the luminal side of the tubovesicular and canalicular structures of the parietal cells. The benzimidazole PPIs are chemically converted by acid to a sulfenamide intermediate that inhibits the proton pump via covalent interaction with cysteine residues (813 or 822) of the pump H^+/K^+ -ATPase (Fig. 21-15).⁵⁶ The acid lability of the benzimidazole PPIs dictates that these drugs must be formulated as delayed-release, enteric-coated granular dosage forms.

The PPIs are more effective in the short term than the H_2 -blockers in healing duodenal ulcers and erosive esophagitis and can heal esophagitis resistant to treatment with the H_2 -blockers.⁵⁷ In addition, the benzimidazole PPIs have antimicrobial activity against *H. pylori* and thus possess efficacy in treating gastric ulcers or with one or more antimicrobials, in eradicating infection by this organism. Four benzimidazole PPIs are currently approved for marketing in the United States (Table 21-3). Adverse effect profiles of the various PPIs are difficult to compare because comparative clinical trials do not usually include sufficient individuals to allow reliable conclusions. Relatively early in its marketing, the use of omeprazole was associated with the occurrence of diarrhea, headache, and rashes; longer-term experience suggests, however, that these adverse responses are rare. Similarly, characterization of adverse reaction profiles of other PPIs must await more extensive use in patients.

The PPIs are eliminated almost entirely by rapid metabolism to inactive or less active metabolites (Fig. 21-16).⁵⁸ Virtually no unchanged drug is excreted in the urine and feces. The cytochrome P-450 enzyme system is primarily involved in PPI metabolism and can be the source of drug–drug interactions for the PPIs. Inhibition of oxidative metabolism by omeprazole (but not esomeprazole) is responsible for prolonging the clearance of benzodiazepines, phenytoin, and warfarin. Lansoprazole decreases theophylline concentration slightly and may decrease the efficacy of oral contraceptives. Pantoprazole and rabeprazole appear to be free of these interactions. Further, the profound and long-lasting inhibition of gastric acid secretion by the PPIs may interfere with the bioavailability of drugs when gastric pH is an important determinant, such as theazole antifungals (e.g., ketoconazole), ampicillin, iron salts, digoxin, and cyanocobalamin.

Omeprazole. Omeprazole, 5-methoxy-2-[(4-methoxy-3,5-dimethyl-2-pyridinyl)methyl]sulfinyl)-1*H*-benzimidazole (Losec), is a white to off-white crystalline powder with very slight solubility in water. Omeprazole is an amphoteric compound (pyridine N, pK_a 4.13; benzimidazole N-H, pK_a 1.68), and consistent with the proposed mechanism of action of the substituted benzimidazoles, it is acid labile. Hence the omeprazole product is formulated as delayed-release capsules containing enteric-coated granules. The absolute bioavailability of orally administered omeprazole is 30 to 40% related to substantial first-pass biotransformation. The drug has a plasma half-life of about 1 hour. Most (77%) of an oral dose of omeprazole is excreted in the urine as metabolites with insignificant antisecretory activity. The pri-

Figure 21-16 ■ Metabolic transformations of benzimidazole PPIs.

major metabolites of omeprazole are 5-hydroxyomeprazole (cytochrome P-450 [CYP] isozyme 2C19) and omeprazole sulfone (CYP 3A4). The antisecretory actions of omeprazole persist for 24 to 72 hours, long after the drug has disappeared from plasma, which is consistent with its suggested mechanism of action involving irreversible inhibition of the proton pump $\text{H}^+/\text{K}^+ - \text{ATPase}$.⁵⁹

Omeprazole is approved for the treatment and reduction of risk of recurrence of duodenal ulcer, GERD, gastric ulcer, and pathological hypersecretory conditions.

Usual adult dose: Oral, 20 mg q.d.

Dosage form: Delayed-release capsules containing 20 mg of omeprazole in enteric-coated granules

Esomeprazole Magnesium. Esomeprazole magnesium, *S*-bis(5-methoxy-2-[(*S*)-[(4-methoxy-3,5-dimethyl-2-pyridinyl)methyl]sulfinyl]-1*H*-benzimidazole-1-yl) magne-

sium trihydrate (Nexium), is the *S* enantiomer of omeprazole. The benzimidazole PPIs contain a chiral sulfur atom that forms an enantiomeric pair that is stable and insoluble under standard conditions. The *S* isomer of omeprazole has slightly greater PPI activity, and its intrinsic clearance is approximately 3 times lower than that of *R* omeprazole (15 versus 43 $\mu\text{L}/\text{min}$). The lower clearance of *S*-omeprazole is related to slower metabolic clearance by the CYP 2C19 isozyme. Although *R*-omeprazole is primarily transformed to the 5-hydroxy metabolite, the *S* isomer is metabolized by *O*-demethylation and sulfoxidation, which contribute little to intrinsic clearance.

Usual adult dose:

Erosive esophagitis: Healing dose: 20 or 40 mg q.d. for 4–8 weeks; maintenance dose: 20 mg q.d.

Treatment of GERD: 20 mg q.d. for 4 weeks;

H. pylori eradication: 40 mg q.d. for 10 days in combination with amoxicillin (1 g b.i.d. for 10 days) and clarithromycin (500 mg b.i.d. for 10 days)

Dosage form:

Oral: Delayed-release capsules, 20 or 40 mg of esomeprazole (present as 22.3 mg or 44.5 mg esomeprazole magnesium trihydrate) as enteric-coated pellets

Lansoprazole. Lansoprazole, 2-[[[3-methyl-4-(2,2,2-trifluoroethoxy)-2-pyridyl]methyl]sulfinyl]benzimidazole (Prevacid), is a white to brownish-white, odorless crystalline powder that is practically insoluble in water. Lansoprazole is a weak base (pyridine N, pK_a 4.01) and a weak acid (benzimidazole N-H, pK_a 1.48). Like omeprazole, lansoprazole is

essentially a prodrug that, in the acidic biophase of the parietal cell, forms an active metabolite that irreversibly interacts with the target ATPase of the pump. Lansoprazole must be formulated as encapsulated enteric-coated granules for oral administration to protect the drug from the acidic environment of the stomach.

In the fasting state, about 80% of a dose of lansoprazole (versus ~50% of omeprazole) reaches the systemic circulation, where it is 97% bound to plasma proteins. The drug is metabolized in the liver (sulfone and hydroxy metabolites) and excreted in bile and urine, with a plasma half-life of about 1.5 hours.⁶⁰

Usual adult dose: Daily oral dose administered before breakfast
Duodenal ulcer: 15 mg once daily

Erosive esophagitis: 30 mg
Zollinger-Ellison syndrome: 60 mg
NSAID-induced gastric ulcers: treatment and prevention
Dosage form: Delayed-release capsules containing 15 and 30 mg of lansoprazole in enteric-coated granules

Pantoprazole Sodium. The active ingredient in Protonix (pantoprazole sodium) is a substituted benzimidazole, sodium 5-(difluoromethoxy)-2-[(3,4-dimethoxy-2-pyridinyl)methyl]sulfinyl]-1*H*-benzimidazole sesquihydrate (1.5 H₂O), a compound with a molecular weight of 432.4. The benzimidazoles have weakly basic (pyridine N, p*K*_a 3.96) and acidic (benzimidazole N-H, p*K*_a 0.89) properties, which facilitate their formulation as salts of alkaline materials (Fig. 21-17). Pantoprazole sodium sesquihydrate is a white to off-white crystalline powder and is racemic. Pantoprazole sodium sesquihydrate is freely soluble in water, very slightly soluble in phosphate buffer at pH 7.4, and practically insoluble in *n*-hexane. The stability of the compound in aqueous solution is pH dependent; the rate of degradation increases with decreasing pH. At ambient temperature, the degradation half-life is approximately 2.8 hours at pH 5.0 and approximately 220 hours at pH 7.8.

The absorption of pantoprazole is rapid (*C*_{max} of 2.5 µg/mL, *T*_{max} ~2.5 hours) after single or multiple oral 40-mg doses. Pantoprazole is well absorbed (~77% bioavailability). Administration of pantoprazole with food may delay its absorption but does not alter its bioavailability. Pantoprazole

Figure 21-17 ■ Ionization of benzimidazole PPIs.

is distributed mainly in extracellular fluid. The serum protein binding of pantoprazole is about 98%, primarily to albumin. Pantoprazole is extensively metabolized in the liver through the CYP system, including O-demethylation (CYP 2C19), with subsequent sulfation. Other metabolic pathways include sulfur oxidation by CYP 3A4. There is no evidence that any of the pantoprazole metabolites have significant pharmacological activity. Approximately 71% of a dose of pantoprazole is excreted in the urine, with 18% excreted in the feces through biliary excretion.

Usual adult dose:

Erosive esophagitis associated with GERD: 40 mg q.d. for ≤ 8 weeks; if not healed after 8 weeks of treatment, an additional 8-week course may be considered

Long-term treatment of erosive esophagitis and GERD: IV treatment of erosive esophagitis as an alternative to continued oral therapy, 40 mg q.d. by infusion for 7–10 days

Short-term treatment (7 to 10 days) of GERD

Treatment of pathological hypersecretory conditions associated with Zollinger-Ellison syndrome

Dosage form:

Protonix: Delayed-release tablet for oral administration; each tablet contains 45.1 mg of pantoprazole sodium sesquihydrate (equivalent to 40 mg pantoprazole)

Protonix I.V.: Freeze-dried powder for injection equivalent to 40 mg pantoprazole/vial

Rabeprazole Sodium. Rabeprazole sodium, 2-[[[4-(3-methoxypropoxy)-3-methyl-2-pyridinyl][methyl]sulfanyl]-1*H*-benzimidazole sodium salt (Acipex), is a substituted benzimidazole with a molecular weight of 381.43. Rabeprazole sodium is a white to slightly yellowish-white solid. It is very soluble in water and methanol, freely soluble in ethanol, chloroform, and ethyl acetate, and insoluble in ether and *n*-hexane. Rabeprazole is a weak base (pyridine N, pK_a 4.90) and a weak acid (benzimidazole N-H, pK_a 1.60).

Rabeprazole sodium is formulated as enteric-coated, delayed-release tablets to allow the drug to pass through the stomach relatively intact. After oral administration of 20 mg, peak plasma concentrations (C_{max}) occur over a range of 2.0 to 5.0 hours (T_{max}). Absolute bioavailability for a 20-mg oral tablet of rabeprazole (versus IV administration) is approximately 52%. The plasma half-life of rabeprazole ranges from 1 to 2 hours. The effects of food on the absorption of rabeprazole have not been evaluated. Rabeprazole is 96.3% bound to human plasma proteins. Rabeprazole is extensively metabolized in the liver. The thioether and sulfone are the primary metabolites measured in human plasma resulting from CYP 3A oxidation. Additionally, desmethyl rabeprazole is formed via the action of CYP 2C19. Approximately 90% of the drug is eliminated in the urine, primarily as thioether carboxylic acid and its glucuronide and mercapturic acid metabolites. The remainder of the dose is recovered in the feces. Total recovery of radioactivity was 99.8%. No unchanged rabeprazole was recovered in the urine or feces

Usual adult dose: Oral, 20 mg once daily (duodenal ulcer for 4 weeks; erosive or ulcerative GERD for 4–8 weeks); gastric hypersecretory disorders, 60 mg once daily titrated to a maximum of 120 mg/day

Dosage form: 20-mg delayed release tablets of the sodium salt

CHEMICAL COMPLEXATION

The sulfate esters and sulfonate derivatives of polysaccharides and lignin form chemical complexes with the enzyme pepsin. These complexes have no proteolytic activity. Because polysulfates and polysulfonates are poorly absorbed from the GI tract, specific chemical complexation appears to be a desirable mechanism of pepsin inhibition. Unfortunately, these polymers are also potent anticoagulants.

The properties of chemical complexation and anticoagulant action are separable by structural variation. In a comparison of selected sulfated saccharides of increasing number of monosaccharide units, from disaccharides through starch-derived polysaccharides of differing molecular size, three conclusions are supported by the data: (a) the anticoagulant activity of sulfated saccharide is positively related to molecular size, (b) anticoagulant activity is absent in the disaccharides, and (c) the inhibition of pepsin activity and the protection against experimentally induced ulceration depend on the degree of sulfation and not on molecular size.

The readily available disaccharide sucrose has been used to develop a useful antiulcer agent, sucralfate.

Sucralfate. Sucralfate, 3,4,5,6-tetra-(polyhydroxyaluminum)- α -D-glucopyranosyl sulfate-2,3,4,5-tetra-(polyhydroxyaluminum)- β -D-fructofuranoside sulfate (Carafate), is the aluminum hydroxide complex of the octasulfate ester of sucrose. It is practically insoluble in water and soluble in strong acids and bases. It has a pK_a value between 0.43 and 1.19.

Sucralfate is minimally absorbed from the GI tract and thus exerts its antiulcer effect through local rather than systemic action. It has negligible acid-neutralizing or buffering capacity in therapeutic doses.

Its mechanism of action has not been established. Studies suggest that sucralfate binds preferentially to the ulcer site

to form a protective barrier that prevents exposure of the lesion to acid and pepsin. In addition, it adsorbs pepsin and bile salts. Either would be very desirable modes of action.

The product labeling states that the simultaneous administration of sucralfate may reduce the bioavailability of certain agents (e.g., tetracycline, phenytoin, digoxin, or cimetidine). It further recommends restoration of bioavailability by separating administration of these agents from that of sucralfate by 2 hours. Presumably, sucralfate binds these agents in the GI tract.

The most frequently reported adverse reaction to sucralfate is constipation (2.2%). Antacids may be prescribed as needed but should not be taken within one-half hour before or after sucralfate.

Usual adult dose: Oral, 1 g q.i.d. on an empty stomach
Dosage form: 1-g sucralfate tablets

PROSTAGLANDINS

The prostaglandins are endogenous 20-carbon unsaturated fatty acids biosynthetically derived from arachidonic acid. These bioactive substances and their synthetic derivatives have been of considerable research and development interest as potential therapeutic agents because of their widespread physiological and pharmacological actions on the cardiovascular system, GI smooth muscle, the reproductive system, the nervous system, platelets, kidney, the eye, etc.⁶¹ Prostaglandins of the E, F, and I series are found in significant concentrations throughout the GI tract. The GI actions of the prostaglandins include inhibition of basal and stimulated gastric acid and pepsin secretion in addition to prevention of ulcerogen or irritant-induced gross mucosal lesions of the stomach and intestine (termed *cytoprotection*). The prostaglandins can both stimulate (PGFs) and inhibit (PGEs and PGI₂) intestinal smooth muscle contractility and accumulation of fluid and electrolytes in the gut lumen (PGEs). Therapeutic application of the natural prostaglandins in the treatment of GI disorders is hindered by their lack of pharmacological selectivity coupled with a less-than-optimal biodisposition profile.

Misoprostol. Misoprostol, (\pm)-methyl 11 α ,16-dihydroxy-16-methyl-9-oxoprost-13E-en-1-oate, is a semisynthetic derivative of PGE₁ that derives some pharmacological selectivity as well as enhanced biostability from its 16-methyl, 16-hydroxy structural features. Misoprostol exhibits both antisecretory and cytoprotective effects characteristic of the natural prostaglandins and has a therapeutically acceptable biodisposition profile. Although the antisecretory effects of misoprostol are thought to be related to its agonistic actions at parietal cell prostaglandin receptors, its cyto-

protective actions are proposed to be related to increases in GI mucus and bicarbonate secretion, increases in mucosal blood flow, and/or prevention of back diffusion of H₃O⁺ into the gastric mucosa.⁶²

Misoprostol

Misoprostol is rapidly absorbed following oral administration and undergoes rapid deesterification to the pharmacologically active free acid with a terminal half-life of 20 to 40 minutes.⁶² Misoprostol is commonly used to prevent NSAID-induced gastric ulcers in patients at high risk of complications from a gastric ulcer, such as elderly patients and patients with a history of ulcer. Misoprostol has also been used in treating duodenal ulcers unresponsive to histamine H₂ antagonists; the drug does not prevent duodenal ulcers, however, in patients taking NSAIDs. Misoprostol can cause miscarriage, often associated with potentially dangerous bleeding.

Usual adult dose: Oral, 200 μ g q.i.d. with food
Dosage form: 100- and 200- μ g tablets

HISTAMINE H₃-RECEPTOR LIGANDS^{63, 64}

Histamine H₃ receptors are members of the G-protein-coupled receptor family involved in the regulation of neurotransmitter release in both central and peripheral neurons. The cDNA for the human histamine H₃ receptor encodes a 445-amino acid protein that, when recombinantly expressed, couples to inhibition of adenylate cyclase, presumably through G α_i . The histamine H₃-receptor mRNA is highly expressed in central nervous tissues. Histamine H₃ heteroreceptors have been identified in stomach, lung, and cardiac tissues of animals. Presynaptic H₃ receptors have been implicated in regulating neurotransmitter release from histaminergic, noradrenergic, dopaminergic, cholinergic, serotonergic, and peptidergic neurons. The potential therapeutic roles of histamine H₃-receptor antagonists in the CNS have been evaluated in models of learning and memory impairment, attention-deficit hyperactivity disorder, obesity, and epilepsy. Studies of the regulation of inflammatory processes, gastroprotection, and cardiovascular function suggest several therapeutic possibilities for peripherally acting histamine H₃-receptor agonists. As yet, no histamine H₃-receptor ligands have been approved for marketing in the United States.

Potent H₃ agonists (Fig. 21-18) are obtained by simple modifications of the histamine molecule. The imidazole ring is a common structural feature in almost all H₃ agonists. Methylation of the aminoethyl side chain of histamine favors

H₃ activity. Introduction of one or two methyl groups to give α -methylhistamine and α,α -dimethylhistamine yields potent H₃ agonists that show little selectivity among the three histamine receptors. The increased potency of α -methylhistamine is ascribed almost completely to its *R* isomer (H₃/H₁ ratio = 17). The clinical use of *R*- α -methylhistamine is compromised by rapid catabolism by histamine-*N*-methyltransferase. Azomethine derivatives of *R*- α -methylhistamine have been developed and shown to possess anti-inflammatory and antinociceptive properties. Other H₃ agonists include the isothiourea derivative, imetit, a highly selective, full agonist that is more potent than *R*- α -methylhistamine. A third type of H₃ agonist is imipip, which may be considered as a histamine analogue with an elongated and cyclized side chain. Imipip is both a highly selective and potent H₃ agonist.

A large number of H₃ antagonists have been described. Antagonist studies have suggested the presence of H₃-receptor subtypes. In general, antagonist structures conform to the following general representation:⁶⁵

The heterocycle component of this general structure is most commonly a 4-monosubstituted imidazole or bioisosteric equivalent. Chains A and B can be of various structures and lengths, and there is also wide latitude in the structural requirements for the polar group. Halogenated phenyl, cycloalkyl, and heteroaryl structures are usually found for the lipophilic moiety (Fig. 21-19).

Thioperamide was the first potent H₃ antagonist to be described. This agent enhances arousal and/or vigilant patterns in a dose-dependent fashion in animals, suggesting possible use of CNS-acting H₃ antagonists in treating sleep disorders characterized by excessive daytime sleep, such as narcolepsy. Other H₃-antagonist structures are shown below, including the natural product verongamine, isolated from a sea sponge.

Analgesic Agents

ROBERT E. WILLETTE

The struggle to relieve pain began with the origin of humanity. Ancient writings, both serious and fanciful, dealt with secret remedies, religious rituals, and other methods of pain relief. Slowly, the present modern era of synthetic analgesics evolved. An *analgesic* may be defined as a drug bringing about insensibility to pain without loss of consciousness. (The etymologically correct term *analgetic* may be used in place of the incorrect but popular *analgesic*, but the latter is used almost universally.)

Tainter¹ has divided the history of analgesic drugs into four major eras, namely:

1. The period of discovery and use of naturally occurring plant drugs
2. Isolation of pure plant principles (e.g., alkaloids) from the natural sources and their identification with analgesic action
3. Development of organic chemistry and the first synthetic analgesics
4. Development of modern pharmacological techniques, making it possible to undertake a systematic testing of new analgesics

A new era has emerged with the discovery of opioid receptors and endogenous chemicals that have analgesic activity.

The isolation of morphine from opium by Sertürner, in 1803, and the discovery of its analgesic activity (he named it *morphine* after the Greek god of dreams, Morpheus) ushered in the second era. It continues today only on a small scale. Wöhler introduced the third era indirectly with his synthesis of urea in 1828. He showed that chemical synthesis could be used to make and produce drugs. In the third era, the first synthetic analgesics used in medicine were the salicylates, originally found in nature (methyl salicylate, salicin) and then synthesized by chemists. Other early synthesized drugs were acetanilid (1886), phenacetin (1887), and aspirin (1899).

These early discoveries were the principal contributions in this field until modern methods of pharmacological testing initiated the fourth era. The effects of small structural modifications of synthetic molecules then could be assessed accurately by pharmacological means. This permitted systematic study of the relationship of structure to activity during this era. The development of these pharmacological testing procedures, coupled with the fortuitous discovery of meperidine by Eisleb and Schaumann,² made possible a period of rapid strides in the development of potent analgesics.

is the most common complaint for which patients seek treatment. For various reasons, however, including politics and lack of training and ignorance, pain is not well managed; less than half of those with pain are adequately treated. This is primarily due to a fear of addiction, which often limits the proper use of the narcotic or opioid class of analgesics, and lack of training of health care professionals. To understand how and when this broad class of drugs is and should be used in the management of pain requires a brief review of pain.

Pain has been classified into the following types: physiological, inflammatory, and neuropathic. The first is the most common, for example, touching a hot object or getting a cut. Inflammatory pain can be initiated in a wide variety of ways, such as infection and tissue injury. The last type is due to injury to the peripheral or central nervous system (CNS). Within these classes of pain there are different levels of pain or categories of pain. These include acute, chronic, cancer, arthropathy (e.g., arthritis), visceral, neuropathic, and diabetic pain. A separate category is recognized for acquired immunodeficiency syndrome (AIDS) because of its disseminated nature. Clearly, these all require different approaches to pain management.

In the following sections of this chapter, several classes of pain-relieving drugs are described. The three major classes of drugs used to manage pain are opioids, nonsteroidal anti-inflammatory agents, and acetaminophen. A newly emerging class, known as *analgesic adjuvants*, is not covered here.

Of these drug classes, the historically important group of drugs in the opioid class has been the most problematic for use in the proper management of pain. The term *opiophobia* was coined to describe the reluctance of physicians to prescribe opioid drugs in adequate amounts or for long enough periods. As early as the 1970s, the National Institutes of Health formed a committee, at the request of the president, to investigate therapies for rare diseases, but the initial focus was on pain management. There was political pressure to approve the use of heroin for pain, under the mistaken impression that a more potent drug was needed, after several studies showed poor pain management. The committee found that the problem was a lack of training of physicians in pain management and misconceptions about the use of opioids and addiction.³

Unfortunately, the problem continued through the end of the 20th century and into the 21st. Over the past few years, major national medical groups, state medical boards, and pharmaceutical groups have formulated guidelines directed at improving pain therapy. Pharmacists and other health professionals must clearly recognize the advances in pain management and the advantages and limitations of the var-

PAIN

The primary use of the drugs covered in this chapter is to relieve pain of a wide array of causes and mechanisms. Pain

ious drugs. For further information on pain and its management, refer to a number of articles and American Pharmaceutical Association continuing education programs.⁴⁻⁷

The consideration of naturally occurring and synthetic analgesics is facilitated greatly by dividing them into two groups: (a) morphine and related compounds and (b) the antipyretic and anti-inflammatory analgesics. Also, numerous drugs that possess distinctive pharmacological activities in other areas also possess analgesic properties and are used as analgesic adjuvants. The analgesic property exerted may be a direct effect or may be indirect, but it is subsidiary to some other, more pronounced effect. Some examples of these, which are discussed elsewhere in this text, are sedatives (e.g., barbiturates), muscle relaxants (e.g., mephenesin, methocarbamol), and tranquilizers (e.g., meprobamate). These drugs are not considered in this chapter.

MORPHINE AND RELATED COMPOUNDS

Historical Perspective

The discovery of morphine early in the 19th century and the demonstration of its potent analgesic properties led directly to the search for similar drugs from plant sources. In tribute to the remarkable potency and action of morphine, it and codeine have remained alone as outstanding and indispensable analgesics from a plant source. Only since 1938 have synthetic compounds rivaling morphine in its action been found, although many earlier synthetic changes made on morphine itself gave more effective agents.

Modifications of the morphine molecule are considered under the following headings:

1. Early changes on morphine before the work of Small, Eddy, and their coworkers
2. Changes on morphine initiated in 1929 by Small, Eddy, and coworkers⁸ under the auspices of the Committee on Drug Addiction of the National Research Council and extending to the present time
3. Research initiated by Eisleb and Schaumann² in 1938, with their discovery of the potent analgesic action of meperidine, a compound that departs radically from the typical morphine molecule
4. Research initiated by Grewe, in 1946, leading to the successful synthesis of the morphinan group of analgesics

EARLY MORPHINE MODIFICATIONS

Morphine is obtained from opium, which is the partly dried latex from incised unripe capsules of *Papaver somniferum*. Opium contains numerous alkaloids (as meconates and sulfates), of which morphine, codeine, noscapine (narcotine), and papaverine are therapeutically the most important. Thebaine, which has convulsant properties, is an important starting material for many other drugs. Other opium alkaloids, such as narceine, have been tested medicinally but are not of great importance. The action of opium is principally due to its morphine content. As an analgesic, opium is not as effective as morphine because of its slower absorption, but it has a greater constipating action and, thus, is better suited for antidiarrheal preparations (e.g., paregoric). Opium, as a constituent of Dover's powders and Brown Mixture, also

exerts a valuable expectorant action that is superior to that of morphine.

Two basic types of structures are recognized among the opium alkaloids, the *phenanthrene* (morphine) type and the *benzylisoquinoline* (papaverine) type (see structures).

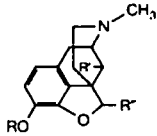

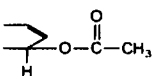

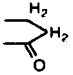

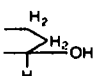

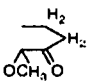

The pharmacological actions of the two types of alkaloids are dissimilar. The morphine group acts principally on the CNS as a depressant and stimulant; the papaverine group has little effect on the nervous system but a marked antispasmodic action on smooth muscle. Clinically, the depressant action of the morphine group is the most useful property, resulting in increased tolerance to pain, a sleepy feeling, a lower perception of external stimuli, and a feeling of well-being (euphoria). Respiratory depression, central in origin, is perhaps the most serious objection to this type of alkaloid, aside from its tendency to cause addiction. The stimulant action is well illustrated by the convulsions produced by certain members of this group (e.g., thebaine).

Before 1929, the derivatives of morphine that were made primarily resulted from simple changes on the molecule, such as esterification of the phenolic and/or alcoholic hydroxyl groups, etherification of the phenolic hydroxyl group, and similar minor changes. The net result was the discovery of some compounds with greater activity than morphine but also with greater toxicity and addiction potential. No compounds were found that completely lacked the addiction liabilities of morphine. (The term *addiction liability* or the preferred term *dependence liability*, as used in this text, indicates the ability of a substance to induce true addictive tolerance and physical dependence and/or to suppress the morphine abstinence syndrome after withdrawal of morphine from addicts.)

Some of the compounds in common use before 1929 are listed in Table 22-1 together with some more recently introduced. All have the common morphine skeleton. Among the earlier compounds is codeine, the phenolic methyl ether of morphine, which also had been obtained from opium. It has survived as a good analgesic and cough depressant, together

TABLE 22-1 Synthetic Derivatives of Morphine

				
Compound Proprietary Name	R	R'	R''	Principal Use
Morphine	H	H		Analgesic
Codone	CH ₃	H	Same as above	Analgesic and to depress cough reflex
Ethymorphine <i>Dionin</i>	C ₂ H ₅	H	Same as above	Ophthalmology
Diacetylmorphine (heroin)	CH ₃ CO	H		Analgesic (prohibited in US)
Hydromorphone (dihydromorphi- none) <i>Diacidid</i>	H	H		Analgesic
Hydrocodone (dihydro- codemone) <i>Dicodid</i>	CH ₃	H	Same as above	Analgesic and to depress cough reflex
Oxymorphone (dihydrohydroxy- morphinone)	H	OH	Same as above	Analgesic
Oxycodone (dihydrohydroxy- codeinone)	CH ₃	OH	Same as above	Analgesic and to depress cough reflex
Dihydrocodeine <i>Paracodin</i>	CH ₃	H		Depress cough reflex
Dihydromorphine	H	H	Same as above	Analgesic
Methyl dihydro- morphinone <i>Motapon</i>	H	H		

with the corresponding ethyl ether, which has found its principal application in ophthalmology. The diacetyl derivative of morphine, heroin, has been known for a long time; it has been banished for years from the United States and is being used less in other countries. It is the most widely used illicit drug among narcotic addicts. Among the reduced compounds are dihydromorphine and dihydrocodeine and their

C-6 oxidized congeners, dihydromorphinone (hydromorphone) and dihydrocodeinone (hydrocodone). Derivatives of the last two compounds that possess a hydroxyl group in position 14 are dihydrohydroxymorphinone, or oxymorphone, and dihydrohydroxycodeinone, or oxycodone. These are the principal compounds that either had been on the market or had been prepared before the studies of Small, Eddy, and coworkers. To this time, no really systematic effort had been made to investigate the structure-activity relationships in the molecule, and only the easily changed peripheral groups had been modified. The only exception is oxymorphone, introduced in the United States in 1959 but mentioned here because it obviously is closely related to oxycodone.

MORPHINE MODIFICATIONS INITIATED BY THE RESEARCH OF SMALL AND EDDY

The avowed purpose of Small, Eddy, and coworkers⁸ in 1929 was to approach the morphine problem from the standpoint that it might be possible to separate chemically the addictive property of morphine from its other, more salutary attributes, or if that was not possible, it might be possible to find other synthetic molecules without this undesirable property. Proceeding on these assumptions, these workers first examined the morphine molecule exhaustively. As a starting point, morphine offered the advantages of ready availability, proven potency, and ease of alteration. In addition to its addictive tendency, they hoped that other liabilities (e.g., respiratory depression, emetic properties, and gastrointestinal tract and circulatory disturbances) could be minimized or abolished as well. Because early modifications of morphine (e.g., acetylation or alkylation of hydroxyls and quaternization of the nitrogen) caused variations in the addictive potency, they felt that the physiological effects of morphine could be related, at least in part, to the peripheral groups.

It was not known if the actions of morphine were primarily a function of the peripheral groups or of the structural skeleton. This did not matter, however, because modification of the groups would alter activity in either case. These groups and the effects on activity by modifying them are listed in Table 22-2. The results of these and earlier studies⁹ have not always shown the effects of simple modifications on the analgesic action of morphine quantitatively, but they do indicate the direction in which the activity is likely to go. The studies are far more comprehensive than Table 22-2 indicates, and the conclusions usually depend on more than one pair of compounds. Unfortunately, these studies on morphine did not eliminate the addiction potential from these compounds. In fact, the studies suggested that any modification that increased the analgesic activity caused a concomitant increase in addiction liability.

The second phase of the studies⁸ dealt with the attempted synthesis of substances with central narcotic and, especially, analgesic action. The morphine molecule contains certain well-defined types of chemical structures. Among these are the phenanthrene nucleus, the dibenzofuran nucleus, and, as a variant of the latter, carbazole. These synthetic studies, although extensive and interesting, provided no significant findings and are not discussed further in this text.

One of the more useful results of the investigations was the synthesis of 5-methyldihydromorphinone (Table 22-1), whose methyl substituent was originally assigned to position

TABLE 22-2 Some Structural Relationships in the Morphine Molecule

Peripheral Groups of Morphine	Modification (On Morphine Unless Otherwise Indicated)	Effects on Analgesic Activity (Morphine or Another Compound as Indicated = 100)
Phenolic hydroxyl	$-\text{OH} \rightarrow -\text{OCH}_3$ (codeine)	15
	$-\text{OH} \rightarrow -\text{OC}_2\text{H}_5$ (ethymorphine)	10
	$-\text{OH} \rightarrow -\text{OCH}_2\text{CH}_2-\text{N} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array} \text{O}$ (pholcodine)	1

	—OH (at position 14 in dihydromorphine)	250 (Dihydromorphine vs. oxymorphone)
	—OH (at position 14 in dihydrocodeinone)	530 (Dihydrocodeinone vs. oxycodone)
	—CH ₃ (at position 6)	280
	—CH ₃ (at position 6 in dihydromorphine)	33 (Dihydromorphine vs. 6-methyldihydromorphine)
	—CH ₃ (at position 6 in dihydrodesoxymorphine-D)	490 (Dihydrodesoxymorphine-D vs. 6-methyldihydrodesoxymorphine)
	—CH ₂ (at position 6 in dihydrodesoxymorphine-D)	600 (Dihydrodesoxymorphine-D vs. 6-methylenedihydrodesoxymorphine)

7.¹⁰ Although it possessed addiction liabilities, it was a very potent analgesic with a minimum of the undesirable side effects of morphine, such as emetic action and mental dullness. Later, the high analgesic activity demonstrated by morphine congeners in which the alicyclic ring is either reduced or methylated (or both) and the alcoholic hydroxyl at position 6 is absent prompted the synthesis of related compounds possessing these features. These include 6-methyldihydromorphine and its dehydrated analogue 6-methyl- Δ^6 -desoxymorphine or methyl-desorphine,¹¹ both of which have high potency. Also of interest were the compounds morphinone; 6-methylmorphine; and 6-methyl-7-hydroxy-, 6-methyl-, and 6-methylenedihydrodesoxymorphine.^{12, 13} In analgesic activity in mice, the last-named compound was 82 times more potent, milligram for milligram, than morphine. Its therapeutic index (TI₅₀) was 22 times that of morphine.¹⁴

The structure-activity relationships of 14-hydroxymorphine derivatives have been reviewed,⁸ and several related compounds were synthesized.¹⁵ Of these, the dihydrodesoxy compounds possessed the most analgesic activity. Also, esters of 14-hydroxycodine derivatives have shown very high activity.¹⁶ For example, in rats, 14-cinnamylloxycodine was 177 times more active than morphine.

In 1963, Bentley and Hardy¹⁷ reported the synthesis of a novel series of potent analgesics derived from the opium alkaloid thebaine. In rats, the most active members of the series (I, R₁ = H, R₂ = CH₃, R₃ = isoamyl; and II, R₁ = COCH₃, R₂ = CH₃, R₃ = *n*-C₃H₇) were several thousand times stronger than morphine.¹⁸ These compounds exhibited marked differences in activity of optical isomers, as well as other interesting structural effects. It was postulated that the more rigid molecular structure might allow them to fit the receptor surface better. Extensive structural and pharmacological studies have been reported.¹⁹ Some of the *N*-cyclopropylmethyl compounds are the most potent antagonists yet discovered and have been studied very intensively.

As indicated in Table 22-2, replacement of the *N*-methyl group in morphine by larger alkyl groups not only lowers analgesic activity, but also confers morphine-antagonistic properties on the molecule (discussed below). In direct contrast to this effect, the *N*-phenethyl derivative has 14 times the analgesic activity of morphine. This enhancement of activity by *N*-aralkyl groups has wide application, as is shown below.

Some of the morphine antagonists, such as nalorphine, are also strong analgesics.²⁰ The similarity of the ethylenic double bond and the cyclopropyl group has prompted the synthesis of *N*-cyclopropylmethyl derivatives of morphine and its derivatives.²¹ This substituent usually confers strong narcotic antagonistic activity, with variable effects on analgesic potency. The dihydronormorphine derivative has only moderate analgesic activity.

MORPHINE MODIFICATIONS INITIATED BY THE RESEARCH OF EISLEB AND SCHAUMANN

In 1938, Eisleb and Schaumann² reported the fortuitous discovery that a simple piperidine derivative, now known as meperidine, possessed analgesic activity. It was prepared as an antispasmodic, a property it also possesses. As the story is told, during the pharmacological testing of meperidine in mice, it was observed to cause the peculiar erection of the tail known as the Straub reaction. Because this reaction is characteristic of morphine and its derivatives, the compound then was tested for analgesic properties and found to be about one fifth as active as morphine. This finding led not only to the discovery of an active analgesic, but far more important, it stimulated research. The status of research on analgesic compounds with an activity comparable to that of morphine was at a low ebb in 1938. Many felt that potent compounds could not be prepared, unless they were very closely related structurally to morphine. The demonstration of high potency in a synthetic compound that was related only distantly to morphine, however, spurred the efforts of various research groups.^{22, 23}

The first efforts, naturally, were made on the meperidine-type molecule in an attempt to enhance its activity further. It was found that replacement of the 4-phenyl group by hydrogen, alkyl, other aryl, aralkyl, and heterocyclic groups reduced analgesic activity. Placement of the phenyl and ester

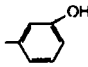

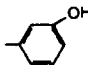

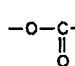

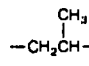

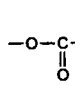

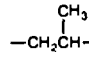

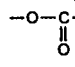

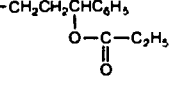

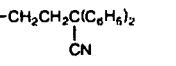

groups at the 4 position of 1-methylpiperidine also gave optimum activity. Several modifications of this fundamental structure are listed in Table 22-3.

Among the simplest changes shown to increase activity is the insertion of an *m*-hydroxyl group on the phenyl ring.

It is in the same relative position as in morphine. The effect is more pronounced on the keto compound (Table 22-3, A-4) than on meperidine (A-1). Ketobemidone is equivalent to morphine in activity and was once widely used.

More significantly, Jensen et al.²⁴ discovered that replace-

TABLE 22-3 Compounds Related to Meperidine

Compound	Structure				Name (If Any)	Analgesic Activity (Meperidine = 1)

ment of the carbethoxyl group in meperidine by acyloxy groups gave better analgesic, as well as spasmolytic, activity. The "reversed" ester of meperidine, the propionoxy compound (A-6), was the most active, being 5 times as active as meperidine. These findings were validated and expanded on by Lee et al.²⁵⁻²⁸ In an extensive study of structural modifications of meperidine, Janssen and Eddy²⁹ concluded that the propionoxy compounds were always more active, usually about twofold, regardless of what group was attached to the nitrogen.

Lee³⁰ had postulated that the configuration of the propionoxy derivative (A-6) more closely resembled that of morphine, with the ester chain taking a position similar to that occupied by C-6 and C-7 in morphine. His speculations were based on space models and certainly did not reflect the actual conformation of the nonrigid meperidine. He did arrive at the correct assumption, however, that introduction of a methyl group into position 3 of the piperidine ring in the propionoxy compound would yield two isomers, one with activity approximating that of desomorphine and the other with less activity. One of the two diastereoisomers (A-7), betaprodine, has an activity in mice about 9 times that of morphine and 3 times that of A-6. Beckett et al.³¹ have established that it is the *cis* (methylphenyl) form. The *trans* form, alphaprodine, is twice as active as morphine. Resolution of the racemates shows that one enantiomer has the predominant activity. In humans, however, the sharp differences in analgesic potency are not so marked. The *trans* form is marketed as the racemate. The significance of the 3-methyl has been attributed to discrimination of the enantiotropic edges of these molecules by the receptor. This is even more dramatic in the 3-allyl and 3-propyl isomers, for which the α -*trans* forms are considerably more potent than the β isomers, indicating that three-carbon substituents are not tolerated in the axial orientation. The 3-ethyl isomers are nearly equal in activity,

further indicating that two or fewer carbons are more acceptable in the drug-receptor interaction.^{32, 33}

A small substituent, such as methyl, attached to the nitrogen had seemed to be optimal for analgesic activity. This was believed to be true not only for the meperidine series of compounds but also for all the other types. It is now well established that replacement of the methyl group by various aralkyl groups can increase activity markedly.²⁹ A few examples of this type of compound in the meperidine series are shown in Table 22-3. The phenethyl derivative (A-9) is about 3 times as active as meperidine (A-1). The *p*-amino congener, anileridine (A-10), is about 4 times more active. Piminodine, the phenylaminopropyl derivative (A-11), has 55 times the activity of meperidine in rats and is about 5 times as effective in humans as an analgesic.³⁴ The most active meperidine-type compounds, to date, are the propionoxy derivative (A-12), which is nearly 2,000 times as active as meperidine, and the *N*-phenethyl analogue of betaprodine, which is over 2,000 times as active as morphine.³¹ Diphenoxylate (A-13), a structural hybrid of meperidine and methadone types, lacks analgesic activity, although it reportedly suppresses the morphine abstinence syndrome in morphine addicts.^{35, 36} It is quite effective as an intestinal spasmolytic and is used for the treatment of diarrhea (Lomotil). Several other derivatives of it have been studied.³⁷ The related *p*-chloro analogue, loperamide (A-14), binds to opiate receptors in the brain but does not penetrate the blood-brain barrier enough to produce analgesia.³⁸

Another way to modify the structure of meperidine with favorable results was to enlarge the piperidine ring to the seven-membered hexahydroazepine (or hexamethylenamine) ring. As was true in the piperidine series, the most active compound is the one containing a methyl group on position 3 of the ring adjacent to the quaternary carbon atom in the propionoxy derivative, that is, 1,3-dimethyl-4-phenyl-

4-propionyloxyhexahydroazepine, to which the name *proheptazine* was given. In the study by Eddy and coworkers, cited above, proheptazine was one of the more active analgesics included and had one of the highest addiction liabilities. The higher ring homologue of meperidine, ethoheptazine, was on the market. Although originally thought to be inactive,³⁹ it is less active than codeine as an analgesic in humans but is free of addiction liability and has a low incidence of side effects.⁴⁰ It is no longer available.

Contraction of the piperidine ring to the five-membered pyrrolidine ring was also successful. The lower ring homologue of alphaprodine, prodilidine (A-16), is an effective analgesic; a dose of 100 mg is equivalent to 30 mg of codeine, but because of its potential abuse liability, it was never marketed.⁴¹

A more unusual modification of the meperidine structure is found in fentanyl (A-17), in which the phenyl and the acyl groups are separated from the ring by a nitrogen. It is a powerful analgesic, 50 times stronger than morphine in humans, with minimal side effects.⁴² Its short duration of action makes it well suited for use in anesthesia.⁴³ It is marketed for this purpose in combination with a neuroleptic, droperidol. The *cis*-(−)-3-methyl analogue with an ester group at the 4 position, like meperidine (A-18), was 8,400 times more potent than morphine as an analgesic. In addition, it has the highest binding affinity to isolated opiate receptors of all compounds tested.³⁸ Fentanyl and its 3-methyl and α -methyl analogues have found their way into the illicit drug market and are sold as substitutes for heroin. Because of their extreme potency, they have caused many deaths.

When the nitrogen ring of morphine is opened, as in the formation of morphimethines, the analgesic activity is virtually abolished. On this basis, predicting whether a compound would or would not have activity without the nitrogen in a ring would favor a lack of activity or, at best, low activity. The first report indicating that this was a false assumption was based on the initial work of Bockmuhl and Ehrhart,⁴⁴ in which they claimed that the type of compound represented by B-1 in Table 22-4 possessed both analgesic and spasmolytic properties. The Hoechst laboratories in Germany followed up this lead during World War II by preparing the ketones corresponding to these esters. Some of the compounds they prepared with high activity are represented by formulas B-2 through B-7. Compound B-2 is the well-known methadone. In the meperidine and bemidone types, the introduction of a *m*-hydroxyl group in the phenyl ring brought about slightly to markedly increased activity, whereas the same operation with the methadone-type compound markedly decreased action. Phenadoxone (B-8), the morpholine analogue of methadone, was marketed in England. The piperidine analogue, dipanone, was once under study in this country after successful results in England.

Methadone was first brought to the attention of American pharmacists, chemists, and allied workers by the Kleiderer report⁴⁵ and by the early reports of Scott and Chen.^{46, 47} Since then, much work has been done on this compound, its isomer isomethadone, and related compounds. The report by Eddy, Touchberry, and Lieberman⁴⁸ covers most of the points concerning the structure-activity relationships of methadone. The *levo* isomer (B-3) of methadone (B-2) and the *levo* isomer of isomethadone (B-4) are twice as effective as their racemic mixtures. Also, all structural derivatives of

methadone demonstrate greater activity than the corresponding structural derivatives of isomethadone. In other words, the superiority of methadone over isomethadone seems to hold, even through the derivatives. Conversely, the methadone series of compounds was always more toxic than the isomethadone group.

More extensive permutations, such as replacing the propionyl group (R_3 in B-2) by hydrogen, hydroxyl, or acetoxyl, decreased activity. In a series of amide analogues of methadone, Janssen and Jageneau⁴⁹⁻⁵¹ synthesized racemoramide (B-12), which is more active than methadone. The (6) isomer, dextromoramide (B-13), is the active isomer and has been marketed. A few of the other modifications that have been carried out and their effect on analgesic activity relative to methadone are described in Table 22-4, which includes most of the methadone congeners that are or were on the market. Much deviation in structure from these examples will result in varying degrees of loss of activity.

Particular attention should be paid to the two phenyl groups in methadone and the sharply decreased action resulting from removal of one of them. It is believed that the second phenyl residue helps to lock the $-\text{COC}_2\text{H}_5$ group of methadone in a position to simulate the alicyclic ring of morphine, even though the propionyl group is not particularly rigid. In this connection, however, the compound with a propionoxy group in place of the propionyl group (R_3 in B-2) lacks significant analgesic action.⁵³ In direct contrast with this is (6)-propoxyphene (B-14), which is a propionoxy derivative with one of the phenyl groups replaced by a benzyl group. In addition, it is an analogue of isomethadone (B-4), making it an exception to the rule. This compound is lower than codeine in analgesic activity, possesses few side effects, and has a limited addiction liability.⁵² Replacement of the dimethylamino group in (6)-propoxyphene with a pyrrolidyl group gives a compound that is nearly three-fourths as active as methadone and possesses morphine-like properties. The *levo* isomer of alphacetylmethadol (B-9), known as LAAM, has been marketed as a long-acting substitute for methadone in the treatment of addicts.⁵³

MORPHINE MODIFICATIONS INITIATED BY GREWE

Grewe, in 1946, approached the problem of synthetic analgesics from another direction when he synthesized the tetracyclic compound that he first named morphan and then revised to *N*-methylnorphinan. The relationship of this compound to morphine is obvious.

N-Methylnorphinan differs from the morphine nucleus in lacking the ether bridge between C-4 and C-5. This compound possesses a high degree of analgesic activity, which suggests that the ether bridge is not essential. The 3-hydroxy derivative of *N*-methylnorphinan (racemorphan) was on the market and had an intensity and duration of action that exceeded that of morphine. The original racemorphan was in-

produced as the hydrobromide and was the (*dl*), or racemic, form as obtained by synthesis. Realizing that the levorotatory form of racemorphan was the analgesically active portion of the racemate, the manufacturer resolved the (*dl*) form and marketed the *levo* form as the tartrate salt (levorphanol). The *dextro* form has found use as a cough suppressant (see

dextromethorphan). The ethers and acylated derivatives of the 3-hydroxyl form also exhibit considerable activity. The 2- and 4-hydroxyl isomers are, not unexpectedly, without value as analgesics. Likewise, the *N*-ethyl derivative lacks activity, and the *N*-allyl compound, levallorphan, is a potent morphine antagonist.

Eddy et al.⁵⁴ reported on an extensive series of *N*-aralkylmorphinan derivatives. The effect of the *N*-aralkyl substitution was more dramatic in this series than it was for morphine or meperidine. The *N*-phenethyl and *N*-*p*-aminophenethyl analogues of levorphanol are about 3 and 18 times more active, respectively, than the parent compound in analgesic activity in mice. The most potent member of the series was the *N*- β -furylethyl analogue, which was nearly 30 times as active as levorphanol or 160 times as active as morphine. The *N*-acetophenone analogue, levophenacymorphan, was once under clinical investigation. In mice, it is about 30 times more active than morphine, and in humans a 2-mg dose is equivalent to 10 mg of morphine in its analgesic response.⁵⁵ It has a much lower physical-dependence liability than morphine.

The *N*-cyclopropylmethyl derivative of 3-hydroxymorphinan (cyclophran) was reported to be a potent morphine antagonist, capable of precipitating morphine withdrawal symptoms in addicted monkeys, indicating that it is nonaddicting.²¹ Clinical studies have indicated that it is about 20 times stronger than morphine as an analgesic, but it has some undesirable side effects, primarily hallucinatory. The *N*-cyclobutyl derivative, butorphanol, possesses mixed agonist-antagonist properties, however, and has been marketed as a potent analgesic.

Since removal of the ether bridge and all the peripheral groups in the alicyclic ring in morphine did not destroy its analgesic action, May et al.⁵⁶ synthesized a series of compounds in which the alicyclic ring was replaced by one or two methyl groups. These are known as *benzomorphans* or, more correctly, *benzazocines*. They may be represented by the following formula:

The trimethyl compound (II, $R_1 = R_2 = \text{CH}_3$) is about 3 times more potent than the dimethyl (II, $R_1 = \text{H}$, $R_2 = \text{CH}_3$). The *N*-phenethyl derivatives have almost 20 times the analgesic activity of the corresponding *N*-methyl compounds. Again, the more potent was the one containing the two ring methyls (II, $R_1 = \text{CH}_3$, $R_2 = \text{CH}_2\text{CH}_2\text{C}_6\text{H}_5$). Dera-cemization proved the *levo* isomer of this compound to be more active, being about 20 times as potent as morphine in mice. The (\pm) form, phenazocine, was on the market but was removed in favor of pentazocine.

May et al.⁵⁷ demonstrated an extremely significant difference between the two isomeric *N*-methyl benzomorphans in which the alkyl in the 5 position is *n*-propyl (R_1) and the alkyl in the 9 position is methyl (R_2). These have been termed the α and the β isomer and have the groups oriented as indicated. The isomer with the alkyl *cis* to the phenyl possesses analgesic activity (in mice) equal to that of morphine but has little or no capacity to suppress withdrawal symptoms in addicted monkeys. On the other hand, the *trans* isomer has one of the highest analgesic potencies among the benzomorphans, but it is quite able to suppress morphine

withdrawal symptoms. Further differences in properties are found between the enantiomers of the *cis* isomer. The (+) isomer has weak analgesic activity, but a high physical-dependence capacity. The (–) isomer is a stronger analgesic, without the dependence capacity, and possesses antagonistic activity.⁵⁸ The same is true of the 5,9-diethyl and 9-ethyl-5-phenyl derivatives. The (–) *trans*-5,9-diethyl isomer is similar, except it has no antagonistic properties. This demonstrates that it is possible to divorce analgesic activity comparable to that of morphine from addiction potential. That *N*-methyl compounds have shown antagonistic properties is of great interest as well. The most potent of these is the benzomorphans with an α -methyl and β -3-oxoheptyl group at position 9. The (–) isomer shows greater antagonistic activity than naloxone and is still 3 times more potent than morphine as an analgesic.⁵⁹

An extensive series of the antagonist-type analgesics in the benzomorphans was reported.⁶⁰ Of these, pentazocine (II, $R_1 = \text{CH}_3$, $R_2 = \text{CH}_2\text{CH} = \text{C}(\text{CH}_3)_2$) and cyclazocine (II, $R_1 = \text{CH}_3$, $R_2 = \text{CH}_2$ -cyclopropyl) have been the most interesting. Pentazocine has about half the analgesic activity of morphine, with a lower incidence of side effects.⁶¹ Its addiction liability is much lower, approximating that of propoxyphene.⁶² It is currently available in parenteral and tablet form. Cyclazocine is a strong morphine antagonist, showing about 10 times the analgesic activity of morphine.⁶³ It was investigated as an analgesic and for the treatment of heroin addiction, but it was never marketed because of hallucinatory side effects.

As mentioned above, replacement of the *N*-methyl group in morphine by larger alkyl groups lowered analgesic activity. In addition, these compounds counteracted the effect of morphine and other morphine-like analgesics and are thus known as *narcotic antagonists*. The reversal of activity increases from ethyl, to propyl, to allyl, with the cyclopropylmethyl usually being maximal. This property was true not only for morphine but also for other analgesics. *N*-Allylnormorphine (nalorphine) was the first of these but because of side effects was taken off the market. Levallorphan, the corresponding allyl analogue of levorphanol, naloxone (*N*-allylnoroxymorphone), and naltrexone (*N*-cyclopropyl-noroxymorphone) are the three narcotic antagonists now on the market. Naloxone and naltrexone appear to be pure antagonists with no morphine- or nalorphine-like effects. They also block the effects of other antagonists. These drugs are used to prevent, diminish, or abolish many of the actions or the side effects encountered with the narcotic analgesics. Some of these are respiratory and circulatory depression, euphoria, nausea, drowsiness, analgesia, and hyperglycemia. They are thought to act by competing with the analgesic molecule for attachment at its, or a closely related, receptor site. The observation that some narcotic antagonists that lack addiction liability are also strong analgesics spurred considerable

interest in them.²⁰ The *N*-cyclopropylmethyl compounds mentioned are the most potent antagonists but appear to produce psychotomimetic effects and may not be useful as analgesics. One of these, buprenorphine, has shown an interesting study profile, however, and has been introduced in Europe and in the United States as a potent analgesic.⁶⁴ It is being introduced as a treatment for narcotic addicts in a novel treatment program, Office Based Opioid Treatment (OBOT), provided by private physicians rather than formal treatment clinics.⁶⁵

Other efforts have been under way to develop narcotic antagonists that can be used to treat narcotic addiction.⁶⁶ The continuous administration of an antagonist will block the euphoric effects of heroin, thereby aiding rehabilitation of an addict. The cyclopropylmethyl derivative of naloxone, naltrexone, has been marketed for this purpose. The oral dose of 100 to 150 mg 3 times a week suffices to block several usual doses of heroin.⁶⁷ Long-acting preparations were once also under study.⁶⁸

Much research, other than that described above, has been carried out by the systematic dissection of morphine to give several interesting fragments. These approaches have not yet produced important analgesics and so are not discussed in this chapter. The interested reader may find a key to this literature, however, in the excellent reviews of Eddy,⁹ Bergel and Morrison,²³ and Lee.³⁰

Structure-Activity Relationships

Several reviews on the relationship between chemical structure and analgesic action have been published.^{9, 35, 69-77} Only the major conclusions are considered here, and the reader is urged to consult these reviews for more complete discussion of the subject.

From the time Small et al. started their studies on the morphine nucleus to the present, there has been much light shed on the structural features connected with morphine-like analgesic action. In a very thorough study made for the United Nations Commission on Narcotics in 1955, Braenden et al.⁷⁰ found that the features possessed by all known morphine-like analgesics were as follows:

- 1 A tertiary nitrogen, with the group on the nitrogen being relatively small
- 2 A central carbon atom, of which none of the valences is connected with hydrogen
- 3 A phenyl group or a group isosteric with phenyl, which is connected to the central carbon atom
- 4 A two-carbon chain separating the central carbon atom from the nitrogen for maximal activity

The above discussion shows that several exceptions to these generalizations exist in the structures of compounds that have been synthesized in the past several years. Eddy³⁵ has discussed the more significant exceptions. Relative to the first feature mentioned, extensive studies of the action of normorphine have shown that it possesses analgesic activity that approximates that of morphine. In humans, it is about one fourth as active as morphine when administered intramuscularly, but it was slightly superior to morphine when administered intracisternally. On the basis of the last-mentioned effect, Beckett et al.⁷⁸ postulated that *N*-dealkylation as a step in the mechanism of analgesic action. This has

been questioned.⁷⁹ Additional studies indicate that dealkylation does occur in the brain, although its exact role is not clear.⁸⁰ It is clear, from the *N*-alkyl derivatives discussed above, that a small group is not necessary.

Several exceptions to the second feature have been synthesized. In these series, the central carbon atom has been replaced by a tertiary nitrogen. They are related to methadone and have the following structures:

Diampromide (III) and its related anilides have potencies that are comparable with those of morphine;⁸¹ they have shown addiction liability, however, and have not appeared on the market. The closely related cyclic derivative fentanyl (Table 22-3, A-17) is used in surgery. The benzimidazoles, such as etomidate (IV), are very potent analgesics but show the highest addiction liabilities yet encountered.^{82, 83}

Possibly an exception to feature 3, and the only one that has been encountered, may be the cyclohexyl analogue of A-6 (Table 22-3), which has significant activity. Eddy³⁵ mentions two possible exceptions to feature 4 in addition to fentanyl.

The many studies on molecules of varying types that possess analgesic activity revealed that activity was associated not only with certain structural features but also with the size and the shape of the molecule. The hypothesis of Beckett and Casy⁸⁴ has dominated thinking for several years in the area of stereochemical specificity of these molecules. They initially noted that the more active enantiomers of the methadone- and thiambutene-type analgesics were related configurationally to (*R*)-alanine. This suggested to them that a stereoselective fit at a receptor could be involved in analgesic activity. To depict the dimensions of an analgesic receptor, they selected morphine (because of its semirigidity and high activity) to provide them with information on a complementary receptor. The features thought to be essential for proper receptor fit were

1. A basic center able to associate with an anionic site on the receptor surface
2. A flat aromatic structure, coplanar with the basic center, allowing van der Waals bonding to a flat surface on the receptor site to reinforce the ionic bond
3. A suitably positioned projecting hydrocarbon moiety forming a three-dimensional geometric pattern with the basic center and the flat aromatic structure

These features were selected, among other reasons, because they are present in *N*-methylmorphinan, which may be looked on as a "stripped down" morphine (i.e., morphine without the characteristic peripheral groups [except for the basic center]). Since *N*-methylmorphinan possessed substantial activity of the morphine type, these three features were considered the fundamental ones determining activity, and the peripheral groups of morphine were considered to essentially modulate the activity.

In accord with the foregoing postulates, Beckett and Casy⁸⁴ proposed a complementary receptor site (Fig. 22-1) and suggested ways^{85, 86} in which the known active molecules could be adapted to it. After their initial postulates, natural (-)-morphine was shown to be related configurationally to methadone and thiambutene, which lent weight to the hypothesis. Fundamental to their proposal was that such a receptor was essentially inflexible and that a lock-and-key-type situation existed. Subsequently, the unnatural (+)-morphine was synthesized and shown to be inactive.⁸⁷

Although the foregoing hypothesis appeared to fit the facts quite well and was a useful hypothesis for several years, it now appears that certain anomalies exist that cannot be accommodated by it. For example, the more active enantiomer of α -methadol is not related configurationally to (*R*)-alanine, in contrast with the methadone and thiambutene series. This is also true for the carbethoxy analogue of methadone (V) and for diampronide (III) and its analogues. Another factor that was implicit in considering a proper receptor fit for the morphine molecule and its congeners was that the phenyl ring at the 4 position of the piperidine moiety should be in the axial orientation for maximum activity. The fact that structure VI has only an equatorial phenyl group, yet possesses activity equal to that of morphine, would seem to cast doubt on the necessity for axial orientation as a receptor-fit requirement.

In view of the difficulty of accepting Beckett and Casy's hypothesis as a complete picture of analgesic-receptor interaction, Portoghesi⁸⁸⁻⁹¹ has offered an alternative hypothesis. This hypothesis is based, in part, on the established ability of enzymes and other types of macromolecules to undergo conformational changes^{91, 92} on interaction with small molecules (substrates or drugs). The fact that configurationally unrelated analgesics can bind and exert activity is interpreted as meaning that more than one mode of binding may be possible at the same receptor. Such different modes of binding may be due to differences in positional or conformational interactions with the receptor. The manner in which

Figure 22-1 ■ Diagram of the surface of the analgesic receptor site with the corresponding lower surface of the drug molecule. The three-dimensional features of the molecule are shown by the bonds: —, ---, and — —, which represent in front of, behind, and in the plane of the paper, respectively. (From Gourel, D. R. H.: *Prog. Drug Res.* 7:36, 1964.)

the hypothesis can be applied to the methadol anomaly is illustrated in Figure 22-2.

After considering activity changes in various structural types (i.e., methadones, meperidines, prodines) as related to the identity of the *N*-substituent, Portoghesi noted that in certain series, when identical changes in *N*-substituents were made, there was parallelism in the direction of activity, whereas in others there appeared to be nonparallelism. He has interpreted parallelism and nonparallelism, respectively, as being due to similar and dissimilar modes of binding. Viewed by this hypothesis, although analgesic molecules must still be bound in a fairly precise manner, the concept of binding is liberalized, in that a response may be obtained by two different molecules binding stereoselectively in two different precise modes at the same receptor. A schematic representation of such different possible binding modes is shown in Figure 22-3. This representation will aid in visualizing the meaning of *similar* and *dissimilar* binding modes. If two different analgesicophores (the analgesic molecule

Figure 22-2 ■ Illustration of how different polar groups in analgesic molecules may cause inversion in the configurational selectivity of an analgesic receptor. A hydrogen-bonding moiety, denoted by X and Y, represents a site that is capable of being hydrogen bonded.

Figure 22-3 ■ Schematic illustration of two different molecular modes of binding to a receptor. ⊕, protonated nitrogen. □, an N-substituent. The anionic sites lie directly beneath the protonated nitrogen.

minus the N-substituent, i.e., that portion of the molecule that gives the characteristic analgesic response) bearing identical N-substituents are positioned on the receptor surface such that the N-substituent occupies essentially the same position, a similar pharmacological response may be anticipated. Thus, as one proceeds from one N-substituent to another, the response should likewise change, resulting in parallelism of effect. On the other hand, if two different analgesiophores are bound to the receptor such that the N-substituents are not arranged identically, one may anticipate nonidentical responses to changing the N-substituent (i.e., a nonparallel response). The preceding statements, as well as the diagram, do not imply that the analgesiophore necessarily will be bound in the identical position within a series. They do suggest, however, that in series with parallel activities, the pairs being compared will be bound identically to produce the parallel effect. Interestingly, when binding modes are similar, Portoghesi has been able to demonstrate the existence of a linear free-energy relationship. There is also the possibility that more than one receptor is involved.

Considerable evidence now demonstrates that multiple receptors exist. Martin has characterized and named these by responses to probe molecules: μ (mu) receptors for morphine-specific effects, δ (delta) for cyclazocine, and κ (kappa) for ketocyclazocine.⁹³ A different designation for these receptors, based on pharmacological criteria, is OP3, OP1, and OP2, respectively. Various combinations of these in different tissues could be responsible for the varying effects observed.^{94, 95}

This discovery has stimulated much research into the search for drugs that have selectivity for single receptors. The natural opiates and related synthetic opioids have predominantly μ receptor agonist activity, with morphine and minor analogues showing 10 to 20 times the selectivity over the other receptors. Other analgesic drugs have shown even higher ratios. The antagonists show lower selectivity. Drugs with high κ receptor affinity have high analgesic activity, lack many of the opioid side effects, but have not been useful because of dysphoric and hallucinogenic effects. There are

also no useful drugs developed to date that are selective for δ receptors.

Another highly important development in structure-activity correlations is the development of highly active analgesics from the *N*-allyl-type derivatives that were once thought to be only morphine antagonists and devoid of analgesic properties. Serendipity played a major role in this discovery: Lasagna and Beecher,⁹⁶ in attempting to find some "ideal" ratio of antagonist (*N*-allylnormorphine, nalorphine) to analgesic (morphine) to maintain the desirable effects of morphine while minimizing the undesirable ones, discovered that nalorphine was, milligram for milligram, as potent an analgesic as morphine. Unfortunately, nalorphine has depersonalizing and psychotomimetic properties that preclude its use clinically as a pain reliever. The discovery led, however, to the development of related derivatives such as pentazocine and cyclazocine. Pentazocine has achieved some success in providing an analgesic with low addiction potential, although it is not totally free of some of the other side effects of morphine. The pattern of activity in these and other *N*-allyl and *N*-cyclopropylmethyl derivatives indicates that most potent antagonists possess psychotomimetic activity, whereas the weak antagonists do not. It is from this latter group that useful analgesics, such as pentazocine, hutorphanol, and nalbuphine, have been found. The latter two possess *N*-cyclobutylmethyl groups.

What structural features are associated with antagonist-like activity is uncertain. The *N*-allyl and dimethylallyl substituent does not always confer antagonist properties. This is true in the meperidine and thevinol series. Demonstration of antagonist-like properties by specific isomers of *N*-methyl benzomorphans has raised still further speculation. The exact mechanisms by which morphine and the narcotic antagonists act are not clear, and much research is presently being carried on. Published reviews and symposia may be consulted for further discussions of these topics.^{66, 97-99}

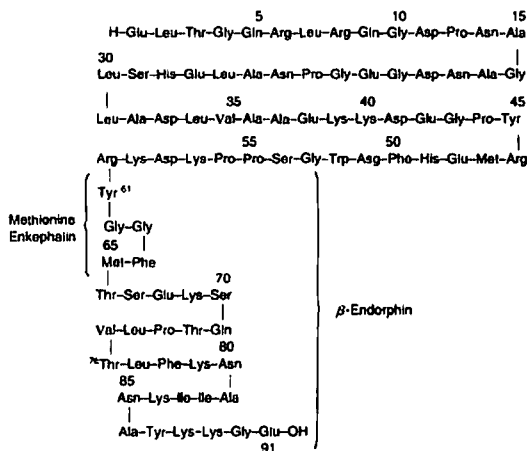

A further problem also is demonstrated in the testing for analgesic activity. The analgesic activity of the antagonists was not apparent from animal testing; it was observed only in humans. Screening in animals can be used to assess the antagonistic action, which indirectly indicates possible analgesic properties in humans.¹⁰⁰

It has been customary in the area of analgesic agents to attribute differences in their activities to structurally related differences in their receptor interactions. This rather universal practice continues in spite of early warnings and recent findings. It now appears clear that much of the difference in relative analgesic potencies can be accounted for on the basis of pharmacokinetic or distribution properties.⁹⁸ For example, a definite correlation was found between the partition coefficients and the intravenous analgesic data for 17 agents of widely varying structures.¹⁰¹ Usual test methods do not help distinguish which structural features are related to receptors and which to distribution phenomena. Studies directed toward distinction have used the measurement of actual brain and plasma levels^{102, 103} or direct injection into the ventricular area,¹⁰¹ the measurement of ionization potentials and partition coefficients,¹⁰⁴ and the application of molecular orbital theories and quantum mechanics.^{99, 105-107} These are providing valuable insight into designing of new and more successful agents.

All of the foregoing work had strongly suggested the exis-

tence of specific binding sites or *receptors* in brain and other tissue. The demonstration of the high steric and structural specificity in the action of the opiates and their antagonists led many investigators to search for such receptors.^{108, 109} Thus in 1971, Goldstein and coworkers demonstrated stereospecific binding in brain homogenates.¹¹⁰ This was quickly followed by refinements and further discoveries by Simon, Terenius, and Pert and Snyder.¹¹¹⁻¹¹³ These receptor-binding studies have now become a routine assay for examining structure-activity relationships.

In addition to the binding studies, considerable attention continued on the use of *in vitro* models, in particular the isolated guinea pig ileum, rat jejunum, and mouse vas deferens.¹¹⁴ While working with these preparations, Hughes was the first to discover the existence of an endogenous factor from pig brains that possessed opiate-like properties.^{115, 116} This factor, given the name *enkephalin*, consisted of two pentapeptides, called *methionine-*, or *metenkephalin*, and *leucine-*, or *leu-enkephalin*. These two enkephalins have subsequently been shown to exist in all animals, including humans, and to possess all morphine-like properties.¹¹⁷⁻¹¹⁹ They exist as segments of a pituitary hormone, the 91-amino acid β -lipotropin, which is cleaved selectively to release specific segments that have now been found to have functions within the body. Thus, segment 61 to 65 is metenkephalin. 61 to 76 is α -endorphin, 61 to 77 is γ -endorphin, and, probably the most important, 61 to 91 is β -endorphin.

β -Lipotropin, β -Endorphin, Methionine-Enkephalin Relationships

The last of these endorphins (short for *endogenous morphine*) has 20 times the analgesic potency of morphine when injected into rat brain. These substances can also produce tolerance and dependence.

Clearly, all of these techniques will lead to new concepts and understanding of the processes of analgesia, tolerance, and dependence. It is hoped that learning how these mechanisms operate will aid in the design and development of better analgesics.

Products

In General Circular No. 253, March 10, 1960, the Treasury Department, Bureau of Narcotics, Washington, DC, pub-

lished an extensive listing of narcotics of current interest in the drug trade. This listing is much more extensive than the following monographs covering compounds primarily of interest to American pharmacists.

Morphine. Morphine was isolated first in 1803 by De-rosne, but the credit for isolation generally goes to Sertürner (1803), who first called attention to the basic properties of this alkaloid. Morphine, incidentally, was the first plant base isolated and recognized as such. Although intensive research was carried out on the structure of morphine, it was in 1925 that Gulland and Robinson¹²⁰ postulated the currently accepted formula. The total synthesis of morphine finally was effected by Gates and Tschudi^{121, 122} in 1952, confirming the Gulland and Robinson formula.

Morphine is obtained only from the opium poppy, *Papaver somniferum*, either from opium, the resin obtained by lancing the unripe pod, or from poppy straw. The latter process is favored, as it helps to eliminate illicit opium from which heroin is readily produced. Morphine occurs in opium in amounts varying from 5 to 20% (*USP* requires not less than 9.5%). It is isolated by various methods, but the final step is usually the precipitation of morphine from an acid solution by use of excess ammonia. The precipitated morphine then is recrystallized from boiling alcohol.

The free alkaloid occurs as levorotatory, odorless, white, needle-like crystals possessing a bitter taste. It is almost insoluble in water (1:5,000, 1:1,100 at the boiling point), ether (1:6,250), or chloroform (1:1,220). It is somewhat more soluble in ethyl alcohol (1:210, 1:98 at boiling point). (Note that in this chapter, a solubility of 1:5,000 indicates that 1 g is soluble in 5,000 mL of the solvent at 25°C. Solubilities at other temperatures are so indicated.) Because of the phenolic hydroxyl group, it is readily soluble in solutions of alkali or alkaline earth metal hydroxides.

Morphine is a monoacidic base and readily forms water-soluble salts with most acids. Thus, because morphine itself is so poorly soluble in water, the salts are the preferred form for most uses. Numerous salts have been marketed, but the ones in use are principally the sulfate and, to a lesser extent, the hydrochloride.

Many writers have pointed out the "indispensable" nature of morphine, based on its potent analgesic properties toward all types of pain. It is properly termed a *narcotic analgesic*. Because it causes addiction so readily, however, it should be used only when other pain-relieving drugs prove inadequate. It controls pain caused by serious injury, neoplasms, migraine, pleurisy, biliary and renal colic, and numerous other conditions. It is often administered as a preoperative sedative, together with atropine to control secretions. With scopolamine, it is given to obtain the so-called twilight sleep. This effect is used in obstetrics, but care is needed to prevent respiratory depression in the fetus. The toxic properties of morphine are much more evident in young and old people.

Morphine Hydrochloride. Morphine hydrochloride may be prepared by neutralizing a hot aqueous suspension of morphine with diluted hydrochloric acid and then concentrating the resultant solution to crystallization. It is no longer commercially available. It occurs as silky, white, glistening

needles, as cubical masses, or as a white crystalline powder. The hydrochloride is soluble in water (1:17.5, 1:0.5 at boiling point), alcohol (1:52, 1:46 at 60°), or glycerin, but it is practically insoluble in ether or chloroform. Solutions have a pH of approximately 4.7 and may be sterilized by boiling. Its uses are the same as those of morphine. The usual oral and subcutaneous dose is 15 mg every 4 hours as needed, with a suggested range of 8 to 20 mg.

Morphine Sulfate, USP. Morphine sulfate is prepared in the same manner as the hydrochloride (i.e., by neutralizing morphine with diluted sulfuric acid). It occurs as feathery, silky, white crystals, as cubical masses of crystals, or as a white crystalline powder. Although it is a fairly stable salt, it loses water of hydration and darkens on exposure to air and light. It is soluble in water (1:16, 1:1 at 80°), poorly soluble in alcohol (1:570, 1:240 at 60°), and insoluble in chloroform or ether. Aqueous solutions have a pH of about 4.8 and may be sterilized by heating in an autoclave.

This common morphine salt is used widely in England, and now in the United States, by oral administration for the management of pain in cancer patients. It has largely replaced Brompton's mixture or cocktail, a combination of heroin and cocaine in chloroform water. In the United States, this preparation has become mistakenly popular, substituting morphine sulfate for the heroin. Moreover, Twycross has advised that the stimulant cocaine is contraindicated because it interferes with sleep,¹²³ and its original use was for cough in tuberculosis patients. Morphine sulfate is available in a variety of dosage forms: tablets, oral solution, parenteral, suppositories, and controlled-release tablets (MS Contin) and capsules (Kadian).

Codeine, USP. Codeine is an alkaloid that occurs naturally in opium, but the amount present is usually too small to be of commercial importance. Consequently, most commercial codeine is prepared from morphine by methylating the phenolic hydroxyl group. The methylation methods make use of reagents such as diazomethane, dimethyl sulfate, and methyl iodide. Newer methods are based on its synthesis from thebaine, which makes it possible to use *Papaver bracteatum* as a natural source (see above).

It occurs as levorotatory, colorless, efflorescent crystals or as a white crystalline powder. It is light sensitive. Codeine is slightly soluble in water (1:120) and sparingly soluble in ether (1:50). It is freely soluble in alcohol (1:2) and very soluble in chloroform (1:0.5). Codeine is a monoacidic base and readily forms salts with acids, with the most important being the sulfate and the phosphate. The acetate and methylbromide derivatives have been used to a limited extent in cough preparations.

The general pharmacological action of codeine is similar to that of morphine, but as indicated above, it does not possess the same analgesic potency. Studies indicate that a dose of 30 to 120 mg of codeine is considerably less efficient parenterally than 10 mg of morphine, and the usual side effects of morphine—respiratory depression, constipation, nausea, and such—occur. Codeine is less effective orally than parenterally, and Houde and Wallenstein¹²⁴ stated that a dose of 32 mg of codeine is about as effective as 650 mg of aspirin in relieving terminal cancer pain. Combinations

of aspirin and codeine act additively as analgesics, however, thus giving some support to the common practice of combining the two drugs.

Codeine has a reputation as an antitussive, depressing the cough reflex, and is used in many cough preparations. It is one of the most widely used morphine-like analgesics. It is considerably less addicting than morphine, and in the usual doses, respiratory depression is negligible, although an oral dose of 60 mg causes such depression in a normal person. Much of codeine's reputation as an antitussive probably rests on subjective impressions rather than on objective studies. The average 5-mL dose contains 10 mg of codeine. Several cough preparations containing codeine are available, with some that may be sold over-the-counter as exempt narcotic preparations. Abuse or misuse of these preparations, however, has led many states to place them on prescription-only status.

Codeine Phosphate, USP. Codeine phosphate may be prepared by neutralizing codeine with phosphoric acid and precipitating the salt from aqueous solution with alcohol. Codeine phosphate occurs as fine, needle-shaped, white crystals or as a white crystalline powder. It is efflorescent and is sensitive to light. It is freely soluble in water (1:2.5, 1:0.5 at 80°) but less soluble in alcohol (1:325, 1:125 at boiling point). Solutions may be sterilized by boiling. Because of its high solubility in water, compared with the sulfate, this salt is used widely. It is often the only salt of codeine stocked by pharmacies and is dispensed, rightly or wrongly, on all prescriptions calling for either the sulfate or the phosphate.

Codeine Sulfate, USP. Codeine sulfate is prepared by neutralizing an aqueous suspension of codeine with diluted sulfuric acid and then effecting crystallization. It occurs as white crystals, usually needle-like, or as a white crystalline powder. The salt is efflorescent and light sensitive. It is soluble in water (1:30, 1:6.5 at 80°), much less soluble in alcohol (1:1,280), and insoluble in ether or chloroform. This salt of codeine is prescribed frequently but is not as suitable as the phosphate for liquid preparations. Solutions of the sulfate and the phosphate are incompatible with alkaloidal reagents and alkaline substances.

Diacetylmorphine Hydrochloride. Although diacetylmorphine hydrochloride, heroin hydrochloride, diamorphine hydrochloride, heroin, is 2 to 3 times more potent than morphine as an analgesic, its sale and use are prohibited in the United States because of its intense addiction liability. It is available in some European countries, where it has a limited use as an antitussive and as an analgesic in terminal cancer patients. Because of its superior solubility over morphine sulfate, arguments have been raised for its availability. The other more potent analgesics described here have, however, significant advantages in being more stable and longer acting. It remains one of the most widely used narcotics for illicit purposes and places major economic burdens on society.

Hydromorphone. Hydromorphone, dihydromorphine, a synthetic derivative of morphine, is prepared by the

catalytic hydrogenation and dehydrogenation of morphine under acidic conditions, using a large excess of platinum or palladium. The free base is similar in properties to morphine, being slightly soluble in water, freely soluble in alcohol, and very soluble in chloroform.

This compound, of German origin, was introduced in 1926. It is a substitute for morphine (5 times as potent) but has approximately equal addicting properties and a shorter duration of action. It possesses the advantage over morphine of giving less daytime sedation or drowsiness. It is a potent antitussive and is often used for coughs that are difficult to control.

Hydromorphone Hydrochloride, USP. Hydromorphone hydrochloride, dihydromorphinone hydrochloride (Dilaudid), occurs as a light-sensitive, white crystalline powder that is freely soluble in water (1:3), sparingly soluble in alcohol, and practically insoluble in ether. It is used in about one-fifth the dose of morphine for any of the indications of morphine. It is available in tablet, liquid, parenteral, and suppository dosage forms. The dose is 1 to 8 mg.

Hydrocodone Bitartrate, USP. Hydrocodone bitartrate, dihydrocodeinone bitartrate (Dicodid, Codone), is prepared by the catalytic rearrangement of codeine or by hydrolyzing dihydrothebaine. It occurs as fine, white crystals or as a white crystalline powder. It is soluble in water (1:16), slightly soluble in alcohol, and insoluble in ether. It forms acidic solutions and is affected by light. The hydrochloride is also available.

Hydrocodone has a pharmacological action midway between those of codeine and morphine, with 15 mg being equivalent to 10 mg of morphine in analgesic power. Although it possesses more addiction liability than codeine, it reportedly gives no evidence of dependence or addiction with long-term use. Its principal advantage is in the lower frequency of side effects encountered with its use. It is more effective than codeine as an antitussive and is used primarily for this purpose. It is on the market in many cough preparations, as well as in tablet and parenteral forms. It has also been marketed in an ion-exchange resin complex form under the trade name of Tussionex. The complex releases the drug at a sustained rate and is said to produce effective cough suppression over a 10- to 12-hour period. Hydrocodone is also marketed in combination with acetaminophen (e.g., Hydrocet, Vicodin, Lortab, and Zydene) and with homatropine as Hycodan. Although this drug found extensive use in antitussive formulations for many years, it has been placed under more stringent narcotic regulations.

Oxymorphone Hydrochloride, USP. Oxymorphone hydrochloride, (–)-14-hydroxydihydromorphinone hydrochloride (Numorphan), introduced in 1959, is prepared by cleavage of the corresponding codeine derivative. It is used as the hydrochloride salt, which occurs as a white crystalline powder freely soluble in water and sparingly soluble in alcohol. In humans, oxymorphone is as effective as morphine in one-eighth to one-tenth the dosage, with good duration and a slightly lower frequency of side effects.¹²⁵ It has high addiction liability. It is used for the same purposes as morphine, such as control of postoperative pain, pain of advanced neo-

plastic diseases, and other types of pain that respond to morphine. Because of the risk of addiction, it should not be used for relief of minor pains that can be controlled with codeine. It has poor antitussive activity and is not used as a cough suppressant. It may be administered orally, parenterally (intravenously, intramuscularly, or subcutaneously), or rectally, and for these purposes is supplied as a solution for injection (1.0 and 1.5 mg/mL) and in suppositories (5 mg).

Nalbuphine Hydrochloride. Nalbuphine hydrochloride, *N*-cyclobutylmethyl-14-hydroxy-*N*-nordihydromorphinone hydrochloride (Nubain), *N*-cyclobutylmethylnoroxymorphone hydrochloride, was introduced in 1979 as a potent analgesic of the agonist-antagonist type, with little to no abuse liability. It is a somewhat less potent analgesic than its parent oxymorphone but shares some of the antagonist properties of the closely related, but pure, antagonists naloxone and naltrexone. Nalbuphine hydrochloride occurs as a white to off-white crystalline powder that is soluble in water and sparingly soluble in alcohol. It is prepared from cyclobutylmethyl bromide and noroxycodone followed by cleavage of the *O*-methyl group.

This analgesic shows a very rapid onset with a duration of action of up to 6 hours. It has relatively low abuse liability, judged to be less than that of codeine and propoxyphene. The injection is, therefore, available without narcotic controls, although caution is urged for long-term administration or use in emotionally disturbed patients. Abrupt discontinuation after prolonged use has given rise to withdrawal signs. Usual doses cause respiratory depression comparable to that of morphine, but no further decrease is seen with higher doses. It has fewer cardiac effects than pentazocine and butorphanol. The most frequent adverse effect is sedation, and as with most other CNS depressants and analgesics, caution should be urged when it is administered to ambulatory patients who may need to drive a car or operate machinery.

Nalbuphine is marketed as an injectable (10 and 20 mg/mL). The usual dose is 10 mg administered subcutaneously, intramuscularly, or intravenously at 3- to 6-hour intervals, with a maximal daily dose of 160 mg.

Oxycodone Hydrochloride. Oxycodone hydrochloride, dihydrohydroxycodeinone hydrochloride, is prepared by the catalytic reduction of hydroxycodeinone prepared by hydrogen peroxide (in acetic acid) oxidation of thebaine. This derivative of morphine occurs as a white crystalline powder that is soluble in water (1:10) or alcohol. Aqueous solutions may be sterilized by boiling. Although this drug is almost as likely to cause addiction as morphine, it is sold in the United States in Percodan and several other products in combination with aspirin or acetaminophen.

It is used as a sedative, an analgesic, and a narcotic. To depress the cough reflex, it is used in 3- to 5-mg doses and as an analgesic in 5- to 10-mg doses. For severe pain, a dose of 20 mg is given subcutaneously. Oxycodone is also marketed as controlled-release tablets (OxyContin, 10 to 160 mg) for use in managing chronic pain. Unfortunately, these high-dose preparations have become popular with drug users and addicts, who crush the tablets, dissolve the contents, and inject the mixture. Several overdose deaths have resulted from this practice, leading to tighter controls over their availability.

Dihydrocodeine Bitartrate. Dihydrocodeine is obtained by the reduction of codeine. The bitartrate salt occurs as white crystals that are soluble in water (1:4.5) and only slightly soluble in alcohol. Subcutaneously, a dose of 30 mg of this drug is almost equivalent to 10 mg of morphine as an analgesic, with faster onset and negligible side effects. It has addiction liability. It is available in combination with aspirin or acetaminophen for pain.

Normorphine. Normorphine may be prepared by N-demethylation of morphine.¹²⁶ In humans, by normal routes of administration, it is about one fourth as active as morphine in producing analgesia but has a much lower physical dependence capacity. Its analgesic effects are nearly equal by the intraventricular route. It does not show the sedative effects of morphine in single doses but does so cumulatively. Normorphine suppresses the morphine abstinence syndrome in addicts, but after its withdrawal, it gives a slow onset and a mild form of the abstinence syndrome.^{127, 128} It was once considered for possible use in the treatment of narcotic addiction, but it has no current use.

Opium. An extract of opium, containing a mixture of the total alkaloids of opium, is available as an alcoholic aqueous solution. It is available as Deodorized Opium Tincture (15 mg/mL of morphine base) and Paregoric (2 mg/mL of morphine base). These are used primarily for the treatment of diarrhea.

Tramadol Hydrochloride. Tramadol hydrochloride, (\pm)-*cis*-2-[(dimethylamino)methyl]-1-(*m*-methoxyphenyl)cyclohexanol hydrochloride (Ultram), represents a fragment of codeine's structure, consisting of the phenyl and cyclohexane rings. The drug possesses opioid activity but has other analgesic activity that is not reversed by naloxone. The principal effect is attributed to the O-demethylated metabolite, which is 6 times more potent than the parent compound, an observation consistent with the differences between codeine and morphine. It produces significantly lower morphine-like side effects. It is available in tablet form for use in moderate-to-severe pain in a dose of 50 to 100 mg every 4 to 6 hours and in combination (37.5 mg) with acetaminophen (Ultracet) for short-term management of acute pain.

Apomorphine Hydrochloride, USP. When morphine or morphine hydrochloride is heated at 140° under pressure with strong (35%) hydrochloric acid, it loses a molecule of water and yields a compound known as apomorphine.

The hydrochloride is odorless and occurs as minute, glistening, white or grayish white crystals or as a white powder.

It is light sensitive and turns green on exposure to air and light. It is sparingly soluble in water (1:50, 1:20 at 80°) and in alcohol (1:50) and is very slightly soluble in ether or chloroform. Solutions are neutral to litmus.

The change in structure from morphine to apomorphine profoundly changes its physiological action. The central depressant effects of morphine are much less pronounced, and the stimulant effects are enhanced greatly, thereby producing emesis by a purely central mechanism. It is administered subcutaneously to obtain emesis. It is ineffective orally. Apomorphine is one of the most effective, prompt (10 to 15 minutes), and safe emetics in use today. Care should be exercised in its use, however, because it may be depressant in already-depressed patients. It is currently classified as an "orphan drug" for use in Parkinson's disease.

Meperidine Hydrochloride, USP. Meperidine hydrochloride, ethyl 1-methyl-4-phenylisopropylcarboxylate hydrochloride, ethyl 1-methyl-4-phenyl-4-piperidinecarboxylate hydrochloride (Demerol Hydrochloride), is a fine, white, odorless crystalline powder that is very soluble in water, soluble in alcohol, and sparingly soluble in ether. It is stable in the air at ordinary temperature, and its aqueous solution is not decomposed by a short period of boiling. The free base may be made by heating benzyl cyanide with bis(β -chloroethyl)methylamine, hydrolyzing to the corresponding acid and esterifying the latter with ethyl alcohol.²

Meperidine first was synthesized to study its spasmolytic character, but it was found to have far greater analgesic properties. The spasmolysis is primarily due to a direct papaverine-like depression of smooth muscle and, also, to some action on parasympathetic nerve endings. In therapeutic doses, it exerts an analgesic effect that lies between those of morphine and codeine, but it shows little tendency toward hypnosis. It is indicated for the relief of pain in most patients for whom morphine and other alkaloids of opium generally are used, but it is especially valuable when the pain is due to spastic conditions of intestine, uterus, bladder, bronchi, and so on. Its most important use seems to be in lessening the severity of labor pains in obstetrics and, with barbiturates or tranquilizers, producing amnesia in labor. In labor, a dose of 100 mg is injected intramuscularly as soon as contractions occur regularly, and a second dose may be given after 30 minutes if labor is rapid or if the cervix is thin and dilated (≥ 2 to 3 cm). A third dose may be necessary an hour or two later, and at this stage a barbiturate may be administered in a small dose to ensure adequate amnesia for several hours. Meperidine possesses addiction liability. Psychic dependence develops in individuals who experience euphoria lasting for an hour or more. The development of tolerance has been observed, and meperidine can be substituted successfully for morphine in addicts who are being treated by gradual withdrawal. Furthermore, mild withdrawal symptoms have been noted in certain persons who have become purposely addicted to meperidine. The possibility of dependence is great enough to put it under the federal narcotic laws. It is available in oral liquid, tablet, and parenteral dosage forms.

Alphaprodine Hydrochloride, USP. Alphaprodine hydrochloride, (\pm)-1,3-dimethyl-4-phenyl-4-piperidinol pro-

panoate hydrochloride, is prepared by the method of Ziering and Lee.¹²⁹ It occurs as a white crystalline powder that is freely soluble in water, alcohol, and chloroform but insoluble in ether. The compound is an effective analgesic, similar to meperidine, and of special value in obstetric analgesia. It appears to be quite safe for use in this capacity, causing little or no respiratory depression in either mother or fetus. It is currently not marketed in the United States.

Anileridine, USP. Anileridine, ethyl 1-(*p*-aminophenethyl)-4-phenylisopropionate (Leritine), is prepared by the method of Weijlard et al.¹³⁰ It occurs as a white to yellowish-white crystalline powder that is freely soluble in alcohol but only very slightly soluble in water. It is oxidized on exposure to air and light. The injection is prepared by dissolving the free base in phosphoric acid solution. Anileridine is more active than meperidine and has the same usefulness and limitations. Its dependence capacity is less, and it is considered a suitable substitute for meperidine. It is currently not marketed in the United States.

Anileridine Hydrochloride, USP. Anileridine hydrochloride, ethyl 1-(*p*-aminophenethyl)-4-phenylisopropionate dihydrochloride (Leritine Hydrochloride), is prepared as cited for anileridine, except that it is converted to the dihydrochloride by conventional procedures. It occurs as a white or nearly white, crystalline odorless powder that is stable in air. It is freely soluble in water, sparingly soluble in alcohol, and practically insoluble in ether and chloroform. This salt has the same activity as anileridine. It is currently not marketed in the United States.

Diphenoxylate Hydrochloride, USP. Diphenoxylate hydrochloride, ethyl 1-(3-cyano-3,3-diphenylpropyl)-4-phenylisopropionate monohydrochloride (Lomotil, Lonox, Logen, Lomanate), occurs as a white, odorless, slightly water-soluble powder with no distinguishing taste. Although this drug has a strong structural relationship to the meperidine-type analgesics, it has very little, if any, such activity itself. Its most pronounced activity is its ability to inhibit excessive gastrointestinal motility, an activity reminiscent of the constipating side effect of morphine itself. Investigators have demonstrated the possibility of addiction,^{35, 36} particularly with large doses, but virtually all studies using ordinary dosage levels show nonaddiction. Its safety is reflected in its classification as an exempt narcotic, with the warning, however, that it may be habit forming. To discourage possible abuse of the drug, the commercial product (Lomotil) once contained a subtherapeutic dose (25 μ g) of atropine sulfate in each 2.5-mg tablet and in each 5 mL of the liquid, which contains a like amount of the drug.

It is indicated in the oral treatment of diarrhea resulting from a variety of causes. The usual initial adult dose is 5 mg 3 or 4 times a day, with the maintenance dose usually substantially lower and individually determined. Appropriate dosage schedules for children are available in the manufacturer's literature.

The incidence of side effects is low, but the drug should be used with caution, if at all, in patients with impaired hepatic function. Similarly, patients taking barbiturates concurrently with the drug should be observed carefully, in view of reports of barbiturate toxicity under these circumstances.

Loperamide Hydrochloride, USP. Loperamide hydrochloride, 4-(4-chlorophenyl)-4-hydroxy-*N,N*-dimethyl- α - α -diphenyl-1-piperidinebutanamide, 4-(4-*p*-chlorophenyl-4-hydroxypiperidino)-*N,N*-dimethyl-2,2-diphenylbutyramide hydrochloride (Imodium), a hybrid of a methadone-like and meperidine molecule, is closely related to diphenoxylate but is more specific, more potent, and longer acting. It acts as an antidiarrheal by a direct effect on the circular and longitudinal intestinal muscles. After oral administration it reaches peak blood levels within 4 hours and has a very long plasma half-life (40 hours). Tolerance to its effects has not been observed.¹³¹ Although it has shown minimal CNS effects, it has been controlled under Schedule V. Loperamide is available as 2-mg capsules (Loperamide hydrochloride capsules, USP) for treatment of acute and chronic diarrhea. Recommended dosage is 4 mg initially, with 2 mg after each loose stool for a maximum of 16 mg/day.

Ethoheptazine Citrate. Ethoheptazine citrate, ethyl hexahydro-1-methyl-4-phenyl-1*H*-azepine-4-carboxylate citrate, 1-methyl-4-carbethoxy-4-phenylhexamethylenimine citrate (Zactane Citrate), is effective orally against moderate pain in doses of 50 to 100 mg, with minimal side effects. Parenteral administration is limited because of central stimulating effects. It appears to have no addiction liability, but toxic reactions have occurred with large doses. A double-blind study in humans rated 100 mg of the hydrochloride salt equivalent to 30 mg of codeine and found that the addition of 600 mg of aspirin increased analgesic effectiveness.³⁹ In another study, a dose of 150 mg was found equal to 65 mg of propoxyphene, with both better than placebo.¹³² It was once available as a 75-mg tablet and in combination with 600 mg of aspirin (Zactirin).

Fentanyl Citrate, USP. Fentanyl citrate, *N*-(1-phenethyl-4-piperidyl)propionanilide citrate (Sublimaze), occurs as a crystalline powder soluble in water (1:40) and methanol and sparingly soluble in chloroform. This novel anilide derivative has analgesic activity 50 times that of morphine in humans.⁴² It has a very rapid onset (4 min) and short duration of action. Side effects similar to those of other potent analgesics are common, particularly respiratory depression and bradycardia. It is used primarily as an adjunct to anesthesia. For use as a neuroleptanalgesic in surgery, it is available in combination with the neuroleptic droperidol (Innovar). It is also available as a transdermal release system (Duragesic) at total dose levels ranging from 20 to 100 mg) for management of chronic pain. It has dependence liability.

Alfentanil Hydrochloride. Alfentanil hydrochloride *N*-[1-[2-(4-ethyl-5-oxo-2-tetrazolin-1-yl)-ethyl]-4-(methoxymethyl)-4-piperidyl]propionanilide hydrochloride monohydrate (Alfenta), is closely related to fentanyl. It is a potent analgesic used as a primary anesthetic or as an adjunct in the maintenance of anesthesia. It has the same properties and side effects as fentanyl. It is available as an injective (0.5 mg/mL).

Remifentanyl Hydrochloride. Remifentanyl hydrochloride, 4-carboxy-4-(*N*-phenylpropionanilido)-1-piperidinepropionic acid methyl ester hydrochloride (Ultiva),

structural analogue of fentanyl, has similar properties and is also used in anesthesia. It is available as an injection (1 mg/mL).

Sufentanil Citrate. Sufentanil citrate, *N*-[4-(methoxymethyl)-1-[2-(2-thienyl)ethyl]-4-piperidyl]propionanilide citrate (Sufenta), a structural analogue of fentanyl, has similar properties and is also used in anesthesia. It is available as an injection (0.05 mg/mL).

Methadone Hydrochloride, USP. Methadone hydrochloride, 6-(Dimethylamino)-4,4-diphenyl-3-heptanone hydrochloride (Dolophine Hydrochloride), occurs as a bitter, white crystalline powder. It is soluble in water, freely soluble in alcohol and chloroform, and insoluble in ether. Methadone is synthesized in several ways. The method of Easton et al.¹³³ is noteworthy, in that it avoids the formation of the troublesome isomeric intermediate aminonitriles.^{44, 133} The analgesic effect and other morphine-like properties are exhibited chiefly by the (–) form. Aqueous solutions are stable and may be sterilized by heat for intramuscular and intravenous use. Like all amine salts, it is incompatible with alkali and salts of heavy metals. It is somewhat irritating when injected subcutaneously.

The toxicity of methadone is 3 to 10 times that of morphine, but its analgesic effect is twice that of morphine and 10 times that of meperidine. It has been placed under federal narcotic control because of its high addiction liability. Methadone is a most effective analgesic, used to alleviate many types of pain. It can replace morphine for the relief of withdrawal symptoms. It produces less sedation and narcosis than morphine and appears to have fewer side reactions in bedridden patients. Methadone is especially valuable in spasm of the urinary bladder and in the suppression of the cough reflex.

The *levo* isomer, levanone, reportedly does not produce euphoria or other morphine-like sensations and has been advocated for the treatment of addicts.¹³⁴ Methadone itself is used quite extensively in addict treatment, although not without some controversy.¹³⁵ It suppresses withdrawal effects and is widely used to maintain former heroin addicts during this rehabilitation. Large doses are often used to “block” the effects of heroin during treatment. The use of methadone in treating addicts is subject to Food and Drug Administration (FDA) regulations that require special registration of physicians and dispensers. Methadone is available for use as an analgesic, however, under the usual narcotic requirements.

levomethadyl Acetate Hydrochloride. Levomethadyl acetate hydrochloride, *l*- α -acetylmethadol, (–)- α -6-(dimethylamino)-4,4-diphenyl-3-heptyl acetate hydrochloride, methadyl acetate, LAAM, occurs as a white crystalline powder that is soluble in water but dissolves with some difficulty. It is prepared by hydride reduction of (+)-methadone followed by acetylation. Of the four possible methadol isomers, the (3*S*,6*S*) isomer LAAM has the unique characteristic of producing long-lasting narcotic effects. Extensive metabolism studies have shown that this is due to its *N*-demethylation to give (–)- α -acetylnormethadol, which is more potent than its parent, LAAM, and possesses a long half-life.¹³⁶

This is further accentuated by its demethylation to the dinor metabolite, which has similar properties.^{136, 137}

Because of the need to administer methadone daily, which inconveniences the maintenance patient and leads to illicit diversion, the long-acting LAAM was actively investigated as an addict-maintenance drug to replace methadone. Generally, an 80- to 100-mg dose 3 times a week suffices for routine maintenance.^{53, 138} The FDA has approved the drug for use, and it is marketed as ORLAAM in solution form (10 mg/mL). By law, it can be dispensed only by treatment programs certified by the Department of Health and Human Services’ Substance Abuse and Mental Health Services Administration and registered with the Drug Enforcement Administration. It also carries a warning about possible serious cardiac arrhythmia. The racemate of the normetabolite, noracetylmethadol, was once studied in the clinic as a potential analgesic.¹³⁹

Propoxyphene Hydrochloride, USP. Propoxyphene hydrochloride, (2*S*,3*R*)-(+)4-(dimethylamino)-3-methyl-1,2-diphenyl-2-butanol propanoate hydrochloride (Darvon, Dolene, Doxaphene), was introduced into therapy in 1957. It may be prepared by the method of Pohland and Sullivan.¹⁴⁰ It occurs as a bitter, white crystalline powder that is freely soluble in water, soluble in alcohol, chloroform, and acetone, but practically insoluble in benzene and ether. It is the α -(+) isomer; the α -(–) isomer and β diastereoisomers are far less potent in analgesic activity. The α -(–) isomer, *levo*-propoxyphene, is an effective antitussive (see below).

In analgesic potency, propoxyphene is approximately equal to codeine phosphate and has a lower frequency of side effects. It has no antidiarrheal, antitussive, or antipyretic effect, thus differing from most analgesic agents. It can suppress the morphine abstinence syndrome in addicts but has shown a low level of abuse because of its toxicity. It is not very effective in deep pain and appears to be no more effective in minor pain than aspirin. Its widespread use in dental pain seems justified, since aspirin is reported to be relatively ineffective. It has been classified as a narcotic and controlled under federal law. It does give some euphoria in high doses and has been abused. It has been responsible for numerous overdosage deaths. Refilling the prescription should be avoided if misuse is suspected. It is available in several combination products with aspirin or acetaminophen (e.g., Wygesic).

Propoxyphene Napsylate, USP. Propoxyphene napsylate, (+)- α -4-dimethylamino-3-methyl-1,2-diphenyl-2-butanol propanoate (ester) 2-naphthylsulfonate (salt) (Darvon-N), is very slightly soluble in water, but soluble in alcohol, chloroform, and acetone. The napsylate salt of propoxyphene was introduced shortly before the patent on Darvon expired. The insoluble salt form is claimed to be less prone to abuse because it cannot be readily dissolved for injection and, on oral administration, gives a slower, less pronounced peak blood level.

Because of its mild narcotic-like properties, it was once investigated as an addict-maintenance drug to be used in place of methadone. It was hoped that it would provide easier withdrawal and serve as an addict-detoxification drug. Unfortunately, toxicity at higher doses has limited this applica-

tion. It is available in combination with acetaminophen (Propacet, Darvocet-N).

Levorphanol Tartrate, USP. Grewe made the basic studies in the synthesis of compounds of the type of levorphanol tartrate, (–)-3-hydroxy-*N*-methylnormorphinan bitartrate (Levo-Dromoran), as mentioned above. Schnider and Gräussner synthesized the hydroxymorphinans, including the 3-hydroxyl derivative, by similar methods. The racemic 3-hydroxy-*N*-methylnormorphinan hydrobromide (racemorphan, (±)-Dromoran) was the original form in which this potent analgesic was introduced. This drug is prepared by resolution of racemorphan. The *levo* compound is available in Europe under the original name, Dromoran. As the tartrate, it occurs in the form of colorless crystals. The salt is sparingly soluble in water (1:60) and is insoluble in ether.

The drug is used for the relief of severe pain and is in many respects similar in its actions to morphine, except that it is 6 to 8 times as potent. The addiction liability of levorphanol is as great as that of morphine and, for that reason, caution should be observed in its use. It is claimed that the gastrointestinal effects of this compound are significantly lower than those experienced with morphine. Naloxone is an effective antidote for overdosage. Levorphanol is useful for relieving severe pain originating from a multiplicity of causes (e.g., inoperable tumors, severe trauma, renal colic, biliary colic). In other words, it has the same range of usefulness as morphine and is considered an excellent substitute. It is supplied in ampuls, in multidose vials, and as oral tablets (2 mg). The drug requires a narcotic form.

Butorphanol Tartrate, USP. Butorphanol tartrate, 17-(cyclobutyl-methyl)morphinan-3,14-diol D-(–)-tartrate, (–)-*N*-cyclobutylmethyl-3,14-dihydroxymorphinan bitartrate (Stadol), a potent analgesic, occurs as a white crystalline powder soluble in water and sparingly soluble in alcohol. It is prepared from the dihydroxy-*N*-normorphinan obtained by a modification of the Grewe synthesis. It is the cyclobutyl analogue of levorphanol and levallorphan, and is as potent an analgesic as the former and a somewhat less active antagonist than the latter.

Butorphanol

The onset and duration of action of the drug are comparable to those of morphine, but it has the advantages of showing a maximal ceiling effect on respiratory depression and a greatly reduced abuse liability. The injectable form was marketed without narcotic controls; this product was considered for placement in Schedule IV, however, because of reported misuse and lack of recognition of its potential abuse liability. The drug has also been used illegally for doping racehorses.

Butorphanol shares the adverse hemodynamic effects of pentazocine, causing increased pressure in specific arteries

and on the heart workload. It should thus be used with caution and only with patients hypersensitive to morphine for the treatment of myocardial infarction or other cardiac problems. Other adverse effects include a high incidence of sedation and, less frequently, nausea, headache, vertigo, and dizziness.¹⁴¹

It is available as a parenteral for intramuscular and intravenous administration in a dose of 1 or 2 mg every 3 to 4 hours, with a maximal single dose of 4 mg. It is also available as a nasal spray (Stadol NS).

Buprenorphine Hydrochloride. Buprenorphine hydrochloride, 21-cyclopropyl-7 α [(*S*)-1-hydroxy-1,2,2-trimethylpropyl]-6,14-*endo*-ethano-6,7,8,14-tetrahydro-*oxypavine* hydrochloride (Buprenex), is a rapidly acting, centrally acting analgesic in the agonist-antagonists class. It is about 30 times more potent than morphine. It is available for treating moderate-to-severe pain as a parenteral for intramuscular or intravenous administration in a dose of 0.3 mg every 6 hours.

After several years of investigation for use in treating opioid addiction, buprenorphine, alone or in combination with naloxone, has been approved for use in a highly regulated treatment program called *Office Based Opioid Treatment* (OBOT). Under federal legislation, the Substance Abuse and Mental Health Administration's Center for Drug Abuse Treatment has established criteria and training programs for private physicians to administer these special dosage forms to opioid addicts. The intent of the program is to make treatment available to persons who are not likely to seek treatment in traditional treatment clinics, such as adolescents, executives, and the like.

Dezocine. Dezocine, (–)-13 β -amino-5,6,7,8,9,10,11,12-octahydro-5 α -methyl-5,11-methanobenzocyclodecen-3-ol (Dalgan), is a synthetic agonist-antagonist analgesic, with an unusual structure. It is similar to morphine in analgesic potency and duration. It produces fewer side effects, due to its antagonist activity, with reported minimal dependence capacity. It is available for treating moderate-to-severe pain as a parenteral for intramuscular or intravenous administration in a dose of 5 to 20 mg every 3 to 6 hours.

Nalbuphine Hydrochloride. Nalbuphine hydrochloride, 17-(cyclobutylmethyl)-4,5 α -epoxymorphinan-3,6 α ,14-triol hydrochloride (Nubain), is a combination of the oxymorphine nucleus and the nitrogen substituent of butorphanol. It is a potent analgesic of the agonist-antagonist class, similar to morphine in potency but with an abuse potential rated less than that of codeine. It is useful in treating moderate-to-severe pain and is available for parenteral use with a usual dose of 10 mg/70 kg every 3 to 6 hours.

Pentazocine, USP. Pentazocine, 1,2,3,4,5,6-hexahydro-*cis*-6,11-dimethyl-3-(3-methyl-2-butenyl)-2,6-methano-3-benzazocin-8-ol, *cis*-2-dimethylallyl-5,9-dimethyl-2'-hydroxy-6,7-benzomorphinan (Talwin), occurs as a white crystalline powder that is insoluble in water and sparingly soluble in alcohol. It forms a poorly soluble hydrochloride salt, but is readily soluble as the lactate.

Pentazocine in a parenteral dose of 30 mg or an oral dose of 50 mg is about as effective as 10 mg of morphine in most patients. There is some evidence that the analgesic action resides principally in the (–) isomer, and a dose of 25 mg is approximately equivalent to 10 mg of morphine sulfate.¹⁴² Occasionally, doses of 40 to 60 mg may be required. Pentazocine's plasma half-life is about 3.5 hours.¹⁴³ At the lower dosage levels, it appears to be well tolerated, although some sedation occurs in about one third of persons receiving it. The incidence of other morphine-like side effects is as high as with morphine and other narcotic analgesics. In patients who have been receiving other narcotic analgesics, large doses of pentazocine may precipitate withdrawal symptoms. It shows an equivalent or greater respiratory depressant activity. Pentazocine has given rise to a few cases of possible dependence. It has been placed under control, and its abuse potential should be recognized and close supervision of its use maintained. Levallorphan cannot reverse its effects, although naloxone can, and methylphenidate is recommended as an antidote for overdosage or excessive respiratory depression.

Pentazocine as the lactate is available in injection form containing the base equivalent of 30 mg/mL, buffered to pH 4 to 5. It should not be mixed with barbiturates. Tablets of 50 mg (as the hydrochloride in combination with naloxone to prevent abuse) are available for oral administration. It is also available in combination with aspirin (Talwin Compound) and with acetaminophen (Talacen).

Methotrimeprazine, USP. Methotrimeprazine, (–)-10-[3-(dimethylamino)-2-methylpropyl]-2-methoxyphenothiazine (Levoprome), a phenothiazine derivative closely related to chlorpromazine, possesses strong analgesic activity. An intramuscular dose of 15 to 20 mg is equal to 10 mg of morphine in humans. It has not shown any dependence liability and appears not to produce respiratory depression. The most frequent side effects are similar to those of phenothiazine tranquilizers, namely, sedation and orthostatic hypotension. These often result in dizziness and fainting, limiting the use of methotrimeprazine to nonambulatory patients. It should be used with caution along with antihypertensives, atropine, and other sedatives. It shows some advantage in patients for whom addiction and respiratory depression are problems.¹⁴⁴

Narcotic Antagonists

Nalorphine Hydrochloride, USP. Nalorphine hydrochloride, *N*-allylnormorphine hydrochloride, may be prepared according to the method of Weijlard and Erickson.¹²⁶ It occurs in the form of white or practically white crystals that slowly darken on exposure to air and light. It is freely soluble in water (1:8), sparingly soluble in alcohol (1:35), and almost insoluble in chloroform and ether. The phenolic hydroxyl group confers water solubility in the presence of fixed alkali. Aqueous solutions of the salt are acid, with a pH of about 5.

Nalorphine has a direct antagonistic effect against morphine, meperidine, methadone, and levorphanol. It has little antagonistic effect toward barbiturate or general anesthetic depression, however. It has strong analgesic properties, but it is not acceptable for such use owing to the high incidence

of undesirable psychotic effects. Because of these properties and the availability of alternate antagonists, it was withdrawn from the market.

Levallorphan Tartrate, USP. Levallorphan tartrate, 17-(2-propenyl)-morphinan-3-ol tartrate, (–)-*N*-allyl-3-hydroxymorphinan bitartrate (Lorfan), occurs as a white or practically white, odorless crystalline powder. It is soluble in water (1:20), sparingly soluble in alcohol (1:60), and practically insoluble in chloroform and ether. Levallorphan resembles nalorphine in its pharmacological action and is about 5 times more effective as a narcotic antagonist. It was useful in combination with analgesics such as meperidine, alphaprodine, and levorphanol to prevent the respiratory depression usually associated with these drugs. It is no longer marketed.

Narcotic Antagonists

Naloxone Hydrochloride, USP. Naloxone hydrochloride, 4,5-epoxy-3,14-dihydroxy-17-(2-propenyl)morphinan-6-one hydrochloride, *N*-allyl-14-hydroxynordihydromorphine hydrochloride (Narcan), *N*-allylnoroxymorphone hydrochloride, is presently on the market as the agent of choice for treating narcotic overdosage. It lacks not only the analgesic activity shown by other antagonists, but also all of the other agonist effects. It is almost 7 times more active than nalorphine in antagonizing the effects of morphine. It shows no withdrawal effects after long-term administration. The duration of action is about 4 hours. It was briefly investigated for the treatment of heroin addiction. With adequate doses of naloxone, the addict does not receive any effect from heroin. It is given to an addict only after a detoxification period. Its long-term usefulness is currently limited because its short duration of action requires large oral doses. Long-acting, alternative antagonists are available (Table 22-5).

Cyclazocine. Cyclazocine, 3-(cyclopropylmethyl)-1,2,3,4,5,6-hexahydro-6,11-dimethyl-2,6-methano-3-benzazocine-8-ol, *cis*-2-cyclopropylmethyl-5,9-dimethyl-2'-hydroxy-6,7-benzomorphan, is a potent narcotic antagonist that has shown analgesic activity in humans in 1-mg doses. It once was investigated as a clinical analgesic. It does possess hallucinogenic side effects at higher doses, which limited its usefulness as an analgesic. It was studied like naloxone in the treatment of narcotic addiction. Voluntary treatment with cyclazocine deprives addicts of the euphorogenic effects of heroin. Its dependence liability is lower, and the effects of withdrawal develop more slowly and are milder. Tolerance develops to the side effects of cyclazocine, but not to its antagonist effects.¹⁴⁷ The effects are long lasting and are not reversed by other antagonists such as nalorphine. It has not been marketed.

Naltrexone. Naltrexone, 17-(cyclopropylmethyl)-4,5- α -epoxy-3,14-dihydroxymorphinan-6-one, *N*-cyclopropylmethyl-14-hydroxynordihydromorphinone, *N*-cyclopropylmethylnoroxymorphone (ReVia, Depade), a naloxone analogue, has been marketed as the preferred agent for treating former opiate addicts. Oral doses of 50 mg daily or 100 mg 3 times weekly suffice to "block" or protect a patient from

TABLE 22-5 Narcotic Antagonists

Name Proprietary Name	Preparations	Usual Adult Dose	Usual Dose Range	Usual Pediatric Dose
Levalorphan tartrate, NF <i>Lorfan</i>	Levallorphan tartrate injection, NF	IV, 1 mg, repeated twice at 10- to 15-minute intervals, if necessary	500 μ g-2 mg, repeated, if necessary	0.05-0.1 mg in neonates to decrease respiratory depression
Naloxone hydrochloride, USP <i>Narcan</i>	Naloxone hydrochloride injection, USP	Parenteral, 400 μ g, repeated at 2- to 3-minute intervals, as necessary		0.01 mg as above

the effects of heroin. Its metabolism,^{148, 149} pharmacokinetics,¹⁵⁰ and pharmacology¹⁵¹ have been studied intensely because of the tremendous governmental interest in developing new agents for the treatment of addiction.⁶⁷

It is available as 50-mg tablets (ReVia) for use in treating narcotic addiction. It has also shown promise for suppressing craving in the treatment of alcoholism and is available for that use. Sustained-release or depot dosage forms of naltrexone were once investigated to avoid the recurrent decision on the part of the former addict of whether a protecting dose of antagonist is needed.^{68, 152}

Nalmefene Hydrochloride. Nalmefene hydrochloride, 17-(cyclopropylmethyl)-4,5 α -epoxy-6-methylenemorphinan-3,14-diol hydrochloride (Revex), is the 6-methylene analogue of naloxone. It is the latest pure antagonist to be introduced for use in reversing the effects of opioid agonists. It is longer acting than naltrexone and is used for the same indications. It is available as an injection (0.1 and 1.0 mg/mL).

Others. Several other narcotic antagonists have been investigated (e.g., diprenorphine¹⁵³ and oxilorphan).¹⁵⁴

ANTITUSSIVE AGENTS

Cough is a protective, physiological reflex that occurs in health as well as in disease. It is very widespread and commonly ignored as a mild symptom. In many conditions, however, it is desirable to take measures to reduce excessive coughing. Many etiological factors cause this reflex, and when a cough has been present for an extended period or accompanies any unusual symptoms, the person should be referred to a physician. Cough preparations are widely advertised and often sold indiscriminately; the pharmacist must warn the public of the inherent dangers.

Among the agents used in the symptomatic control of cough are those that act by depressing the cough center located in the medulla. These have been termed *anodynes*, *cough suppressants*, and *centrally acting antitussives*. Until recently, the only effective drugs in this area were narcotic analgesic agents. The more important and widely used ones are morphine, hydromorphone, codeine, hydrocodone, methadone, and levorphanol, which are discussed above.

In recent years, several compounds have been synthesized that possess antitussive activity without the addiction liability

ties of the narcotic agents. Some of these act in a similar manner through a central effect. In a hypothesis for the initiation of the cough reflex, Salem and Aviado¹⁵⁵ proposed that bronchodilatation is an important mechanism for the relief of cough. Their hypothesis suggests that irritation of the mucosa initially causes bronchoconstriction that in turn excites the cough receptors.

Chappel and von Seemann¹⁵⁶ have pointed out that most antitussives of this type fall into two structural groups. The larger group has structures that bear a resemblance to methadone. The other group has large, bulky substituents on the acid portion of an ester, usually connected by means of a long, ether-containing chain to a *tertiary* amino group. The notable exceptions are benzonate and sodium dibutylate. Noscapine could be considered as belonging to the first group.

Many of the cough preparations sold contain various other ingredients in addition to the primary antitussive agent. The more important ones include antihistamines, useful when the cause of the cough is allergic, although some antihistaminic drugs (e.g., diphenhydramine) have a central antitussive action as well; sympathomimetics, which are quite effective owing to their bronchodilatory activity, the most useful being ephedrine, methamphetamine, phenylpropanolamine, homarylamine, isoproterenol, and isooctylamine; parasympatholytics, which help to dry secretions in the upper respiratory passages; and expectorants. It is not known if these drugs potentiate the antitussive action, but they usually are considered adjuvant therapy. The more important drugs in this class are discussed in the following section. For more exhaustive coverage of the field, the reader is urged to consult the excellent review of Chappel and von Seemann.¹⁵⁷

Products

Some of the narcotic antitussive products are discussed above with the narcotic analgesics. Others are discussed below (Table 22-6).

Noscapine, USP. Noscapine, (-)-narcotine (Tuscapine), an opium alkaloid, was isolated in 1817 by Robiquet. It is isolated rather easily from the drug by ether extraction. It makes up 0.75 to 9% of opium. With the discovery of its unique antitussive properties, the name of this alkaloid was changed from narcotine to noscapine. It was realized that it would not meet with widespread acceptance as long as its name was associated with the narcotic opium alkaloids. The name *noscapine* was probably selected because a precedent

TABLE 22-6 Antitussive Agents

Name Proprietary Name	Preparations	Usual Adult Dose	Usual Dose Range
Dextromethorphan hydrobromide, USP <i>Romilar</i>	Dextromethorphan hydrobromide syrup, USP	15–30 mg qd to qid	
Levopropoxyphene napsylate, USP <i>Novrad</i>	Levopropoxyphene napsylate capsules, USP Levopropoxyphene napsylate oral suspension, USP	50–100 mg of levopropoxyphene, as the napsylate, every 4 hours	
Benzonate, USP <i>Tessalon</i>	Benzonate capsules, USP	100 mg tid	100–200 mg

existed in the name of (\pm)-narcotine, namely, *gnoscopine*. It was once available in various cough preparations.

Dextromethorphan Hydrobromide, USP. Dextromethorphan hydrobromide, (+)-3-methoxy-17-methyl-9 α ,13 α ,14 α -morphinan hydrobromide (Romilar), is the O-methylated (+)-form of racemorphan left after the resolution necessary in the preparation of levorphanol. It occurs as practically white crystals or as a crystalline powder, with a faint odor. It is sparingly soluble in water (1:65), freely soluble in alcohol and chloroform, and insoluble in ether.

It possesses the antitussive properties of codeine, without the analgesic, addictive, central depressant, and constipating features. Ten milligrams is suggested as equivalent to a 15-mg dose of codeine in antitussive effect. It affords an opportunity to note the specificity exhibited by very closely related molecules. Here, the (+) and (–) forms both must attach to receptors responsible for the suppression of the cough reflex, but the (+) form is apparently in a steric relationship that precludes attaching to the receptors involved in analgesic, constipative, addictive, and other actions exhibited by the (–) form. It has largely replaced many older antitussives, including codeine, in prescription and nonprescription cough preparations.

Benzonate, USP. Benzonate, 2,5,8,11,14,17,20,23,26-nonaaoctacosan-28-yl *p*-(butylamino)benzoate (Tessalon), introduced in 1956, is a pale-yellow, viscous liquid insoluble in water and soluble in most organic solvents. It is chemically related to *p*-aminobenzoate local anesthetics, except that the aminoalcohol group has been replaced by a methylated polyethylene glycol group.

Benzonate reportedly possesses both peripheral and central activity in producing its antitussive effect. It somehow blocks the stretch receptors thought to be responsible for cough. Clinically, it is not as effective as codeine, but it produces far fewer side effects and has very low toxicity. It is available in 100-mg capsules ("perles").

Carbetapentane Citrate. Carbetapentane citrate, 2-[2-(diethylamino)-ethoxy]ethyl 1-phenylcyclopentanecarboxylate citrate, is a white, odorless crystalline powder that is freely soluble in water (1:1), slightly soluble in alcohol, and insoluble in ether. It is reportedly equivalent to codeine as an antitussive. Introduced in 1956, it is well tolerated and has

a low frequency of side effects. It is available as a pediatric suspension (2.5 mg/5 mL) or as capsules (20 mg, Cophene-X), and in various combinations with antihistamines and decongestants. The tannate is also available (Rynatuss) as a 60-mg tablet and is said to give a more sustained action.

ANTI-INFLAMMATORY ANALGESICS

The early growth of the anti-inflammatory analgesic group was related closely to the belief that lowering or "curing" fever was an end in itself. Drugs that induced a drop in temperature in feverish conditions were considered quite valuable and were sought eagerly. The decline of interest in these drugs coincided more or less with the realization that fever was an outward symptom of some other, more fundamental ailment. During the use of the several antipyretics, however, some were noted to be excellent analgesics for the relief of minor aches and pains. These drugs have survived to the present time on the basis of the analgesic, rather than the antipyretic, effect. Although these drugs are still widely used for the alleviation of minor aches and pains, they are also used extensively in the symptomatic treatment of rheumatic fever, rheumatoid arthritis (RA), and osteoarthritis (OA). The dramatic effect of salicylates in reducing the inflammatory effects of rheumatic fever is time honored, and even with the development of the corticosteroids, these drugs are still of great value in this respect. The steroids are reportedly no more effective than the salicylates in preventing the cardiac complications of rheumatic fever.¹⁵⁷

The analgesic drugs that fall into this category have been disclaimed by some as not deserving the term *analgesic* because of their low activity in comparison with the morphine-type compounds. Indeed, Fourneau has suggested the name *antalgics* to designate this general category and, in this way, to emphasize the distinction from the narcotic or so-called true analgesics. Two of the principal features distinguishing these analgesics from the narcotic analgesics are the low activity for a given dose (which is not increased significantly at a higher dosage) and the lack of addiction potential.

Research has intensified in an effort to find new nonsteroidal anti-inflammatory drugs (NSAIDs). Long-term therapy with the corticosteroids is often accompanied by various side effects. Efforts to discover new agents have been limited, for the most part, to structural analogues of active com-

pounds owing to a lack of knowledge about the causes and mechanisms of inflammatory diseases.¹⁵⁸ Although several new agents have been introduced for use in RA, aspirin remains one of the most widely used drugs for this purpose. It also protects against myocardial infarctions.

A significant stimulus to this search was the observation that prostaglandins play a major role in the inflammatory processes.¹⁵⁹ Drugs such as aspirin and indomethacin inhibit prostaglandin synthesis in several tissues.¹⁶⁰ Furthermore, almost all classes of NSAIDs strongly inhibit the conversion of arachidonic acid into prostaglandin E_2 (PGE_2).^{161, 162} This occurs at the stage of conversion of arachidonic acid, released by the action of phospholipase A on damaged tissues, by prostaglandin H_2 synthetase, now called *cyclooxygenase*, to the cyclic endoperoxides PGG_2 and PGH_2 . These are known to cause vasoconstriction and pain. They, in turn, are converted in part to PGE_2 and $PGF_{2\alpha}$, which can cause pain and vasodilatation. This effect of the NSAIDs parallels their relative potency in various tests and is stereospecific.¹⁶¹

The search for specific inhibitors of cyclooxygenase has opened a new area of research in this field. This enzyme occurs in two forms, cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2). COX-1 is a constitutive enzyme and plays a role in the production of essential prostaglandins. Inhibition of this enzyme by all the older, nonselective NSAIDs is primarily responsible for a number of their side effects. The COX-2 enzyme is induced in response to the release of several proinflammatory mediators, leading to the inflammatory response and pain. Thus, there was an active search for specific inhibitors of the COX-2 enzyme. This has been successful with the approval of three COX-2 inhibitors, discussed below.

Even with the significant advances achieved in the discovery of new and more specific NSAIDs, they all have a ceiling effect on their ability to relieve all pain. It is becoming common practice to use combinations of the opioid drugs with NSAIDs to treat severe and intractable pain. These drugs are considered below in their various chemical categories.

Salicylic Acid Derivatives

Historically, the salicylates were among the first of this group to achieve recognition as analgesics. Leroux, in 1827, isolated salicin, and Piria, in 1838, prepared salicylic acid. After these discoveries, Cahours (1844) obtained salicylic acid from oil of wintergreen (methyl salicylate), and Kolbe and Lautermann (1860) prepared it synthetically from phenol. Sodium salicylate was introduced in 1875 by Buss, followed by the introduction of phenyl salicylate by Nencki in 1886. Aspirin, or acetylsalicylic acid, was first prepared in 1853 by Gerhardt but remained obscure until Felix Hoffmann discovered its pharmacological activities in 1899. It was tested and introduced into medicine by Dreser, who named it *aspirin* by taking the *a* from acetyl and adding it to *spirin*, an old name for salicylic or spiric acid, derived from its natural source of spirea plants.

The pharmacology of the salicylates and related compounds has been reviewed extensively by Smith.^{163, 164} Salicylates, in general, exert their antipyretic action in febrile patients by increasing heat elimination of the body via the mobilization of water and consequent dilution of the blood. This brings about perspiration, causing cutaneous dilatation.

This does not occur with normal temperatures. The antipyretic and analgesic actions are believed to occur in the hypothalamic area of the brain. Some think that the salicylates exert their analgesia by their effect on water balance, reducing the edema usually associated with arthralgias. Aspirin is particularly effective for this. For an interesting account of the history of aspirin and a discussion of its mechanisms of action, the reader should consult an article by Collier,¹⁶⁵ as well as the reviews by Smith^{163, 164} and by Nickander et al.¹⁶²

The possibility of hypoprothrombinemia and concomitant capillary bleeding in conjunction with salicylate administration accounts for the inclusion of menadione in some salicylate formulations. There is some doubt, however, about the necessity for this measure. A more serious aspect of salicylate medication is the possibility of inducing hemorrhage from direct irritative contact with the mucosa. Alvarez and Summerskill have pointed out a definite relationship between salicylate consumption and massive gastrointestinal hemorrhage from peptic ulcer.¹⁶⁶ Barager and Duthie¹⁶⁷ in an extensive study found, however, no danger of increased anemia or development of peptic ulcer. Leonards and Levy¹⁶⁸ used radiolabeled iron and demonstrated that bleeding does occur following administration of aspirin. The effects varied with the formulation. Davenport¹⁶⁹ suggests that back diffusion of acid from the stomach is responsible for capillary damage.

Because of these characteristics of aspirin, it has been extensively studied as an antithrombotic agent in the treatment and prevention of clinical thrombosis.^{170, 171} It is thought to act by its selective action on the synthesis of the prostaglandin-related thromboxane A_2 and prostacyclin, which are the counterbalancing factors involved in platelet aggregation and are released when tissue is injured. It is unique from the other NSAIDs, in that it irreversibly inhibits the cyclooxygenase enzymes by acetylation. Aspirin has now been approved for the prevention of transient ischemic attacks, indicators of an impending stroke.¹⁷²

The salicylates are readily absorbed from the stomach and the small intestine and depend strongly on the pH of the media. Absorption slows considerably as the pH rises (more alkaline) because of the acidic nature of these compounds and the necessity for the presence of undissociated molecules for absorption through the lipoidal membrane of the stomach and the intestines. Therefore, buffering agents administered at the same time in excessive amounts decrease the rate of absorption. In small quantities, their principal effect may be to aid in the dispersion of the salicylate into fine particles. This would help to increase absorption and decrease the possibility of gastric irritation by the accumulation of large particles of the undissolved acid and their adhesion to the gastric mucosa. Levy and Hayes¹⁷³ have shown that the absorption rate of aspirin and the incidence of gastric distress were a function of the dissolution rate of its particular dosage form. A more rapid dissolution rate of calcium and buffered aspirin was believed to account for faster absorption. They also demonstrated significant variations in dissolution rates of different nationally distributed brands of plain aspirin tablets. This may account for some of the conflicting reports and opinions concerning the relative advantages of plain and buffered aspirin tablets. Lieberman et al.¹⁷⁴ have also shown that buffering is effective in raising the blood levels of aspi-

rin. A measure of the antianxiety effect of aspirin by means of electroencephalograms (EEGs) found differences between buffered, brand name, and generic aspirin preparations.¹⁷⁵

Potential of salicylate activity by simultaneous administration of *p*-aminobenzoic acid or its salts has been the basis for the introduction of numerous products of this kind. Salassa and coworkers have shown that this effect is due to the inhibition of both salicylate metabolism and excretion in the urine.¹⁷⁶ This effect has been proved amply, provided that the ratio of 24 g of *p*-aminobenzoic acid to 3 g of salicylate per day is observed. There is no strong evidence, however, to substantiate any significant elevation of plasma salicylate levels when less *p*-aminobenzoic acid is used.

The derivatives of salicylic acid are of two types [I and II (a and b)]:

Type I represents those that are formed by modifying the carboxyl group (e.g., salts, esters, or amides). Type II (a and b) represents those that are derived by substitution on the hydroxyl group of salicylic acid. The derivatives of salicylic acid were introduced in an attempt to prevent the gastric symptoms and the undesirable taste inherent in the common salts of salicylic acid. Most hydrolysis of type I takes place in the intestine, and most of the type II compounds are absorbed unchanged into the bloodstream (see aspirin).

COMPOUNDS OF TYPE I

The alkyl and aryl esters of salicylic acid (type I) are used externally, primarily as counterirritants, where most of them are well absorbed through the skin. This type of compound is of little value as an analgesic. A few inorganic salicylates are used internally when the effect of the salicylate ion is intended. These compounds vary in their irritation of the stomach. To prevent the development of pink or red coloration in the product, contact with iron should be avoided in their manufacture.

Sodium Salicylate, USP. Sodium salicylate may be prepared by the reaction, in aqueous solution, between 1 mole each of salicylic acid and sodium bicarbonate; evaporating to dryness yields the white salt. Generally, the salt has a pinkish tinge or is a white microcrystalline powder. It is odorless or has a faint, characteristic odor, and it has a sweet, saline taste. It is affected by light. The compound is soluble in water (1:1), alcohol (1:10), and glycerin (1:4).

In solution, particularly in the presence of sodium bicarbonate, the salt will darken on standing (see salicylic acid). This darkening may be lessened by the addition of sodium sulfite or sodium bisulfite. Also, use of recently boiled distilled water and dispensing in amber-colored bottles lessens color change. Sodium salicylate forms a eutectic mixture with antipyrine and produces a violet coloration with iron or its salts. Solutions of the compound must be neutral or slightly basic to prevent precipitation of free salicylic acid. The USP salt forms neutral or acid solutions, however.

This salt is the one of choice for salicylate medication and usually is administered with sodium bicarbonate to lessen gastric distress, or it is administered in enteric-coated tablets. The use of sodium bicarbonate¹⁷⁷ is ill advised because it decreases the plasma levels of salicylate and increases the excretion of free salicylate in the urine.

Sodium Thiosalicylate. Sodium thiosalicylate (Rexolate) is the sulfur or thio analogue of sodium salicylate. It is more soluble and better absorbed, thus allowing lower dosages. It is recommended for gout, rheumatic fever, and muscular pains in doses of 100 to 150 mg every 3 to 6 hours for 2 days, and then 100 mg once or twice daily. It is available only for injection.

Magnesium Salicylate, USP. Magnesium salicylate (Mobidin, Magan) is a sodium-free salicylate preparation for use when sodium intake is restricted. It is claimed to produce less gastrointestinal upset. The dosage and indications are the same as those for sodium salicylate.

Choline Salicylate. Choline salicylate (Arthropan) is extremely soluble in water and is available as a flavored liquid. It is claimed to be absorbed more rapidly than aspirin, giving faster peak blood levels. It is used when salicylates are indicated in a recommended dose of 870 mg to 1.74 g 4 times daily. It is also available in combination with magnesium salicylate (Trilisate, Tricosal).

Others. Ammonium, lithium, and strontium salts of salicylic acid have also found use. They offer no distinct advantage over sodium salicylate.

SALOL PRINCIPLE

Nencki introduced salol in 1886 and so presented to the science of therapy the "salol principle." In salol, two toxic substances (phenol and salicylic acid) were combined into an ester that taken internally slowly hydrolyzes in the intestine to give the antiseptic action of its components. This type of ester is referred to as a *full salol* or *true salol* when both components of the ester are active compounds. Examples are guaiacol benzoate, β -naphthol benzoate, and salol. The salol principle can be applied to esters in which only the alcohol or the acid is the toxic, active or corrosive portion; this type is called a *partial salol*. Examples of partial salols that contain an active acid are ethyl salicylate and methyl salicylate. Examples of partial salols that contain an active phenol are creosote carbonate, thymol carbonate, and guaiacol carbonate. Although many salol-type compounds have been prepared and used to some extent, none is presently

valuable in therapeutics, and all are surpassed by other agents.

Phenyl Salicylate. Phenyl salicylate, salol, occurs as fine white crystals or a white crystalline powder with a characteristic taste and a faint, aromatic odor. It is insoluble in water (1:6,700), slightly soluble in glycerin, and soluble in alcohol (1:6), ether, chloroform, acetone, or fixed and volatile oils. Damp or eutectic mixtures form readily with many organic materials, such as thymol, menthol, camphor, chloral hydrate, and phenol.

Salol is sold in combination with methenamine and atropine alkaloids as a urinary tract antiseptic and analgesic (e.g., Prosed/OS, Trac Tabs, Urised and others). Salol is insoluble in gastric juice but is slowly hydrolyzed in the intestine into phenol and salicylic acid. Because of this property, coupled with its low melting point (41 to 43°C), it has been used in the past as an enteric coating for tablets and capsules. It is not efficient as an enteric-coating material, however, and its use has been superseded by more effective materials. It has also been used externally as a sun filter (10% ointment) for sunburn prevention (Rayderm).

Salicylamide. Salicylamide, *o*-hydroxybenzamide, is a derivative of salicylic acid that has been known for almost a century. It is readily prepared from salicyl chloride and ammonia. The compound occurs as a nearly odorless, white crystalline powder. It is fairly stable to heat, light, and moisture. It is slightly soluble in water (1:500); soluble in hot water, alcohol (1:15), and propylene glycol; and sparingly soluble in chloroform and ether. It is freely soluble in solutions of alkalis. In alkaline solution with sodium carbonate or triethanolamine, decomposition takes place, resulting in a yellow to red precipitate.

Salicylamide reportedly exerts a moderately quicker and deeper analgesic effect than aspirin. Long-term studies on rats revealed no untoward symptomatic or physiological reactions. Its metabolism differs from that of other salicylic compounds, and it is not hydrolyzed to salicylic acid.¹⁶³ Its analgesic and antipyretic activity is probably no greater than that of aspirin, and possibly less. It can be used in place of salicylates, however, and is particularly useful for patients with a demonstrated sensitivity to salicylates. It is excreted much more rapidly than other salicylates, which probably accounts for its lower toxicity and, thus, does not permit high blood levels.

The dose for simple analgesic effect may vary from 300 mg to 1 g administered 3 times daily; but for rheumatic conditions, the dose may be increased to 2 to 4 g 3 times a day. Gastric intolerance may limit the dosage, however. The usual period of the higher dosage should not exceed 3 to 6 days. It is available in several combination products (e.g., Saleto, BC Powder).

Aspirin, USP. Aspirin, acetylsalicylic acid (Aspro, Empirin), was introduced into medicine by Dreser in 1899. It is prepared by treating salicylic acid, which was first prepared by Kolbe in 1874, with acetic anhydride. The hydrogen atom of the hydroxyl group in salicylic acid is replaced by the acetyl group; this also may be accomplished by using acetyl chloride with salicylic acid or ketene with salicylic acid.

Aspirin occurs as white crystals or as a white crystalline powder. It is slightly soluble in water (1:300) and soluble in alcohol (1:5), chloroform (1:17), and ether (1:15). Also, it dissolves easily in glycerin. Aqueous solubility may be increased by using acetates or citrates of alkali metals, although these are said to decompose it slowly. It is stable in dry air, but in the presence of moisture, it slowly hydrolyzes into acetic and salicylic acids. Salicylic acid will crystallize out when an aqueous solution of aspirin and sodium hydroxide is boiled and then acidified.

Aspirin itself is acidic enough to produce effervescence with carbonates and, in the presence of iodides, to cause the slow liberation of iodine. In the presence of alkaline hydroxides and carbonates, it decomposes, although it does form salts with alkaline metals and alkaline earth metals. The presence of salicylic acid, formed on hydrolysis, may be confirmed by the formation of a violet color on the addition of ferric chloride solution.

Aspirin is not hydrolyzed appreciably on contact with weakly acid digestive fluids of the stomach but, on passage into the intestine, is subjected to some hydrolysis. Most of it is absorbed unchanged, however. Garrett¹⁷⁸ has ascribed the gastric mucosal irritation of aspirin to salicylic acid formation, the natural acidity of aspirin, or the adhesion of undissolved aspirin to the mucosa. He has also proposed that the nonacidic anhydride of aspirin is superior for oral administration. Davenport¹⁶⁹ concludes that aspirin alters mucosal cell permeability, allowing back diffusion of stomach acid, which damages the capillaries. A number of proprietaries (e.g., Bufferin) use compounds such as sodium bicarbonate, aluminum glycinate, sodium citrate, aluminum hydroxide, or magnesium trisilicate to counteract this acidic property. One of the better antacids is dihydroxyaluminum aminoacetate, USP. Aspirin is unusually effective when prescribed with calcium glutamate. The more stable, nonirritant calcium acetylsalicylate is formed, and the glutamate portion (glutamic acid) maintains a pH of 3.5 to 5.

Preferably, dry dosage forms (i.e., tablets, capsules, or powders) should be used, since aspirin is somewhat unstable in aqueous media. In tablet preparations, the use of acid-washed talc improves the stability of aspirin.¹⁷⁹ Also, aspirin has been found to break down in the presence of phenylephrine hydrochloride.¹⁸⁰ Aspirin in aqueous media will hy-

hydrolyze almost completely in less than 1 week; solutions made with alcohol or glycerin do not decompose as quickly. Citrates retard hydrolysis only slightly. Some studies have indicated that sucrose tends to inhibit hydrolysis. A study of aqueous aspirin suspensions indicated that sorbitol exerts a pronounced stabilizing effect.¹⁸¹ Stable liquid preparations are available that use triacetin, propylene glycol, or a polyethylene glycol. Aspirin lends itself readily to combination with many other substances but tends to soften and become damp with methenamine, aminopyrine, salol, antipyrine, phenol, or acetanilid.

Aspirin is one of the most widely used compounds in therapy and, for many years, was not associated with untoward effects. Allergic reactions to aspirin are now observed commonly. Asthma and urticaria are the most common manifestations and, when they occur, are extremely acute and difficult to relieve. Like sodium salicylate, aspirin caused congenital malformations when administered to mice.¹⁸² Pretreatment with sodium pentobarbital or chlorpromazine significantly lowered these effects.¹⁸³ Similar effects have been attributed to the consumption of aspirin by women, and its use during pregnancy should be avoided. Other studies, however, found no untoward effects. The reader is urged to consult the excellent review by Smith for an account of the pharmacological aspects of aspirin.^{163, 164}

Practically all salts of aspirin, except those of aluminum and calcium, are unstable for pharmaceutical use. These salts appear to have fewer undesirable side effects and to induce analgesia faster than aspirin. A timed-release preparation of aspirin is available. It does not appear to offer any advantages over aspirin, except for bedtime dosage.

Aspirin is used as an antipyretic, analgesic, and antirheumatic, usually in powder, capsule, suppository, or tablet form. Its use in rheumatism has been reviewed, and it is reportedly the drug of choice over all other salicylate derivatives.^{184, 185} There is some anesthetic action when applied locally, especially in powder form in tonsillitis or pharyngitis, and in ointment form for skin itching and certain skin diseases. In the usual dose, 52 to 75% is excreted in the urine, in various forms, in a period of 15 to 30 hours. Analgesia is believed to be due to the unhydrolyzed acetylsalicylic acid molecule.¹⁶³⁻¹⁶⁵

A low-dosage form of aspirin, 81 mg, equivalent to the dose recommended for infants (the "baby aspirin"), is recommended as a daily dose for individuals who are at even a low cardiovascular risk. Several large studies found that this low dose of aspirin reduces the number of heart attacks and thrombotic strokes. Other salicylates and NSAIDs have not shown similar effects. In fact, the NSAIDs can interfere with aspirin's cardiovascular benefits, and they should not be taken within 12 hours of each other.

Salsalate. Salsalate, salicylsalicylic acid (Amigesic, Disalacid, etc.), is the ester formed between two salicylic acid molecules to which it is hydrolyzed following absorption. It reportedly causes less gastric upset than aspirin because it is relatively insoluble in the stomach and is not absorbed until it reaches the small intestine. Limited clinical trials¹⁸⁶⁻¹⁸⁸ suggest that it is as effective as aspirin and that it may have fewer side effects.¹⁸⁹ The recommended dose is 325 to 1,000 mg 2 or 3 times a day. It is available only on prescription.

Diffunisal. Over the years, several hundred analogues of aspirin have been made and tested to produce a compound that was more potent, was longer acting, and had less gastric irritation. By the introduction of a hydrophobic group in the 5 position, diffunisal, 5-(2,4-difluorophenyl)salicylic acid, 2',4'-difluoro-4-hydroxy-3-biphenylcarboxylic acid (Dolobid), appears to meet these criteria. In animal tests, it is at least 4 times more potent. In humans, it appears to be about twice as effective, with twice the duration.¹⁹⁰ Like other aryl acids, it is highly bound to plasma protein as its deacylated metabolite. It is marketed in tablets (250 and 500 mg) for treating mild-to-moderate pain and RA and OA.

N-Arylanthranilic Acids

One of the early advances in the search for nonnarcotic analgesics was centered in the *N*-arylanthranilic acids. Their outstanding characteristic is that they are primarily NSAIDs, and secondarily, some possess analgesic properties.

Mefenamic Acid. Mefenamic acid, *N*-2,3-xylylanthranilic acid (Ponstel), occurs as an off-white crystalline powder that is insoluble in water and slightly soluble in alcohol. It appears to be the first genuine antiphlogistic analgesic discovered since aminopyrine. Because it is believed that aspirin and aminopyrine owe their general purpose analgesic efficacy to a combination of peripheral and central effects,¹⁹¹ a wide variety of arylanthranilic acids were screened for antinociceptive (analgesic) activity if they showed significant anti-inflammatory action. The combination of both effects is a rarity among these compounds. The mechanism of analgesic action is believed to be related to the ability to block prostaglandin synthetase. No relationship to lipid-plasma distribution, partition coefficient, or pK_a has been noted. The interested reader, however, will find additional information on antibradykinin and anti-UV erythema activities of these compounds, together with speculations on a receptor site, in the literature.¹⁹²

Mefenamic acid in a dose of 250 mg is superior to 600 mg of aspirin as an analgesic, and doubling the dose sharply increases its efficacy.¹⁹³ A study examining this drug relative to gastrointestinal bleeding indicated a lower incidence of this side effect than exhibited by aspirin.¹⁹⁴ Diarrhea, drowsiness, and headache have accompanied its use. The possibility of blood disorders has prompted limitation of its administration to 7 days. It is not recommended for children or during pregnancy. It has been approved for use in the management of primary dysmenorrhea (PD), which is thought to be caused by excessive concentrations of prostaglandins and endoperoxides.

Meclofenamate Sodium. Meclofenamate sodium, sodium *N*-(2,6-dichloro-*m*-tolyl)anthranilate, Meclomen, is

available in 50- and 100-mg capsules for use in the treatment of acute and chronic RA. The most significant side effects are gastrointestinal, including diarrhea.

Arylacetic Acid Derivatives

The arylacetic acid derivative group of agents has received the most intensive attention for new clinical candidates. As a group, they show high analgesic potency in addition to their anti-inflammatory activity.

Indomethacin, USP. Indomethacin, 1-(*p*-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid (Indocin), occurs as a pale-yellow to yellow-tan crystalline powder that is soluble in ethanol and acetone and practically insoluble in water. It is unstable in alkaline solution and sunlight. It shows polymorphism; one form melts at about 155°C, and the other at about 162°C. It may occur as a mixture of both forms with a melting range between these melting points.

Since its introduction in 1965, it has been widely used as an anti-inflammatory analgesic in RA, spondylitis, and OA, and to a lesser extent in gout. Although both its analgesic and anti-inflammatory activities are well established, it appears to be no more effective than aspirin.¹⁹⁵

The most frequent side effects are gastric distress and headache. It has also been associated with peptic ulceration, blood disorders, and possible deaths. The side effects appear to be dose related and sometimes can be minimized by reducing the dose. It is not recommended for use in children because of possible interference with resistance to infection. Like many other acidic compounds, it circulates bound to blood protein, thus requiring caution in the concurrent use of other protein-binding drugs. Indomethacin is recommended only for patients who cannot tolerate aspirin and in place of phenylbutazone in long-term therapy, for which it appears to be less hazardous than corticosteroids or phenylbutazone.

Sulindac, USP. Sulindac, (Z)-5-fluoro-2-methyl-1-[(*p*-(methylsulfinyl)phenyl)methylene]-1*H*-indene-3-acetic acid (Clinoril), occurs as yellow crystals soluble in alkaline but insoluble in acidic solutions. The drug reaches peak blood levels within 2 to 4 hours and undergoes a complicated, reversible metabolism as follows:

The parent sulfinyl has a plasma half-life of 8 hours, and that of the active sulfide metabolite is 16.4 hours. The more polar and inactive sulfoxide is virtually the only form excreted. The long half-life is due to extensive enterohepatic recirculation.¹⁹⁶ Only the sulfide species inhibits prostaglandin synthetase *in vitro*. Although these forms are highly protein bound, the drug does not appear to affect binding of anticoagulants or hypoglycemics. Coadministration of aspirin is contraindicated because it considerably reduces the sulfide blood levels.

Careful monitoring of patients with a history of ulcers is recommended. Gastric bleeding, nausea, diarrhea, dizziness, and other adverse effects have been noted, but with a lower frequency than with aspirin. Sulindac is recommended for RA, OA, and ankylosing spondylitis in a 150- to 200-mg dose, twice daily.^{197, 198} It is available as tablets (150 and 200 mg).

Tolmetin Sodium, USP. Tolmetin sodium, 1-methyl-5-(*p*-toluoyl)pyrrole-2-acetate dihydrate sodium, MeN-2559 (Tolectin), is an arylacetic acid derivative with a pyrrole as the aryl group. This drug is absorbed rapidly, with a relatively short plasma half-life (1 hour). It is recommended for use in the management of acute and chronic RA. It shares similar, but less frequent, adverse effects with aspirin. It does not potentiate coumarin-like drugs nor alter the blood levels of sulfonylureas or insulin. Like other drugs in this class, it inhibits prostaglandin synthetase and lowers PGE blood levels.

Available as tablets (200 and 600 mg) and a capsule (400 mg), a dose of 400 mg 3 times daily, with a maximum of 2,000 mg, is recommended. Clinical trials indicate a usual daily dose of 1,200 mg is comparable in relief to 3.9 g of aspirin and 150 mg of indomethacin per day.¹⁹⁹

Ibuprofen, USP. Ibuprofen, 2-(4-isobutylphenyl)propionic acid (Motrin, Advil, Nuprin), was introduced into clinical

cal practice following extensive clinical trials. It appears to be comparable to aspirin in the treatment of RA, with a lower incidence of side effects.²⁰² It has also been approved for use in PD.

In this series of compounds, potency was enhanced by introduction of the α -methyl group on the acetic acid moiety. The precursor ibufenac (R = H), which was abandoned owing to hepatotoxicity, was less potent. Moreover, the activity resides in the (*S*)-(+) isomer, not only in ibuprofen but throughout the arylacetic acid series. Furthermore, these isomers are the more potent inhibitors of prostaglandin synthetase.¹⁶¹ The recommended dosage is 400 mg. Ibuprofen is also available over-the-counter as 200-mg tablets.

Naproxen, USP. Naproxen, (+)-6-methoxy- α -methyl-2-naphthaleneacetic acid (Anaprox, Naprosyn), occurs as white to off-white crystals that are sparingly soluble in acidic solutions, freely soluble in alkaline solutions, and highly soluble in organic or lipid-like solutions. After oral administration, it is well absorbed, giving peak blood levels in 2 to 4 hours and a half-life of 13 hours. A steady-state blood level is usually achieved after four to five doses. Naproxen is very highly protein bound and displaces must protein-bound drugs. Dosages of these must be adjusted accordingly.

Naproxen is recommended for use in rheumatoid and gouty arthritis. It shows good analgesic activity—400 mg is comparable to 75 to 150 mg of oral meperidine and superior to 65 mg of propoxyphene and 325 mg of aspirin plus 30 mg of codeine. A 220- to 330-mg dose is comparable to 600 mg of aspirin alone. It reportedly produces dizziness, drowsiness, and nausea, with infrequent mention of gastrointestinal tract irritation. Like aspirin, it inhibits prostaglandin synthetase and prolongs blood-clotting time. It is not recommended for pregnant or lactating women or children under 16.²⁰⁴ It is also available over-the-counter as 200-mg tablets (Aleve).

Ibuprofen Calcium, USP. Fenopropfen calcium, α -methyl-3-phenoxybenzeneacetic acid dihydrate calcium (Kalfon), occurs as a white crystalline powder that is slightly soluble in water, soluble in alcohol, and insoluble in benzene. It is rapidly absorbed orally, reaches peak blood levels within 2 hours, and has a short plasma half-life (3 hours). It is highly protein bound like the other arylacetic acids, and caution is needed when it is used concurrently with hydantoin, sulfonamides, and sulfonyleureas. It shares many of the adverse effects common to this group of drugs, with

gastrointestinal bleeding, ulcers, dyspepsia, nausea, sleepiness, and dizziness reported at a lower incidence than with aspirin. It inhibits prostaglandin synthetase.²⁰⁵

Available as capsules (200 and 300 mg) and tablets (600 mg), it is recommended for RA and OA in divided doses 4 times a day for a maximum of 3,200 mg/day. It should be taken at least 30 minutes before or 2 hours after meals. It is not yet recommended for the management of acute flare-ups. Doses of 2.4 g per day are comparable to 3.9 g per day of aspirin in arthritis. For pain relief, 400 mg gave results similar to 650 mg of aspirin.²⁰⁶

Ketoprofen. Ketoprofen, 3-benzoyl- α -methylbenzeneacetic acid, *m*-benzoylhydratropic acid (Orudis), is closely related to fenopropfen in structure, properties, and indications. It has a low incidence of side effects and has been approved for over-the-counter sale (Orudis KT, Actron). It is available as capsules and tablets (25 and 50 mg), with a recommended daily dose of 150 to 300 mg divided into three or four doses. It is also available as extended-release capsules (100, 150, and 200 mg).

Flurbiprofen, USP. Flurbiprofen, (\pm)-2-(2-fluoro-4-biphenyl)propionic acid (Ansaid, Ocufen), is another hydrotropic acid analogue that is used in the acute or long-term management of RA and OA. It is available as tablets (50 and 100 mg), with a recommended dose of 200 to 300 mg divided into 2, 3, or 4 times daily.

Diclofenac Potassium and Sodium. Diclofenac sodium, sodium [*o*-(2,6-dichloroanilino)phenyl]acetate (Vularen), is indicated for short- and long-term treatment of RA, OA, and ankylosing spondylitis. The potassium salt (Cataflam), which is faster acting, is indicated for the management of acute pain and PD. The sodium salt is available as delayed-release tablets (25, 50, 75, and 100 mg), with a recommended daily dose of 100 to 200 mg in divided doses. The potassium salt is available as a tablet (50 mg), with a recommended dose of 50 mg 3 times daily.

Nabumetone. Nabumetone, 4-(6-methoxy-2-naphthyl)-2-butanone (Relafen), serves as a prodrug to its active metabolite, 6-methoxy-2-naphthylacetic acid. Like the other arylacetic acid drugs, it is used in short- or long-term management of RA and OA. It is available as tablets (500 and 750 mg), with a recommended single daily dose of 1,000 mg.

Ketorolac Tromethamine. Ketorolac tromethamine, (\pm)-benzoyl-2,3-dihydro-1*H*-pyrrolizine-1-carboxylic acid compound with 2-amino-2-(hydroxymethyl)-1,3-propane-

diol (Toradol), is a potent NSAID analgesic indicated for the treatment of moderately severe, acute pain. Because of a number of potential side effects, its administration should not exceed 5 days. Treatment is usually initiated by intravenous (30 mg) or intramuscular (60 mg) administration, with analgesia maintained by initial oral doses of 20 or 30 mg, followed by 10 mg every 4 to 6 hours.

Etodolac. Etodolac, 1,8-diethyl-1,3,4,9-tetrahydropyrano[3,4-*b*]indole-1-acetic acid (Lodine), possesses an indole ring as the aryl portion of this group of NSAID drugs. It shares many of the properties of this group and is indicated for short- and long-term management of pain and OA. It is available as capsules (200 and 300 mg), tablets (400 and 500 mg) and extended-release tablets (400, 500, and 600 mg), with a recommended daily dose of 800- to 1,200-mg in divided doses.

Oxaprozin. Oxaprozin, 4,5-diphenyl-2-oxazolepropionic acid (Daypro), differs from the other members of this group in being an arylpropionic acid derivative. It shares the same properties and side effects of other members in this group. It is indicated for the short- and long-term management of OA and RA, administered as a single 1,200-mg dose. It is available as 600-mg capsules.

Piroxicam, USP. Piroxicam, 4-hydroxy-2-methyl-*N*-2-pyridyl-2*H*-1,2-benzothiazine-3-carboximide 1,1-dioxide (Feldene), represents a class of acidic inhibitors of prostaglandin synthetase, although it does not antagonize PGE₂ directly.²⁰⁷ This drug is very long acting, with a plasma half-life of 50 hours, thus requiring a dose of only 20 to 30 mg once daily. It is reported to give results similar to those from 25 mg of indomethacin or 400 mg of ibuprofen 3 times a day.^{208, 209}

Meloxicam. Like piroxicam in structure, meloxicam, 4-hydroxy-2-methyl-*N*-(5-methyl-2-thiazoyl)-2*H*-1,2-benzothiazine-3-carboxamide 1,1-dioxide (Mobic), is also indicated for use in OA. It also has a relatively long half-life of 15 to 20 hours. Available as a 7.5-mg tablet, the recommended dose is 7.5 mg/day, with a maximum of 15 mg/day.

Celecoxib. The first of the COX-2 inhibitor drugs to be marketed, celecoxib, 4-[5-(4-methylphenyl)-3-(trifluorophenyl)-1*H*-pyrazol-1-yl]benzenesulfonamide (Celebrex), has been approved for use in RA and OA, with a dose of 100 or 200 mg twice a day for RA and 200 mg/day for OA in a single dose of 200 mg or 100 mg twice a day. It has also been approved for reducing the number of adenomatous colorectal polyps in familial adenomatous polyposis (FAP). It is available as 100- and 200-mg tablets.

Rofecoxib. Rofecoxib, 4-[4-(methylsulfinyl)phenyl]-3-phenyl-2(5*H*)-furanone (Vioxx), is a COX-2 inhibitor with greater potency and a longer half-life than celecoxib (17 versus 11 hours). It is approved for use in OA, acute pain, and PD, with a dose of 12.5 mg/day and a maximum of 25 mg/day for OA, and a single dose of 50 mg daily recommended for a maximum of 5 days for acute pain and PD. It is available as tablets (12.5, 25, and 50 mg) and suspensions (12.5 and 25 mg/mL).

Valdecoxib. Introduced in late 2001, the COX-2 inhibitor valdecoxib, 4-[5-methyl-3-phenylisoxazol-4-yl]benzenesulfonamide (Bextra), had the same approved uses as celecoxib and rofecoxib, with a recommended dose of 10 mg/day for RA and OA and 40 mg for PD. It is available as 10- and 20-mg tablets. Several other COX-2 enzyme inhibitors are under investigation and clinical trials, including the highly specific etoricoxib and the parenteral parecoxib.

Aniline and *p*-Aminophenol Derivatives

The introduction of aniline derivatives as analgesics is based on the discovery by Cahn and Hepp, in 1886, that aniline (C-1) and acetanilid (C-2) (Table 22-7) both have powerful antipyretic properties. The origin of this group from aniline has led to their being called "coal tar analgesics." Acetanilid was introduced by these workers because of the known toxicity of aniline itself. Aniline brings about the formation of methemoglobin, a form of hemoglobin that cannot function as an oxygen carrier. The acyl derivatives of aniline were thought to exert their analgesic and antipyretic effects by first being hydrolyzed to aniline and the corresponding acid, after which the aniline was oxidized to *p*-aminophenol (C-3). This is then excreted in combination with glucuronic or sulfuric acid.

The aniline derivatives do not appear to act on the brain cortex; the pain impulse appears to be intercepted at the hypothalamus, wherein also lies the thermoregulatory center of the body. It is not clear if this is the site of their activity because most evidence suggests that they act at peripheral thermoreceptors. They are effective in returning feverish individuals to normal temperature. Normal body temperatures are not affected by the administration of these drugs. Of the antipyretic analgesic group, the aniline derivatives show little if any anti-inflammatory activity.

Table 22-7 shows some of the types of aniline derivatives that have been made and tested in the past. In general, any type of substitution on the amino group that reduces its basicity also lowers its physiological activity. Acylation is one type of substitution that accomplishes this effect. Acetanilid (C-2) itself, although the best of the acylated derivatives, is toxic in large doses, but when administered in analgesic doses, it is probably without significant harm. Formanilid (C-4) is readily hydrolyzed and too irritant. The higher homologues of acetanilid are less soluble and, therefore, less active and less toxic. Those derived from aromatic acids (e.g., C-5) are virtually without analgesic and antipyretic effects. One of these, salicylanilide (C-6), is used as a fungicide and antimildew agent. Exalgin (C-7) is too toxic.

The hydroxylated anilines (*o*, *m*, *p*), better known as the aminophenols, are considerably less toxic than aniline. The *para* compound (C-3) is of particular interest from two

TABLE 22-7 Some Analgesics Related to Aniline

Compound	Structure			Name
	R ₁	R ₂	R ₃	
C-1	—H	—H	—H	Aniline
C-2	—H	—H		Acetanilid
C-3	—OH	—H	—H	<i>p</i> -Aminophenol
C-4	—H	—H		Formanilid
C-5	—H	—H		Benzanilid
C-6	—H	—H		Salicylanilide (not an analgesic, but is an antifungal agent)
C-7	—H	—CH ₃		Exalgin
C-8	—OH	—H		Acetaminophen
C-9	—OCH ₃	—H	—H	Anisidine
C-10	—OC ₂ H ₅	—H	—H	Phenoldine
C-11	—OC ₂ H ₅	—H		Phenacetin
C-12	—OC ₂ H ₅	—H		Lactylphenetidin
C-13	—OC ₂ H ₅	—H		Phenocoll
C-14	—OC ₂ H ₅	—H		Kryoline
C-15		—H		<i>p</i> -Acetoxyacetanilid
C-16		—H		Phenetsal
C-17	—OCH ₂ CH ₂ OH	—H		Portonal

standpoints: namely, it is the metabolic product of aniline, and it is the least toxic of the three possible aminophenols. It also possesses a strong antipyretic and analgesic action. It is too toxic to serve as a drug, however, and therefore, numerous modifications were attempted. One of the first was the acetylation of the amine group to provide *N*-acetyl-*p*-aminophenol (acetaminophen) (C-8), a product that retained a good measure of the desired activities. Another approach to the detoxification of *p*-aminophenol was the etherification of the phenolic group. The best known of these are anisidine (C-9) and phenetidine (C-10), which are the methyl and ethyl ethers, respectively. A free amino group in these compounds however, although promoting a strong antipyretic action, was also conducive to methemoglobin formation. The only exceptions to this were compounds in which a carboxyl group or sulfonic acid group had been substituted on the benzene nucleus. In these compounds, however, the antipyretic effect also had disappeared. These considerations led to the preparation of the alkyl ethers of *N*-acetyl-*p*-aminophenol, of which the ethyl ether was the best and is known as phenacetin (C-11). The methyl and propyl homologues were undesirable from the standpoint of causing emesis, salivation, diuresis, and other reactions. Alkylation of the nitrogen with a methyl group potentiates the analgesic action but, unfortunately, has a highly irritant action on mucous membranes.

The phenacetin molecule has been modified by changing the acyl group on the nitrogen, with sometimes beneficial results. Among these are lactylphenetidin (C-12), phenocoll (C-13), and kryofine (C-14). None of these, however, is in current use.

Changing the ether group of phenacetin to an acyl type of derivative has not always been successful. *p*-Acetoxyacetanilid (C-15) has about the same activity and disadvantages as the free phenol. The salicyl ester (C-16), however, exhibits diminished toxicity and increased antipyretic activity. Pertonal (C-17) is a somewhat different type in which glycol has been used to etherify the phenolic hydroxyl group. It is very similar to phenacetin. None of these is currently on the market.

Relative to the fate in humans of the types of compounds just discussed, Brodie and Axelrod²¹⁰⁻²¹² point out that acetanilid and phenacetin are metabolized by two different routes. Acetanilid is metabolized primarily to *N*-acetyl-*p*-aminophenol and acetaminophen and only a small amount to aniline, which they showed to be the precursor of phenylhydroxylamine, the compound responsible for methemoglobin formation. Phenacetin is mostly deethylated to acetaminophen, whereas a small amount is converted by deacetylation to *p*-phenetidine, also responsible for methemoglobin formation. With both acetanilid and phenacetin, the metabolic acetaminophen is believed to be responsible for the analgesic activity. Because of the toxicity described above, both are no longer available, replaced primarily by acetaminophen.

Acetaminophen, USP. Acetaminophen, *N*-Acetyl-*p*-aminophenol, 4-hydroxyacetanilide, APAP (Panado, Tempra, Tylenol, etc.), may be prepared by reduction of *p*-nitrophenol in glacial acetic acid, acetylation of *p*-aminophenol with acetic anhydride or ketene, or from *p*-hydroxy-acetophenone hydrazone. It occurs as a white, odorless, slightly bitter crystalline powder. It is slightly soluble

in water and ether and is soluble in boiling water (1:20), alcohol (1:10), and sodium hydroxide T.S.

Acetaminophen has analgesic and antipyretic activities comparable to those of acetanilid and is used in the same conditions. It exerts its effects by inhibiting the cyclooxygenase enzyme centrally but has very little effect peripherally. Although it possesses the same toxic effects as acetanilid, they occur less frequently and are less severe; therefore, it is considered safer. Several precautions should be recognized, however, including not to exceed the recommended dosages and the risk of liver toxicity in chronic alcoholics.

It is available in several nonprescription forms and, also, is marketed in combination with aspirin and caffeine (Excedrin, Vanquish).

Pyrazolone and Pyrazolidinedione Derivatives

The simple doubly unsaturated compound containing two nitrogen and three carbon atoms in the ring, with the nitrogen atoms neighboring, is known as *pyrazole*. The reduction products, named as are other rings of five atoms, are pyrazoline and pyrazolidine. Several pyrazoline substitution products are used in medicine. Many of these are derivatives of 5-pyrazolone. Some can be related to 3,5-pyrazolidinedione

Ludwig Knorr, a pupil of Emil Fischer, while searching for antipyretics of the quinoline type, in 1884, discovered the 5-pyrazolone now known as *antipyrine*. This discovery initiated the beginnings of the great German drug industry that dominated the field for about 40 years. Knorr, although at first mistakenly believing that he had a quinoline-type compound, soon recognized his error, and the compound was interpreted correctly as a pyrazolone. Within 2 years, the analgesic properties of this compound became apparent when favorable reports began to appear in the literature, particularly with reference to its use in headaches and neuralgias. Since then, it has retained some of its popularity as an analgesic, although its use as an antipyretic has declined steadily. Since its introduction into medicine, there have been more than 1,000 compounds made in an effort to find others with more potent analgesic action combined with less toxicity. Many modifications of the basic compound have been made. The few derivatives and modifications on the market are listed in Tables 22-8 and 22-9. Phenylbutazone, although analgesic itself, was originally developed as a solubilizer for the insoluble aminopyrine. It is now being used for the relief of many forms of arthritis, in which capacity it also reduces swelling and spasm by an anti-inflammatory action.

TABLE 22-8 Derivatives of 5-Pyrazole

Compound Proprietary Name	Structure			
	R ₁	R ₂	R ₃	R ₄
Antipyrine Phenazone	—C ₆ H ₅	—CH ₃	—CH ₃	—H
Aminopyrine Amidopyrine	—C ₆ H ₅	—CH ₃	—CH ₃	—N(CH ₃) ₂
Dioyone Methampyrone	—C ₆ H ₅	—CH ₃	—CH ₃	—NCH ₂ SO ₃ Na CH ₃

Antipyrine, USP. Antipyrine, 2,3-dimethyl-1-phenyl-3-pyrazolin-5-one, phenazone, was one of the first important drugs to be made (1887) synthetically. Antipyrine and many related compounds are prepared by the condensation of hydrazine derivatives with various esters. Antipyrine itself is prepared by the action of ethyl acetoacetate on phenylhydrazine and subsequent methylation.

It consists of colorless, odorless crystals or a white powder, with a slightly bitter taste. It is very soluble in water, alcohol, or chloroform and less so in ether. Its aqueous solution is neutral to litmus paper. It is basic in nature, however, which is due primarily to the nitrogen at position 2.

Locally, antipyrine exerts a paralytic action on the sensory and the motor nerves, resulting in some anesthesia and vasoconstriction, and it also exerts a feeble antiseptic effect. Systemically, it causes results that are very similar to those of acetanilid, although they are usually more rapid. It is readily absorbed after oral administration, circulates freely, and is excreted chiefly by the kidneys without having been changed chemically. Any abnormal temperature is reduced rapidly

by an unknown mechanism, usually attributed to an effect on the serotonin-mediated thermal regulatory center of the nervous system. It has greater anti-inflammatory activity than aspirin, phenylbutazone, and indomethacin. It also lessens perception to pain of certain types, without any alteration in central or motor functions, which differs from the effects of morphine. Very often it produces unpleasant and possibly alarming symptoms, even in small or moderate doses. These are giddiness, drowsiness, cyanosis, great reduction in temperature, coldness in the extremities, tremor, sweating, and morbilliform or erythematous eruptions; very large doses produce asphyxia, epileptic convulsions, and collapse. Treatment for such untoward reactions must be symptomatic. It is probably less likely to produce collapse than acetanilid and is not known to cause the granulocytopenia that sometimes follows aminopyrine.

The great success of antipyrine in its early years led to the introduction of a great many derivatives, especially salts with a variety of acids, but none of these has any advantage over the parent compound. Its use is limited to a combination with benzocaine as an ear drop. Other drugs in this group, which once included aminopyrine, phenylbutazone, and oxypnenbutazone, are no longer marketed. The pharmacology of these and other analogues has been reviewed extensively.^{21,3, 21,4}

Steroid Hormones and Therapeutically Related Compounds

PHILIP J. PROTEAU

Steroid hormones and related products represent one of the most widely used classes of therapeutic agents. These drugs are used primarily in birth control, hormone-replacement therapy (HRT), inflammatory conditions, and cancer treatment. Most of these agents are chemically based on a common structural backbone, the steroid backbone. Although they share a common structural foundation, the variations in the structures provide specificity for the unique molecular targets. Five general groups of steroid hormones are discussed: estrogens, progestins, androgens, glucocorticoids, and mineralocorticoids. The structural bases for the differences in actions and the various therapeutic uses for these compounds are explored. Several review articles and texts provide excellent coverage of the pharmacology and chemistry of steroid hormones.¹⁻³

STEROID NOMENCLATURE, STEREOCHEMISTRY, AND NUMBERING

As shown in Figure 23-1, nearly all steroids are named as derivatives of cholestane, androstane, pregnane, or estrane. The standard system of numbering is illustrated with 5 α -cholestane.

The absolute stereochemistry of the molecule and any substituents is shown with solid (β) and dashed (α) bonds. Most carbons have one β bond and one α bond, with the β bond lying closer to the "top" or C18 and C19 methyl side of the molecule. Both α and β substituents may be axial or equatorial. This system of designating stereochemistry can best be illustrated by use of 5 α -androstane (Fig. 23-2).

Numbering and Primary Steroid Names

Examples of Common and Systematic Names

Figure 23-1 ■ Steroid nomenclature and numbering.

5 α -Androstane5 β -Androstane5 α ,8 α -Androstane

Figure 23-2 ■ Steroid nomenclature—stereochemistry.

The stereochemistry of the H at C5 is always indicated in the name. The stereochemistry of the other H atoms is not indicated unless it differs from 5 α -cholestane. Changing the stereochemistry of any of the ring juncture or backbone carbons (shown in Fig. 23-1 with a heavy line on 5 α -cholestane) greatly changes the shape of the steroid, as seen in the examples of 5 α ,8 α -androstane and 5 β -androstane (Fig. 23-2).

Because of the immense effect that "backbone" stereochemistry has on the shape of the molecule, the International Union of Pure and Applied Chemistry (IUPAC) rules⁴ strongly recommend that the stereochemistry at all backbone carbons be clearly shown. That is, all hydrogens along the backbone should be drawn. When the stereochemistry is not known, a wavy line is used in the drawing, and the Greek letter xi (ξ) is used in the name instead of α or β . Methyls are explicitly indicated as CH₃.

The terms *cis* and *trans* are occasionally used in steroid

5 α -Androst-8(14)-ene or 5 α - $\Delta^{8(14)}$ -Androstene

Figure 23-3 ■ Steroid nomenclature—double bonds.

5 α -Androstane

Figure 23-4 ■ Alternative representations of steroids.

nomenclature to indicate the backbone stereochemistry between rings. For example, 5 α steroids are A/B *trans*, and 5 β steroids are A/B *cis*. The terms *syn* and *anti* are used analogously to *trans* and *cis* for indicating stereochemistry in bonds connecting rings (e.g., the C9:C10 bond that connects rings A and C). The use of these terms is indicated in Figure 23-2.

The position of double bonds can be designated in any of the various ways shown below. Double bonds from C8 may go toward C9 or C14, and those from C20 may go toward C21 or C22. In such cases, both carbons are indicated in the name if the double bond is not between sequentially numbered carbons (e.g., 5 α -androst-8(14)-ene or 5 α - $\Delta^{8(14)}$ -androstene; see Fig. 23-3). These principles of modern steroid nomenclature are applied to naming several common steroid drugs shown in Figure 23-1.

Such common names as *testosterone* and *cortisone* are obviously much easier to use than the long systematic names. Substituents must always have their position and stereochemistry clearly indicated, however, when common names are used (e.g., 17 α -methyltestosterone, 9 α -fluorocortisone).

Steroid drawings sometimes appear with lines drawn instead of methyls (CH₃), and backbone stereochemistry is not indicated unless it differs from that of 5 α -androstane (Fig. 23-4). This manner of representation should only be used when there is no ambiguity in the implied stereochemistry.

STEROID BIOSYNTHESIS

Steroid hormones in mammals are biosynthesized from cholesterol, which in turn is made *in vivo* from acetyl-coenzyme A (acetyl-CoA) via the mevalonate pathway. Although humans do obtain approximately 300 mg of cholesterol per day in their diets, a greater amount (about 1 g) is biosynthesized per day. A schematic outline of these biosynthetic pathways is shown in Figure 23-5.

Conversion of cholesterol to pregnenolone is the rate-limiting step in steroid hormone biosynthesis. It is not the enzymatic transformation itself that is rate limiting, however; the translocation of cholesterol to the inner mitochondrial membrane of steroid-synthesizing cells is rate limiting.⁵ A key protein involved in the translocation is the *Steroidogenic*

Figure 23-5 ■ Outline of the biosynthesis of steroid hormones. **3β-HSD**, 3β-hydroxysteroid dehydrogenase/ $\Delta^{5,4}$ isomerase; **17β-HSD**, 17β-hydroxysteroid dehydrogenase.

Acute Regulatory protein (StAR). Defects in the StAR gene lead to congenital lipoid adrenal hyperplasia, a rare condition marked by a deficiency of adrenal and gonadal steroid hormones.⁶ The enzymes involved in the transformation of cholesterol to the hormones are mainly cytochromes P-450 and dehydrogenases. The main routes of biosynthesis of the hormones are depicted in Figure 23-5. Estradiol, testosterone, progesterone, aldosterone, and hydrocortisone are representatives of the distinct steroid receptor ligands that are shown. Further metabolic fates of these compounds are presented under the specific structural class.

An enzyme denoted cytochrome P-450_{sc} (SCC for side chain cleavage) mediates the cleavage of the C17 side chain on the D ring of the steroid to provide pregnenolone, the C21

precursor of the steroids. This enzyme mediates a three-step process involved in the oxidative metabolism of the side chain. Successive hydroxylations at C20 and C22 are followed by oxidative cleavage of the C20–C22 bond, providing pregnenolone. Pregnenolone can be either directly converted into progesterone or modified for synthesis of glucocorticoids, estrogens, and androgens. Introduction of unsaturation into the A ring leads to the formation of progesterone. Specifically, oxidation of the alcohol at C3 to the ketone provides a substrate in which isomerization of the $\Delta^{5,6}$ double bond to the $\Delta^{4,5}$ double bond is facilitated. This transformation is mediated by a bifunctional enzyme, **3β-hydroxysteroid dehydrogenase/ $\Delta^{5,4}$ isomerase (3β-HSD)**. This enzyme can act on several 3-ol-5-ene steroids in addi-

tion to pregnenolone. Hydroxylation at C17 provides the precursor for both sex steroid hormones and glucocorticoids. Cytochrome P-450c17 hydroxylates pregnenolone and progesterone to provide the corresponding 17 α -hydroxylated compounds. 17 α -Hydroxypregnenolone can be converted to 17 α -hydroxyprogesterone by 3 β -HSD. Cytochrome P-450c17 is also a bifunctional enzyme, with lyase activity in addition to the hydroxylase action. The C17.20 lyase activity is crucial for the formation of the sex hormones. The lyase oxidatively removes the two carbons at C17, providing the C17 ketone. In the case of 17 α -hydroxypregnenolone, the product is dehydroepiandrosterone (DHEA). If 17 α -hydroxyprogesterone is the substrate for the lyase, androstenedione results. The conversion of 17 α -hydroxyprogesterone to androstenedione is limited in humans, although in other species this is an important pathway. DHEA is converted to androstenedione by the action of 3 β -HSD. Androstenedione can either be converted to testosterone by the action of 17 β -hydroxysteroid dehydrogenase (17 β -HSD) or be transformed into estrone by aromatase, a unique cytochrome P-450 that aromatizes the A ring of certain steroid precursors. Testosterone is aromatized to 17 β -estradiol by the same enzyme. 17 β -HSD acts on estrone to form 17 β -estradiol. If testosterone is acted on by 5 α -reductase, 5 α -dihydrotestosterone (DHT), an androgen important in the prostate is produced.

The major route to glucocorticoids diverges at 17 α -hydroxypregnenolone. Instead of oxidative cleavage at C17, 3 β -HSD acts on this substrate to provide 17 α -hydroxyprogesterone. Small amounts of 17 α -hydroxyprogesterone can be produced directly from progesterone, although this is not a major pathway in humans. Sequential action of 21-hydroxylase (Cyp21) and 11 β -hydroxylase (Cyp11B1) provide hydrocortisone, the key glucocorticoid in humans.

If progesterone is directly acted on by 21-hydroxylase (Cyp21), 11-deoxycorticosterone is produced, a precursor to the mineralocorticoid aldosterone. In tissues where aldosterone is synthesized, the multifunctional enzyme aldosterone synthase (Cyp11B2) mediates the hydroxylation at C11 as well as the two-step oxidation of C18 to an aldehyde, providing aldosterone, which exists predominantly in the cyclic hemiacetal form.

CHEMICAL AND PHYSICAL PROPERTIES OF STEROIDS

With few exceptions, the steroids are white crystalline solids. They may be in the form of needles, leaflets, platelets, or amorphous particles, depending on the particular compound, the solvent used in crystallization, and the skill and luck of the chemist. As the steroids have 17 or more carbon atoms, it is not surprising that they tend to be water insoluble. Addition of hydroxyl or other polar groups (or decreasing carbons) increases water solubility slightly, as expected. Salts are the most water soluble. Examples are shown in Table 23-1.

CHANGES TO MODIFY PHARMACOKINETIC PROPERTIES OF STEROIDS

As with many other compounds described in previous chapters, the steroids can be made more lipid soluble or more

TABLE 23-1 Solubilities of Steroids

	Solubility (g/100 mL)		
	CHCl ₃	EtOH	H ₂ O
Cholesterol	22	1.2	Insoluble
Testosterone	50	15	Insoluble
Testosterone propionate	45	25	Insoluble
Dehydrocholic acid	90	0.33	0.02
Estradiol	1.0	10	Insoluble
Estradiol benzoate	0.8	8	Insoluble
Betamethasone	0.1	2	Insoluble
Betamethasone acetate	10	3	Insoluble
Betamethasone NaPO ₄ salt	Insoluble	15	50
Hydrocortisone	0.5	2.5	0.01
Hydrocortisone acetate	1.0	0.4	Insoluble
Hydrocortisone NaPO ₄ salt	Insoluble	1.0	75
Prednisolone	0.4	3	0.01
Prednisolone acetate	1.0	0.7	Insoluble
Prednisolone NaPO ₄ salt	0.8	13	25

water soluble by making suitable ester derivatives of hydroxyl groups. Derivatives with increased lipid solubility are often made to decrease the rate of release of the drug from intramuscular injection sites (i.e., in depot preparations). More lipid-soluble derivatives also have improved skin absorption properties and thus are preferred for dermatological preparations. Derivatives with increased water solubility are needed for intravenous preparations. Since hydrolyzing enzymes are found throughout mammalian cells, especially in the liver, converting hydroxyl groups to esters does not significantly modify the activity of most compounds.

Some steroids (e.g., estradiol, progesterone, and testosterone) are particularly susceptible to rapid metabolism after absorption or rapid inactivation in the gastrointestinal tract before absorption. These inactivation processes limit the effectiveness of these hormones as orally available drugs, although micronized forms of estradiol and progesterone are available for oral administration. Sometimes, a simple chemical modification can decrease the rate of inactivation and, thereby, increase the drug's half-life or make it possible to be taken orally.

Examples of common chemical modifications are illustrated in Figure 23-6. Drugs such as testosterone cyclopentylpropionate (cypionate) and methylprednisolone sodium succinate are *prodrugs* that require hydrolysis to release the active hormone in the body.

STEROID HORMONE RECEPTORS

Steroid hormones regulate tissue-specific gene expression. The individual hormones exhibit remarkable tissue selectivity, even though their structural differences are relatively minor. Estrogens such as estradiol increase uterine cell proliferation, for example, but not prostate cell proliferation

1. Increase Lipid Solubility (Slower rate of release for depot preparation; increase skin absorption)2. Increase Water Solubility (Suitable for IV use)3. Decrease Inactivation

Figure 23–6 ■ Common steroid modifications to alter therapeutic utility. *, prodrug.

Androgens such as testosterone do the reverse, but neither androgens nor estrogens affect stomach epithelium. The basis for this selectivity is the presence of selective steroid hormone receptors in individual tissues. This section provides an overview of steroid hormone receptors and their mode of action.^{1, 2}

The steroid receptors themselves are key players in gene expression, but many other proteins are involved in this process. Chaperone proteins, for example, help fold the receptor proteins into the proper three-dimensional shape for binding

the steroid ligand. Together, the steroid hormone receptor and associated proteins (Fig. 23-7) make up the mature receptor complex. Once the ligand is bound to the receptor, the chaperone proteins dissociate, and the receptors dimerize and are posttranslationally modified, typically by phosphorylation. Some of the steroid receptor–ligand complexes must be transported into the nucleus prior to interaction with DNA. The activated receptor–ligand complex binds to target DNA, and various coactivators or corepressors are recruited to the DNA–receptor complex. Transcription (or repression

Figure 23-7 ■ Generic structural model of a steroid hormone-receptor complex and its activation for gene transcription. *AT*, histone acetyltransferase; *CA*, coactivator; *CC*, co-chaperone; *HSP*, heat shock protein; *SHR*, steroid hormone receptor

of transcription) occurs when all of the necessary associated proteins have been recruited to the DNA-receptor complex.

Structure of Steroid Hormone Receptors

The complementary DNAs (cDNAs) of all the major steroid hormone receptors have been cloned, giving the complete amino acid sequence of each. Although the whole three-dimensional structure of a steroid hormone receptor has not been solved (structures of the ligand-binding domains of the estrogen, androgen, and progesterone receptors have been elucidated; see below in this section), the functional role of each part is well known (see Fig. 23-8).⁷ The organization of the domains for all types of steroid hormone receptors is

Figure 23-8 ■ Functional domains of the steroid hormone receptors. *AR*, androgen receptor; *ER*, estrogen receptor; *GR*, glucocorticoid receptor; *MR*, mineralocorticoid receptor; and *PR*, progesterone receptor.

the same, but the number of amino acids for each receptor varies:

1. *N-terminal ("A/B") domain*. Once the steroid receptor complex has bound to the target gene(s), this domain (also called the *A/B modulator domain*) activates the hormone response element adjacent to the genes. The hormone response elements are on the DNA adjacent to the target gene. They contain about 12 to 18 base-pair DNA sequences and consist of two "half sites" that are separated by a variable spacer. In the nucleus, steroid hormone receptor complexes exist as dimers; the dimeric structure allows access to both half sites. The nucleotide sequence and spacing between the half sites are essential for the specificity of the various steroid hormone complexes. After the dimer binds and all accessory proteins have been recruited to the receptor-DNA complex, transcription is initiated.
2. *DNA-binding ("C") domain*. This short section is made up of about 65 amino acids, organized into two zinc finger motifs. It is important for recognition and binding to the DNA response elements. The zinc fingers are also responsible for dimerization of the receptor.
3. *Hinge ("D") domain*. This variable linker region appears to be involved with nuclear localization and transport (translocation of the steroid-receptor complex into the nucleus).
4. *C-terminal "ligand-binding" ("E") domain (LBD)*. The C-terminal domain includes about 250 amino acids. This section contains the steroid hormone-binding site and is also involved with ligand-dependent transcriptional activation, receptor dimerization, and nuclear localization.

tion, binding to chaperone proteins (discussed below), and, in some cases, repressing ("silencing") particular genes.

Structure of Steroid Hormone Receptor Complexes

Steroid hormone receptor complexes include the steroid hormone receptor as well as other proteins, predominantly chaperone (heat shock) proteins, cochaperones, and immunophilins (Fig. 23-7).^{8,9} Their role is to "chaperone" the correct conformation and folding of complex proteins, which is otherwise much more difficult as temperatures increase. At normal physiological temperatures, the chaperone proteins assist the proper folding of large proteins such as steroid hormone receptors. The individual components vary depending on the type of steroid hormone receptor. Without the chaperones, the steroid hormone-binding site on the receptor does not have the proper folding and conformation for optimal steroid binding.

Once the steroid hormone binds to the receptor, a conformational change of the receptor occurs, and the mature receptor complex dissociates (Fig. 23-7). The receptor is dimerized, phosphorylated, and transported into the nucleus, if necessary. There, the zinc fingers on the steroid hormone receptor bind to the target gene(s) in the DNA. Additional proteins are recruited to the receptor-DNA complex prior to initiation or repression of transcription.¹⁰ These additional proteins include coactivators or corepressors and histone acetyltransferases. Typically, the receptor-DNA-coactivator complex displays histone acetyltransferase action, which relaxes the chromatin structure, allowing binding of RNA polymerase II and the subsequent initiation of transcription. If corepressors are recruited to the complex, deacetylation of the histone complex is facilitated, preventing transcription.

X-RAY CRYSTALLOGRAPHY AND STEROID FIT AT THE RECEPTOR

As mentioned above, x-ray structures have been solved for the ligand-binding domains of several of the steroid hormone receptors. The structures for the ligand-binding domains for the estrogen receptors α and β ,¹¹⁻¹³ the progesterone receptor,¹⁴ and the androgen receptor¹⁵ have all been determined. Homology modeling structures for the glucocorticoid and mineralocorticoid receptors have been created based on the progesterone structure.^{16,17}

The x-ray crystal structures of the estrogen, progesterone, and androgen receptors have revealed a key difference that leads to the unique ligand specificity of the estrogen receptors.^{12,18} In the region of the ligand-binding domain, where the A ring of steroids binds, are key residues that bind to either the phenolic A ring of estrogens or the enone A ring of progesterone or testosterone. In the case of the estrogen receptor, glutamate and arginine residues are important in a hydrogen-bonding network that involves the phenolic hydroxyl. In contrast to this structural arrangement, the progesterone and androgen receptors have glutamine and arginine residues that hydrogen bond to the A-ring enones of progesterone and testosterone. The change from glutamate, a hydrogen-bond acceptor, to glutamine, a hydrogen-bond donor, is critical for the discrimination between estrogens and other steroid hormones.

The x-ray crystal structures of the steroid hormones them-

selves have also provided important information. Although the conformations of rigid molecules in crystals and their preferred conformations in solution with receptors can differ, it is now clear from x-ray crystallography studies of steroids, prostaglandins, thyroid compounds, and many other drug classes that this technique can be a powerful tool in understanding drug action and in designing new drugs.¹⁹⁻²¹ The relationship is straightforward: Steroid drugs usually do not have a charge and, as a result, are held to their receptors by relatively weak forces of attraction. The same is true for steroid molecules as they "pack" into crystals. In both events, the binding energy is too small to hold any but low-energy conformations. In short, the steroid conformation observed in steroid crystals often is the same or very similar to that at the receptor.

ESTROGEN RECEPTORS

There are two distinct estrogen receptors (ERs), estrogen receptor α (ER $_{\alpha}$) and estrogen receptor β (ER $_{\beta}$), which are encoded by different genes.²² The ERs have distinct tissue distributions and can have distinct actions on the target genes. ER $_{\alpha}$ can be found in high abundance in the uterus, vagina, and ovaries, as well as in the breast, the hypothalamus, endothelial cells, and vascular smooth muscle. ER $_{\beta}$ is found in greatest abundance in the ovaries and the prostate, with reduced occurrence in the lungs, brain, and vasculature.²³ Although many ligands bind with similar affinities to both receptor subtypes, some ligands are selective for one or the other receptor.²⁴⁻²⁶ ERs have received extensive investigation, to date, and although much has been learned about how the ERs function when bound to agonists or antagonists, new insights are continually being gained.²⁶⁻³⁰

PROGESTERONE RECEPTORS

The progesterone receptor can also be found in two forms, but these are derived from a single gene. PR $_{A}$ has had 164 amino acids truncated from the N terminus of PR $_{B}$, providing a receptor that has different interactions with target genes and associated proteins. PR $_{B}$ mainly mediates the stimulatory actions of progesterone. PR $_{A}$ acts as a transcriptional inhibitor of estrogen, androgen, glucocorticoid, mineralocorticoid, and PR $_{B}$ receptors.³¹ These differential actions are believed to be due to interactions with different coactivators and corepressors. The DNA- and ligand-binding domains for the two receptors are identical.

ANDROGEN, GLUCOCORTICOID, AND MINERALOCORTICOID RECEPTORS

The androgen, glucocorticoid, and mineralocorticoid receptors are present in only a single form. Only one gene and one protein are known for each receptor. Mutant forms of the androgen³¹ and glucocorticoid³² receptors are known, and evidence is mounting that some of these mutant receptors are associated with disease states.

GnRH AND GONADOTROPINS

The gonadotropins are peptides that have a close functional relationship to the estrogens, progesterone, and testosterone.

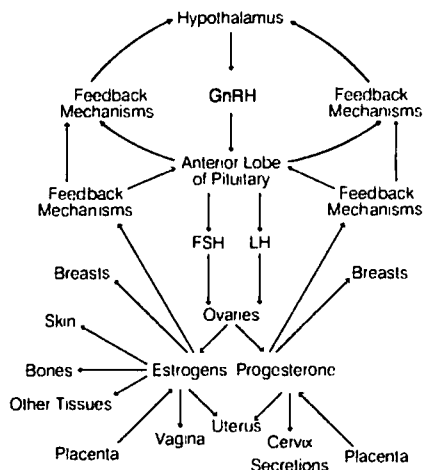

Figure 23-9 ■ Regulation of ovulation by GnRH.

They are called *gonadotropins* because of their actions on the gonads. As shown in Figures 23-9 through 23-11, they control ovulation, spermatogenesis, and development of sex organs, and they maintain pregnancy. An additional peptide, gonadotropin-releasing hormone (GnRH), regulates release of the gonadotropins. Included in this group are the following:

- Gonadotropin-releasing hormone (GnRH)
- Luteinizing hormone (LH)
- Follicle-stimulating hormone (FSH)
- Chorionic gonadotropin (CG; hCG is human gonadotropin), a glycoprotein produced by the placenta; its pharmacological actions are essentially the same as those of LH

GnRH

The hypothalamus releases GnRH, a peptide that stimulates the anterior pituitary to secrete LH and FSH in males and females. This peptide controls and regulates both male and female reproduction (Figs. 23-9 and 23-10). GnRH is a modified

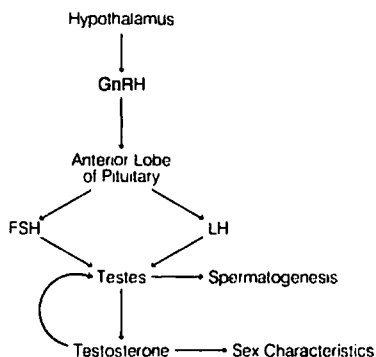

Figure 23-10 ■ Regulation of spermatogenesis.

ified decapeptide (10 amino acids): PyroGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH₂. The pyroglutamate at the N terminus and the C-terminal amide distinguish this peptide from unmodified decapeptides. Analogues of GnRH that are used therapeutically are covered in Chapter 25.

Pituitary Gonadotropins: LH and FSH

The pituitary gonadotropins LH and FSH, their structures, genes, receptors, biological roles, and their regulation (including by negative feedback actions of steroid hormones) have been studied intensively.^{31, 34} FSH, LH, and CG are all glycoprotein dimers with the same α subunit but different β subunits.

In females, LH and FSH regulate the menstrual cycle (see Figs. 23-9 and 23-11). At the start of the cycle, plasma concentrations of estradiol and other estrogens (Fig. 23-11) and progesterone are low. FSH and LH stimulate several ovarian follicles to enlarge and begin developing more rapidly than others. After a few days, only one follicle continues developing to the release of a mature ovum. The granulosa cells of the maturing follicles begin secreting estrogens, which then cause the uterine endometrium to thicken. Vaginal and cervical secretions increase. Gonadotropins and estrogen reach their maximum plasma concentrations at about day 14 of the cycle. The release in LH causes the follicle to break open, releasing a mature ovum. Under the stimulation of LH, the follicle changes into the corpus luteum, which begins secreting progesterone as well as estrogen.

The increased concentrations of estrogens and progesterone regulate the hypothalamus and the anterior pituitary by a feedback inhibition process that decreases GnRH, LH, and FSH production. The result is that further ovulation is inhibited. As described below in this chapter, this is the primary mechanism by which steroid birth control products inhibit ovulation.

If fertilization does not occur by about day 25, the corpus luteum begins to degenerate, slowing down its production of

Figure 23-11 ■ Hormone changes in the normal menstrual cycle.

hormones. The concentrations of estrogens and progesterone become too low to maintain the vascularization of the endometrium, and menstruation results.

The pharmacological actions of hCG are essentially the same as those of LH. In females during pregnancy, the hCG secreted by the placenta maintains the corpus luteum to continue secretion of estrogen and progesterone, thus inhibiting ovulation and menstruation.

In males (Fig. 23-10), LH stimulates testosterone synthesis by the testes, and together, testosterone and LH promote spermatogenesis (sperm production) and development of the testes. Testosterone is also essential for development of secondary sex characteristics in males. FSH stimulates production of proteins and nutrients required for sperm maturation.

SEX HORMONES

Although the estrogens and progesterone are usually called female sex hormones and testosterone is called a male sex hormone, all of these steroids are biosynthesized in both males and females. For example, examination of the biosynthetic pathway in Figure 23-5 reveals that progesterone serves as a biosynthetic precursor to hydrocortisone and aldosterone and, to a lesser extent, to testosterone and the estrogens. Testosterone is one of the precursors of the estrogens. The estrogens and progesterone are produced in much larger amounts in females, however, as is testosterone in males. These hormones play profound roles in reproduction, in the menstrual cycle, and in giving women and men their characteristic physical differences.

Several modified steroidal compounds, as well as some nonsteroidal compounds, have estrogenic activity. A large number of synthetic or semisynthetic steroids with biological activities similar to those of progesterone have been made, and these are commonly called *progestins*. Although the estrogens and progestins have had their most extensive use as chemical contraceptive agents for women and in HRT, their wide spectrum of activity has given them a diversity of therapeutic uses in women as well as a few uses in men.

Testosterone has two primary kinds of activities—*androgenic* (promoting male physical characteristics) and *anabolic* (muscle building). Many synthetic and semisynthetic androgenic and anabolic steroids have been prepared. Despite efforts to prepare selective anabolic agents (e.g., for use in aiding recovery from debilitating illness or surgery), all “anabolic” steroids have androgenic effects. The androgenic agents are mainly used in males, but they do have some therapeutic usefulness in women (e.g., in the palliation of certain sex organ cancers).

In summary, although many sex hormone products have their greatest therapeutic uses in either women or men, nearly all have some uses in both sexes. Nevertheless, the higher concentrations of estrogens and progesterone in women and of testosterone in men cause the development of the complementary reproductive systems and characteristic physical differences of women and men.

Estrogens³⁵

ENDOGENOUS ESTROGENS

The active endogenous estrogens are estradiol, estrone, and estriol. Estradiol provides the greatest estrogenic activity,

with less activity for estrone, and the least activity with estriol. This range of activity parallels the affinity of these estrogens for the ER,³⁶ but the *in vivo* activities of these compounds are also affected by interconversions between active and inactive metabolites.

BIOSYNTHESIS

The estrogens are synthesized by the action of the enzyme aromatase on androstenedione or testosterone (Fig. 23-5). They are normally produced in relatively large quantities in the ovaries and placenta, in lower amounts in the adrenal glands, and in trace quantities in the testes. In postmenopausal women, most estrogens are synthesized in adipose tissue and other nonovarian sites. About 50 to 350 $\mu\text{g/day}$ of estradiol are produced by the ovaries (especially the corpus luteum) during the menstrual cycle. During the first months of pregnancy, the corpus luteum produces larger amounts of estradiol and other estrogens; the placenta produces most of the circulating hormone in late pregnancy. During pregnancy, the estrogen blood levels are up to 1,000 times higher than during the menstrual cycle.

METABOLISM OF ESTROGENS

The metabolism of natural estrogens has been reviewed in detail.³⁷ The three primary estrogens in women are 17 β -estradiol, estrone, and estriol (16 α ,17 β -estriol). Although 17 β -estradiol is produced in the greatest amounts, it is quickly oxidized (see Fig. 23-12) to estrone, the estrogen found in highest concentration in the plasma. Estrone, in turn, is converted to estriol, the major estrogen found in human urine, by hydroxylation at C16 (to provide the 16 α -hydroxyl) and reduction of the C17 ketone (17 β -hydroxyl). Estradiol can also be directly converted to estriol. In the human placenta, the most abundant estrogen synthesized is estriol. In both pregnant and nonpregnant women, however, the three primary estrogens are also metabolized to small amounts of other derivatives (e.g., 2-hydroxyestrone, 2-methoxyestrone, 4-hydroxyestrone, and 16 β -hydroxy-17 β -estradiol). Only about 50% of therapeutically administered estrogens (and their various metabolites) are excreted in the urine during the first 24 hours. The remainder are excreted into the bile and reabsorbed; consequently, several days are required for complete excretion of a given dose.

Conjugation appears to be very important in estrogen transport and metabolism. Although the estrogens are unconjugated in the ovaries, significant amounts of conjugated estrogens may predominate in the plasma and other tissues. Most of the conjugation takes place in the liver. The primary estrogen conjugates found in plasma and urine are glucuronides and sulfates. As sodium salts, they are quite water soluble. The sodium glucuronide of estriol and the sodium sulfate ester of estrone are shown in Figure 23-12.

BIOLOGICAL ACTIVITIES OF ESTROGENS

In addition to having important roles in the menstrual cycle (described above), the estrogens and, to a lesser extent, progesterone are largely responsible for the development of secondary sex characteristics in women at puberty. The estrogens cause a proliferation of the breast ductile system, and progesterone stimulates development of the alveolar system.

Figure 23-12 ■ Metabolites of 17β-estradiol and estrone.

The estrogens also stimulate the development of lipid and other tissues that contribute to breast shape and function. Pituitary hormones and other hormones are also involved. Fluid retention in the breasts during the later stages of the menstrual cycle is a common effect of the estrogens.

The estrogens directly stimulate the growth and development of the vagina, uterus, and fallopian tubes and, in combination with other hormones, play a primary role in sexual arousal and in producing the body contours of the mature woman. Pigmentation of the nipples and genital tissues and growth stimulation of pubic and underarm hair (possibly with the help of small amounts of testosterone) are other results of estrogen action.

The physiological changes at menopause emphasize the important roles of estrogens in the young woman. Breast and reproductive tissues atrophy, the skin loses some of its suppleness, coronary atherosclerosis and gout become potential health problems for the first time, and the bones begin to lose density because of decreased mineral content.

STRUCTURAL CLASSES—ESTROGENS

As shown in Figure 23-13, there are three structural classes of estrogens: steroidal estrogens, diethylstilbestrol and derivatives, and phytoestrogens. (Each class is summarized in the sections that follow.) The steroidal estrogens include the naturally occurring estrogens found in humans and other mammals, as well as semisynthetic derivatives of these com-

pounds. Because of rapid metabolism, estradiol itself has poor oral bioavailability. The addition of a 17α-alkyl group to the estradiol structure blocks oxidation to estrone. Ethinyl estradiol is therefore very effective orally, whereas estradiol itself is not. Most of the therapeutically useful steroidal estrogens are produced semisynthetically from natural precursors such as diosgenin, a plant sterol.

Steroidal Estrogens—Conjugated Estrogens, Esterified Estrogens. Conjugated estrogens (sometimes called equine estrogens) are estradiol-related metabolites originally obtained from the urine of horses, especially pregnant mares. Premarin, the major conjugated estrogen product on the market, is a mixture of numerous components that is still obtained from mare urine. Equine estrogens are largely mixtures of estrone sodium sulfate and equilin sodium sulfate. Little or no equilin and equilinenin are produced in humans. The sulfate groups must be removed metabolically to release the active estrogens. Conjugated estrogens that derive exclusively from plant precursors are also on the market. Esterified estrogens are also mainly a combination of estrone sodium sulfate and equilin sodium sulfate, but in a different ratio than in conjugated estrogens. The esterified estrogens are now prepared exclusively from plant sterols.

Diethylstilbestrol Derivatives. At first glance, it might be surprising that nonsteroidal molecules such as diethylstil-

bestrol (DES) could have the same activity as estradiol or other estrogens. DES can be viewed, however, as a form of estradiol with rings B and C open and a six-carbon ring D. The activity of DES analogues was explained in 1946.³⁸ It was proposed that the distance between the two DES phenol OH groups was the same as the 3-OH to 17-OH distance of estradiol; therefore, they could both fit the same receptor. Modern medicinal chemists have shown the OH-to-OH distance to be actually 12.1 Å in DES and 10.9 Å in estradiol. In aqueous solution, however, estradiol has two water molecules hydrogen-bonded to the 17-OH. If one of the two water molecules is included in the distance measurement, there is a perfect fit with the two OH groups of DES (Fig. 23-14). This suggests that water may have an important role for estradiol in its receptor site. It is now generally accepted that the estrogens must have a phenolic moiety for binding.

but some investigators propose that the receptor may be flexible enough to accommodate varying distances between the two key hydroxyls. This point about estrogens needing a phenolic ring for high-affinity binding to the ER is critical. Steroids with a phenolic A ring and related phenolic compounds lack high-affinity binding to the other steroid hormone receptors.

Thousands of DES analogues were synthesized, and from them emerged many products, including dienestrol and benzoestrol. As long as the OH-to-OH distance relationship is maintained, significant estrogenic activity is usually found in the DES derivative. Without the central double bond and two ethyl or other alkyl groups, the molecule loses all its rigidity and shape, the OH-to-OH distance is not fixed, and activity is abolished. Reduction of the double bond of DES results in two diastereomers of hexestrol. The *meso* form is

active because the OH-to-OH distance is maintained. In the *threo* isomer, however, there is steric repulsion of the two ethyl groups. The two phenol groups rotate to relieve the repulsion, the OH-to-OH distance is changed, and consequently, the *threo* isomer is inactive (Fig. 23-15).

Phytoestrogens. Several natural plant substances that have general structural features similar to those of DES and estradiol also have estrogenic effects and have been termed *phytoestrogens*.³⁹ These include genistein, from soybeans and a species of clover; daidzein, from soybeans; and coumestrol, found in certain legumes. Genistein and daidzein are

examples of isoflavones. These and others have antifertility activity in animals.⁴⁰ Many claims have been made about the beneficial effects of consuming products containing these phytoestrogens, including preventing and treating cardiovascular disease, reducing postmenopausal symptoms, and preventing osteoporosis. Because of the numerous other components present in many of the commercial products as well as a lack of well-designed studies to test the effects of the phytoestrogens themselves, however, positive health effects specifically due to direct hormonal action of the phytoestrogens are uncertain. Questions have also been raised about a possible contribution of phytoestrogens to an increased

Figure 23-14 ■ Computer graphics. Superposition of estradiol (H_2O)₂ (dark lines) with DES (light lines). (Courtesy of Medical Foundation of Buffalo, Inc.)

incidence of breast cancer. These concerns, however, are contradicted by studies that suggest a chemoprotective role for soy products containing phytoestrogens (this could well be due to other components of the mixture). The long history of use of soy products in the world and no global correlations with increased breast cancer risks suggest that any connection between phytoestrogens in general and breast cancer is quite small.⁴¹

Recent studies have demonstrated that genistein (and likely other phytoestrogens) binds preferentially to ER_β over ER_α .⁴² The clinical relevance of this difference in binding is unclear, but it suggests differences between the phytoestrogens and classical estrogens that should be explored.

THERAPEUTIC USES OF ESTROGENS

Birth Control. A major use of estrogens is for inhibition of ovulation, in combination with progestins. Steroidal birth control agents containing estrogens are discussed in the section on chemical contraception later in this chapter.

Figure 23-15 ■ Importance of conformation and rigidity in estrogen activity.

Hormone Replacement Therapy. Another major use of estrogens is in HRT for postmenopausal women. For this use, a progestin is often included to oppose the effects of estrogens on endometrial tissue. HRT is covered in more depth later in the chapter.

Treatment of Estrogen Deficiency From Ovarian Failure or After Oophorectomy. Estrogen therapy, usually with a progestin, is common in cases of ovarian failure and after an oophorectomy.

Treatment of Advanced, Inoperable Breast Cancer in Men and Postmenopausal Women and of Advanced, Inoperable Prostate Cancer in Men. Estrogens are used to treat inoperable breast cancer in men and in postmenopausal women, but estrogen therapy can actually stimulate existing breast cancers in premenopausal women. The selective ER modulator tamoxifen is reported to have fewer side effects; hence, it is usually preferred. Estrogens have also been used to treat inoperable prostate cancer, but GnRH analogues are now generally preferred because of fewer unwanted side effects.

Estrogens and Cancer. Many years of study have firmly established an association between estrogen use and increased risk of breast cancer. The risk is associated, however, with the timing of estrogen exposure, the estrogen dose, the length of use, and the type of estrogen used.⁴³ A patient should discuss the potential risks of breast cancer with her doctor carefully before starting estrogen therapy. Unopposed estrogens in HRT for postmenopausal women are also linked to an increased risk of endometrial carcinoma, which is the basis for inclusion of a progestin in many forms of HRT.⁴⁴

DES Babies. During the late 1930s through the early 1950s, it was believed that DES treatment could help pregnant women who tended to miscarry to have full-term pregnancies. Not only was the belief incorrect, it was subsequently reported that daughters of women who had taken DES during pregnancy ("DES babies") had a high risk of vaginal, cervical, and uterine abnormalities, along with a low risk of vaginal clear cell adenocarcinoma.⁴⁵ Women exposed to DES in utero who developed genital tract problems have a much higher risk of infertility than unexposed women.⁴⁶ A long-term effect on women who were treated with DES during their pregnancies is a slightly higher risk of breast cancer than for women who were not exposed, although no increased risk of ovarian, endometrial, or other cancers was observed.⁴⁷

ESTROGEN PRODUCTS

Estrogens are commercially available in a wide variety of dosage forms: oral tablets, vaginal creams and foams, transdermal patches, and intramuscular dosage preparations.

Estradiol, USP. Estradiol, *estra-1,3,5(10)-triene-3,17β-diol*, is the most active of the natural steroid estrogens. Although its 17β-OH group is vulnerable to bacterial and enzymatic oxidation to estrone (Fig. 23-12), it can be temporarily protected as an ester or permanently protected by adding

a 17 α -alkyl group (giving 17 α -ethinyl estradiol and the 3-methyl ether, mestranol, the most commonly used estrogens in oral contraceptives). The increased oil solubility of the 3- and 17 β -esters (relative to estradiol) permits the esters to remain in oil at the injection site for extended periods. These derivatives illustrate the principles of steroid modification shown in Figure 23-6. Transdermal estradiol products avoid first-pass metabolism, allowing estradiol to be as effective as oral estrogens for treating menopausal symptoms. Estradiol itself is typically not very effective orally because of rapid metabolism, but an oral formulation of micronized estradiol that allows more rapid absorption of the drug is available (Estrace). The commercially available estradiol esters are the following:

Estradiol 3-benzoate, USP
Estradiol 17-valerate, USP
Estradiol 17-cypionate, USP

Estrone, USP. Estrone, 3-hydroxyestra-1,3,5(10)-trien-17-one, is less active than estradiol but more active than its metabolite, estriol. As the salt of its 3-sulfate ester, estrone is the primary ingredient in conjugated estrogens, USP, and esterified estrogens, USP. Although originally obtained from the urine of pregnant mares (about 10 mg/L), estrone is now prepared synthetically.

PIPERAZINE ESTRONE SULFATE (3-SULFOXY-ESTRA-1,3,5(10)-TRIEN-17-ONE PIPERAZINE SALT), USP. All the estrone 3-sulfate salts have the obvious pharmaceutical advantage of increased water solubility and better oral absorption. Acids convert the salts to the free 3-sulfate esters and cause some hydrolysis of the ester. This does not seem to affect absorption adversely, but precipitation of the free sulfate esters in acidic pharmaceutical preparations should be avoided. The dibasic piperazine molecule acts as a buffer, giving it somewhat greater stability.

CONJUGATED ESTROGENS, USP. The term *conjugated estrogens* refers to the mix of sulfate conjugates of estrogenic components isolated from pregnant mare urine (Premarin). These compounds are also referred to as CEE (conjugated equine estrogens). Conjugated estrogens contain 50 to 65% sodium estrone sulfate and 20 to 35% sodium equilin sulfate (based on the total estrogen content of the product). Premarin also contains the sulfate esters of 17 α -estradiol, 17 α -dihydroequilin, and 17 β -dihydroequilin, in addition to other minor components. Although most commonly used in HRT to treat postmenopausal symptoms, the conjugated estrogens are used for the entire range of indications described above, except birth control.

SYNTHETIC CONJUGATED ESTROGENS, A. Cenestin is a mixture of nine estrogenic substances (Fig. 23-13): sodium estrone sulfate, sodium equilin sulfate, sodium equilenin sulfate, sodium 17 α -estradiol sulfate, sodium 17 β -estradiol sulfate, sodium 17 α -dihydroequilin sulfate, sodium 17 β -dihydroequilin sulfate, sodium 17 α -dihydroequilenin sulfate, and sodium 17 β -dihydroequilenin sulfate. These estrogenic substances are synthesized from soy sterols. The term *synthetic* has been added before conjugated estrogens to indicate that

this product is distinct from (not equivalent to) the conjugated estrogens derived from mare urine. The "A" following the name indicates that this is the first approved mixture of synthetic conjugated estrogens. Subsequent synthetic conjugated estrogen products will be named in order, with the final descriptors "B, C, D," etc. Cenestin is approved for the treatment of moderate-to-severe vasomotor symptoms and vulvar and vaginal atrophy associated with menopause.

ESTERIFIED ESTROGENS, USP. Esterified estrogens (Estratab, Menest) contain some of the same sulfate conjugates of estrogens present in conjugated estrogens, but the ratios of these components and the composition of minor components of the products differ. These products contain 75 to 85% sodium estrone sulfate and 6 to 15% sodium equilin sulfate, in such proportion that the total of these 2 components is 90% of the total esterified estrogens content. The esterified estrogens find the same uses as the conjugated estrogens.

Estriol, USP. Estriol, *estra-1,3,5(10)-triene-3,16 α ,17 β -triol*, is available for compounding into a number of different formulations for use in HRT. It can be used alone or in combinations with estradiol (Bi-Est) or with estradiol and estrone (Tri-Est).

Ethinyl Estradiol, USP. 17 α -Ethinyl estradiol has the great advantage over other estradiol products of being orally active. It is equal to estradiol in potency by injection but is 15 to 20 times more active orally. The primary metabolic path for ethinyl estradiol is 2-hydroxylation by cytochrome P-450 isozyme 3A4 (CYP 3A4), followed by conversion to the 2- and 3-methyl ethers by catechol-*O*-methyltransferase. The 3-methyl ether of ethinyl estradiol is mestranol, USP, used in oral contraceptives. Mestranol is a prodrug that is 3-*O*-demethylated to the active ethinyl estradiol. An oral dose of about 50 μ g of mestranol has an estrogenic action approximately equivalent to 35 μ g of oral ethinyl estradiol. The demethylation is mainly mediated by CYP 2C9.⁴⁸

Diethylstilbestrol, USP. Diethylstilbestrol, *α,α -diethyl-(E)-4,4'-stilbenediol*, DES, is the most active of the nonsteroidal estrogens (see under the heading, Structural Classes—Estrogens, above), having about the same activity as estrone when given intramuscularly. The *cis* isomer has only one-tenth the activity of the *trans*. This is mainly due to the improper positioning and distance ($\sim 7\text{\AA}$) between the hydroxyls in the *cis* isomer. The *trans* isomer is well absorbed orally and metabolized slowly and, consequently, was a popular estrogen for many medical purposes, but undesirable side effects have severely limited its use. The diphosphate ester, *diethylstilbestrol diphosphate*, USP, available for intravenous use, is used only for cancer of the prostate. Cardiovascular toxicity including deep vein thrombosis and myocardial infarction limit its use, however.⁴⁹ The diphosphate salt has great water solubility, as one would predict from Table 23-1. Prior to the 1970s, DES was used extensively in low doses as an aid to fatten cattle, but due to a potential link to cancer, it was banned as an additive in animal feed.

Note: All stilbene derivatives, such as DES and dienestrol, are light sensitive and must be kept in light-resistant containers.

Dienestrol, USP. Dienestrol, 4,4'-(1,2-diethylidene-1,2-ethanediyl)bisphenol, is orally active but is only currently available as a topical cream. The cream is used to treat atrophic vaginitis.

SELECTIVE ESTROGEN RECEPTOR MODULATORS AND ANTIESTROGENS

Whereas estrogens have been very important in chemical contraception and HRT, compounds that can antagonize the ER have been of great interest for the treatment of estrogen-dependent breast cancers. Tumor biopsies have shown ER to be present in about 60% of primary breast cancers, and most are responsive to estrogen blockade. Unfortunately, most of these ER-related breast cancers also develop resistance to antiestrogen therapy within 5 years. In contrast, only about 6% of nonmalignant breast tissues have significant ER present. Three compounds that are used clinically for estrogen antagonist action in the treatment of breast cancer are tamoxifen, toremifene, and fulvestrant (Fig. 23-16). Two

additional agents that can antagonize ERs are clomiphene, which is used as an ovulation stimulant, and raloxifene, which is used for the prevention and treatment of osteoporosis.

Tamoxifen and clomiphene were traditionally called *estrogen receptor (ER) antagonists or antiestrogens*. Referring to these compounds as ER antagonists, however, does not accurately portray how these compounds work in vivo. While tamoxifen is an ER antagonist in breast tissue, it has agonist actions on the endometrium, liver, bone, and cardiovascular system. Because of the differential agonist and antagonist effects of these types of compounds on the ER, depending on the specific tissue, a new term was coined: *selective estrogen receptor modulators (SERMs)*. A SERM is a drug that has tissue-specific estrogenic activity. Although many compounds exhibit SERM activity, a few agents are antagonists in all tissues. These compounds are termed *antiestrogens*, and fulvestrant is one example (Fig. 23-16). Tamoxifen and clomiphene are often referred to in older literature as *antiestrogens*.

Figure 23-16 ■ Selective estrogen receptor modulators (SERMs) and antiestrogens.

Tamoxifen has seen extensive use in treating primary breast cancers that are ER dependent.^{50, 51} For premenopausal women with metastatic disease, tamoxifen is an alternative and adjuvant with oophorectomy, ovarian irradiation, and mastectomy. Tamoxifen use, however, is not problem free. Tamoxifen increases the incidence of endometrial polyps, hyperplasia, and carcinoma and uterine sarcomas. The risk of endometrial cancer resulting from tamoxifen is, however, much lower than the "modest but highly significant reductions in morbidity and mortality of breast cancer."⁵² Because of the increased risk of endometrial cancer with tamoxifen therapy, tamoxifen should be used to prevent breast cancer only in women at high risk. Women without a family history of breast cancer or other risks should not use tamoxifen in this manner.

Raloxifene is another SERM, but its profile of activity differs from that of tamoxifen. Raloxifene is an ER antagonist in both breast and endometrial tissue, but has agonist action on bone and acts as an estrogen agonist in lowering total cholesterol and low-density lipoprotein (LDL). The subtle structural differences between the two drugs underlie the distinct activity profiles.⁵³ The agonist action on bone tissue is the basis for the use of this drug for treating osteoporosis.

A key question is why do compounds like tamoxifen and raloxifene exhibit antagonist action in some tissues, but agonist action in other tissues? Major developments in the past few years are beginning to provide the answer to this question.^{11, 26, 27, 54} Tamoxifen,⁵⁵ raloxifene, and estradiol¹¹ all bind to the ER at the same site, but their binding modes are different. In addition, each induces a distinct conformation in the transactivation region of the ligand-binding domain.¹¹ These unique conformations dictate how the receptor–ligand complex will interact with coregulator proteins (coactivators or corepressors).²⁷ In all tissues, the estradiol–ER complex recruits coactivators, so gene transcription is stimulated. In breast tissue, both raloxifene- and tamoxifen-bound receptors prevent the association with coactivators, but rather recruit corepressors, so antagonist action is observed. In uterine tissue, however, the raloxifene–ER complex recruits corepressors, whereas the tamoxifen–ER complex recruits a coactivator, SRC-1, which leads to agonist action.⁵⁴ An additional factor involved in this agonist action of tamoxifen is the context in which the liganded receptor interacts with the target gene. The liganded ER can interact directly with DNA or can interact indirectly by being tethered to other transcription factors. When the tamoxifen-bound receptor interacts in a tethered manner with the target genes in uterine tissue, the SRC-1 coactivator is recruited, and gene transcription is promoted.^{27, 54} A deeper understanding of how the liganded receptors interact with target genes and the mechanisms for recruitment of coregulators may help to explain the phenomenon of tamoxifen resistance, which results from increased tamoxifen agonism in breast tissue.²⁷

Lasofloxifene, bazedoxifene, and arzoxifene are several of the newer SERMs that are in late-stage clinical trials (Fig. 23-16). Lasofloxifene and bazedoxifene are being studied for use in the treatment of osteoporosis, while arzoxifene is being investigated for breast cancer treatment. Structurally, arzoxifene is most similar to raloxifene, with an ether bridge, rather than a carbonyl bridge, attached to the benzothiophene core. Bazedoxifene uses an indole ring system in place of

the benzothiophene of raloxifene. Bazedoxifene was the result of a screening program that selected for compounds that did not stimulate breast or uterine tissue.⁵⁶ Lasofloxifene can be viewed as a constrained, saturated analogue of 4-hydroxy-tamoxifen.

Clomiphene is another drug that exhibits antiestrogen actions, but it is not used for treating breast cancer or osteoporosis; rather, it is used for increasing the odds of a successful pregnancy. Clomiphene's therapeutic application as an ovulation stimulant results from its ability to increase GnRH production by the hypothalamus. The mechanism is presumably a blocking of feedback inhibition of ovary-produced estrogens (via ER antagonism). The hypothalamus and pituitary interpret the false signal that estrogen levels are low and respond by increasing the production of GnRH. The increased GnRH, in turn, leads to increased secretion of LH and FSH, maturation of the ovarian follicle, and ovulation (as described above in this chapter; see Fig. 23-9). Support for the feedback inhibition mechanism is provided by tests with experimental animals in which clomiphene has no effect in the absence of a functioning pituitary gland.

Multiple births occur about 10% of the time with patients taking clomiphene, and birth defects in 2 to 3% of live newborns. Vasomotor "hot flashes" occur about 10% of the time, and abnormal enlargement of the ovaries about 14%. Abdominal discomfort should be discussed immediately with the physician.

SERM AND ANTIESTROGEN PRODUCTS

Tamoxifen Citrate, USP. Tamoxifen, 2-[4-(1,2-diphenyl-1-butenyl)phenoxy]-*N,N*-dimethylethanamine (Nolvadex), is a triphenylethylene SERM used to treat early and advanced breast carcinoma in postmenopausal women. Tamoxifen is used as adjuvant treatment for breast cancer in women following mastectomy and breast irradiation. It reduces the occurrence of contralateral breast cancer in patients receiving adjuvant tamoxifen therapy. It is also effective in the treatment of metastatic breast cancer in both women and men. In premenopausal women with metastatic breast cancer, tamoxifen is an alternative to oophorectomy or ovarian irradiation. Tamoxifen can be used preventatively to reduce the incidence of breast cancer in women at high risk. Antiestrogenic and estrogenic side effects can include hot flashes, nausea, vomiting, platelet reduction, and (in patients with bone metastases) hypercalcemia. Like all triphenylethylene derivatives, it should be protected from light.

The major metabolite of tamoxifen is *N*-desmethyltamoxifen, which reaches steady-state levels higher than tamoxifen itself. It is believed that *N*-desmethyltamoxifen contributes significantly to the overall antiestrogenic effect. Another metabolite, 4-hydroxytamoxifen, is a more potent antiestrogen than tamoxifen, but because it is only a minor metabolite of tamoxifen, it probably does not contribute significantly to the therapeutic effects. 4-Hydroxytamoxifen, with its greater affinity for the ERs, however, has been used extensively in pharmacological studies of these receptors. Tamoxifen concentrations are reduced if coadministered with rifampin, a cytochrome P-450 inducer.

Toremifene Citrate, USP. Toremifene, 2-[4-(1,2-dichloro-1,2-diphenyl-1-butenyl)phenoxy]-*N,N*-dimethyl-

ethanamine (Fareston), differs structurally from tamoxifen only by having a chloroethyl group (rather than an ethyl group) attached to the triphenylethylene structure. As might be expected, the pharmacological actions of toremifene and tamoxifen are quite similar. Toremifene is also a SERM, with estrogen antagonist action in breast tissue but agonist action in the endometrium, on bone tissue, and on serum lipid profiles. Although toremifene appears to carry less risk of causing endometrial cancer than tamoxifen, its limited use in comparison with tamoxifen requires the use of caution in evaluating the safety profile for toremifene.⁵⁷ Toremifene is used in the treatment of metastatic breast cancer in postmenopausal women.

Raloxifene, USP. Raloxifene, [6-hydroxy-2-(4-hydroxyphenyl)benzo[*b*]thien-3-yl][4-[2-(1-piperidinyl)ethoxy]phenyl]methanone (Evista), is a benzothiophene derivative that differs slightly from the triphenylethylene SERMs. A key structural difference is the carbonyl "hinge" that connects the modified phenolic side chain to the benzothiophene ring system. This hinge is the key structural element that leads to the differing actions at the ERs.⁵³ Raloxifene, unlike tamoxifen and toremifene, has antagonist properties on the endometrium and breast tissue and agonist properties on bone and the cardiovascular system. The lack of agonist action on endometrial tissue has been suggested as a reason for the lack of endometrial cancer associated with raloxifene use. Raloxifene is approved for the prevention and treatment of osteoporosis in postmenopausal women and is being studied for the prevention of breast cancer in women at high risk.

Fulvestrant, USP. Fulvestrant, 7 α -[9-(4,4,5,5,5-pentafluoropentyl)sulfinyl]nonyl]estra-1,3,5(10)-triene-3, 17 β -diol (Faslodex), is an antagonist structurally based on the estradiol structure, with a long, substituted alkyl chain attached at the 7 α position of the steroid skeleton. When bound to the ERs, this alkyl chain induces a conformation of the receptor distinctive from that formed upon estradiol or tamoxifen binding, preventing agonist action. Fulvestrant is a pure antagonist at both ER α and ER β , and an ER downregulator (stimulates degradation of the ER), completely lacking the agonist activity that is seen with tamoxifen or raloxifene. The different pharmacological profile of fulvestrant allows the use of this agent in women who have had disease progression after prior antiestrogen therapy (typically tamoxifen), providing an alternative to aromatase inhibitors.⁵⁸

Clomiphene Citrate, USP. Clomiphene citrate, 2-[4-(2-chloro-1,2-diphenylethenyl)phenoxy]-*N,N*-diethylethanamine (Clomid), is used as an ovulation stimulant in women desiring pregnancy. Although early literature refers to clomiphene as an estrogen antagonist, it is more accurately a SERM.⁵⁹ Clomiphene is chemically a mixture of two geometric isomers, zuclomiphene, the *cis* isomer, and enclomiphene, the *trans* isomer. In animal studies, these isomers have different estrogenic actions in different tissues. Zuclomiphene appears to have weak agonist actions on all tissues studied, whereas enclomiphene has antagonist actions on uterine tissue, but agonist action on bone tissue.⁶⁰ The actions of clomiphene in humans are likely a composite of the actions of the two isomers.

Figure 23-17 ■ Conversion of androstenedione to estrone by aromatase

AROMATASE INHIBITORS

Aromatase is a cytochrome P-450 enzyme complex that catalyzes the conversion of androstenedione to estrone and testosterone to estradiol (Figs. 23-5 and 23-17).^{61, 62} The complex is made up of reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome P-450 reductase, and cytochrome P-450 hemoprotein. In the first two steps, the C19 methyl is hydroxylated to CH₂OH, and then to an aldehyde hydrate form that dehydrates to provide the C19 aldehyde. In the final aromatization step, the C19 carbon is oxidatively cleaved to formate. A hydride shift, proton transfer, and free radical pathways have been proposed, with *cis* elimination of the 1 β and 2 β hydrogens.⁶⁴ In premenopausal women, aromatase is primarily found in ovaries, but in postmenopausal women, aromatase is largely in muscle and adipose tissue.

As discussed above with SERMs, some types of breast cancer are estrogen dependent. Because the aromatase reaction is unique in steroid biosynthetic pathways, it would be anticipated that aromatase inhibitors would be very specific in their estrogen biosynthesis blockade. This has proved to be true, and aromatase inhibitors offer a useful approach to decreasing estrogen levels in the treatment of estrogen-dependent breast cancer. Initially, aromatase inhibitors were used as second-line therapy in postmenopausal women who failed on tamoxifen therapy. Recent studies have indicated, however, that the newer aromatase inhibitors can be used as first-line therapy and possibly for cancer prevention in patients at high risk.⁶⁵

Aromatase inhibitors include both steroidal and nonsteroidal compounds. Examples of aromatase inhibitors are shown in Fig. 23-18. The first-generation aromatase inhibitors were aminoglutethimide, a nonsteroidal compound, and the steroid-based testolactone, two compounds that were developed before it was recognized that their effectiveness in breast cancer treatment was due to aromatase inhibition.⁶⁶ Aminoglutethimide also inhibits other P-450s involved in steroid hormone biosynthesis, which limits its use in breast cancer treatment. The newer drugs are more potent and more specific inhibitors of aromatase than the earlier compounds.

In addition to testolactone, two other steroid analogues have been used. A well-studied steroid analogue is 4-hydroxy-

Figure 23-18 ■ Aromatase inhibitors.

androstenedione (4-OHA; formestane; Lentaron), which has been marketed in the United Kingdom since the early 1990s for treatment of breast cancer. Although initially thought to be a completely reversible inhibitor, it is now known that formestane is an enzyme activated irreversible ("suicide") inhibitor of aromatase. A limitation for formestane is lack of oral availability. Exemestane is the latest steroidal aromatase inhibitor. It is another mechanism-based inactivator of aromatase, but it is orally available and is highly selective for aromatase. Both compounds reflect minor structural modifications to the natural substrate, androstenedione.

The nonsteroidal aromatase inhibitors are competitive inhibitors that bind to the enzyme active site by coordinating the iron atom present in the heme group of the P-450 protein. Aside from aminoglutethimide, the first selective aromatase inhibitor to be marketed in the United States was anastrozole (Arimidex). Anastrozole incorporates a triazole ring into its structure that can coordinate to the heme iron. Letrozole is another triazole-containing inhibitor that is also effective in the treatment of breast cancer.

Currently available inhibitors suppress plasma estrogen levels (estradiol, estrone, and estrone sulfate) by 80 to 95%. Earlier aromatase inhibitors, such as aminoglutethimide and testolactone, suppressed plasma estrogens to a lesser extent. The side effects often seen with aminoglutethimide because of additional inhibition of other biosynthetic enzymes are avoided with the newest agents. The selectivity of these drugs for aromatase is quite high.

As with the SERMs, these drugs are only effective when the breast cancer cells are "estrogen receptor (ER) posi-

tive," meaning that they respond and proliferate in the presence of estrogen. Aromatase inhibitors can cause fetal harm in pregnant women and are therefore contraindicated.

Additional nonsteroidal inhibitors are based on the flavone structure. Chrysin is a flavonoid natural product that has aromatase inhibitory action in vitro similar to that of aminoglutethimide.⁶⁷ It is isolated from *Passiflora coerulea* and other plants. While this compound is not used therapeutically as an aromatase inhibitor, it has found questionable use as a nutritional supplement in combination with anabolic steroids to enhance muscle building and athletic performance. The theory for use is that an aromatase inhibitor reduces the estrogenic side effects of androgenic compounds. Although a variety of nutritional supplement products containing chrysin are available, it is unlikely that significant aromatase inhibition is being achieved in vivo. The oral bioavailability of chrysin is very low, mainly because of efficient conversion to the corresponding glucuronide and sulfate conjugates, so the plasma concentration of free chrysin is minimal.⁶⁸

AROMATASE INHIBITOR PRODUCTS

Anastrozole, USP. Anastrozole, $\alpha,\alpha,\alpha',\alpha'$ -tetramethyl-5-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-benzenediacetonitrile, was the first specific aromatase inhibitor approved in the United States. It is indicated for first-line treatment of postmenopausal women with advanced or metastatic breast cancer and for second-line treatment of postmenopausal patients with advanced breast cancer who have had disease progression following tamoxifen therapy. An additional indication

for adjuvant treatment of women with early breast cancer was added in 2002. Patients who did not respond to tamoxifen therapy rarely respond to anastrozole.

Anastrozole reduces serum estradiol approximately 80% after 14 days of daily dosing. Due to an elimination half-life of 50 hours, anastrozole is effective with once-daily dosing (1 mg). Metabolism of anastrozole includes hydroxylation and glucuronidation, as well as N-dealkylation to produce triazole. The metabolites of anastrozole are inactive. Although anastrozole can inhibit CYPs 1A2, 2C9, and 3A4 with K_i values in the low micromolar range, the concentrations of anastrozole reached under standard therapeutic dosing are much lower, so anastrozole should lack significant P-450 interactions.⁶⁹

Letrozole, USP. Letrozole, 4,4'-(1H-1,2,4-triazol-1-yl-methylene)dibenzonitrile (Femara), is used for most of the same indications as anastrozole. It reduces concentrations of estrogens by 75 to 95%, with maximal suppression achieved within 2 to 3 days. Letrozole is specific for aromatase inhibition, with no additional effects on adrenal corticoid biosynthesis. CYPs 3A4 and 2A6 are involved in the metabolism of letrozole to the major carbinol metabolite, which is inactive. The loss of the triazole ring, which is involved in coordination of the heme iron, would explain the loss of activity. Letrozole strongly inhibits CYP 2A6 in vitro, with moderate inhibition of CYP 2C19. The effect of this in vitro inhibition on the pharmacokinetics of coadministered drugs is unknown. Tamoxifen reduces the levels of letrozole significantly if they are used together, so combination treatment with these agents is not recommended.⁷⁰

Exemestane, USP. Exemestane, 6-methylenandrosta-1,4-diene-3,17-dione (Aromasin), is the first steroid-based aromatase inhibitor approved for the treatment of breast cancer in the United States. It is a mechanism-based inactivator that irreversibly inhibits the enzyme. Plasma estrogen levels are reduced by 85 to 95% within 2 to 3 days, and effects last 4 to 5 days. Exemestane does not inhibit any of the major cytochromes P-450 and has essentially no interaction with steroid receptors, with only a very weak affinity for the androgen receptor. The 17 β -hydroxyexemestane reduction product, however, has much higher affinity for the androgen receptor than the parent (still several fold less than DHT, 0.28% for parent versus ~30% for metabolite). The clinical significance of the affinity is likely minimal because of the low levels of the metabolite produced.

Aminoglutethimide, USP. Aminoglutethimide, 3-(4-aminophenyl)-3-ethyl-2,6-piperidinedione, is mainly used to treat Cushing's syndrome, a condition of adrenal steroid excess, a use in which the P-450_{c11} inhibition of this compound is exploited rather than its aromatase inhibition. Aminoglutethimide is a weak inhibitor of aromatase and has been used successfully in the treatment of estrogen-dependent breast cancer. Because of the development of more selective aromatase inhibitors, the use of aminoglutethimide for its ability to inhibit aromatase is not supported.

Testolactone, USP. Testolactone, 13-hydroxy-3-oxo-13,17-secoandrosta-1,4-dien-17-oic acid δ -lactone, was

originally synthesized as a possible anabolic steroid, considering its structural similarity to testosterone. The key structural difference from anabolic steroids is the D-ring lactone instead of the typical cyclopentyl ring. Although considered in many texts an androgen or anabolic steroid (it is a Schedule III drug because of its classification as an anabolic steroid), testolactone lacks androgenic effects in vivo. Its action is believed to be due to irreversible inhibition of aromatase. It is a relatively weak inhibitor of aromatase, but the irreversible nature of the inhibition can lead to prolonged effects. Its relatively weak inhibition of aromatase and its undesirable dosage schedule (5 \times 50-mg tablets q.i.d.) give this older agent only limited use in breast cancer treatment because of better available options.

Formestane. Formestane, 4-hydroxyandrost-4-ene-3,17-dione (Lentaron), was originally believed to be a competitive inhibitor of aromatase, but later studies determined it to be a mechanism-based irreversible inactivator of aromatase. Formestane was the first aromatase inhibitor approved for use in treating breast cancer in Europe, but it is not available in the United States. It lacks oral activity and is used as a once-every-2-weeks injection.

Progestins

ENDOGENOUS PROGESTINS

The key endogenous steroid hormone that acts at the progesterone receptors is progesterone. All other endogenous steroids lack significant progestational action.

BIOSYNTHESIS

Progesterone is produced in the ovaries, testes, and adrenal glands. Much of the progesterone that is synthesized from pregnenolone is immediately converted to other hormonal intermediates and is not secreted. See the biosynthetic pathway (Fig. 23-5). The corpus luteum secretes the most progesterone, 20 to 30 mg/day during the last or "luteal" stage of the menstrual cycle. Normal men secrete about 1 to 5 mg of progesterone daily.

METABOLISM OF PROGESTERONE

Progesterone has a half-life of only about 5 minutes when taken orally, because of rapid metabolism. Progesterone can be transformed to many other steroid hormones (Fig. 23-5) and, in that sense, has numerous metabolic products. The principal excretory product of progesterone metabolism, however, is 5 β -pregnane-3 α ,20 α -diol and its conjugates (Fig. 23-19). The steps that are involved in the formation of this metabolite are reduction of the C4-5 double bond, reduction of the C3 ketone providing the 3 α -ol, and reduction of the C20 ketone. The reduction at C5 must precede the reduction of the C3 ketone, but the timing of the C20 can vary, depending on the tissue.^{71, 72} Structural features that can block reduction at C5 or C20 have greatly increased the half-lives of progesterone derivatives.

BIOLOGICAL ACTIVITIES OF THE PROGESTINS¹

Like the estrogens, progesterone has a variety of pharmacological actions, with the main target tissues being the uterus,

Figure 23-19 ■ Progesterone metabolism (timing of the reduction steps can vary). HSD, hydroxysteroid dehydrogenase.

breast, and brain. Progesterone decreases the frequency of the hypothalamic pulse generator and increases the amplitude of LH pulses released from the pituitary. The actions of progesterone in the uterus include development of the secretory endometrium. When release of progesterone from the corpus luteum at the end of the menstrual cycle declines, menstruation begins. Progesterone also acts to thicken cervical secretions, decreasing cervical penetration by sperm. Progesterone is critical for the maintenance of pregnancy by suppressing menstruation and decreasing uterine contractility. Progesterone has important actions in the breast during pregnancy, acting in conjunction with estrogens to prepare for lactation.

A thermogenic action is also associated with progesterone. During the menstrual cycle, progesterone mediates a slight temperature increase near midcycle and maintains the increased temperature until the onset of menstruation. The exact mechanism for this temperature increase is not known. Progesterone and its metabolites have additional central effects, which are being actively explored.⁷³

STRUCTURAL CLASSES—PROGESTINS

Progestins are compounds with biological activities similar to those of progesterone. They include three structural classes: (a) progesterone and derivatives, (b) testosterone and 19-nortestosterone derivatives, and (c) miscellaneous synthetic progestins (Fig. 23-20). Progesterone itself has low oral bioavailability because of poor absorption and almost complete metabolism in one passage through the liver. A recently available oral formulation is micronized progesterone in gelatin capsules. The micronized drug is much more readily absorbed, allowing oral delivery of progesterone, even though the dose must be much higher than a parenteral dose to compensate for extensive liver metabolism. Adding 17 α -acyl groups slows metabolism of the 20-one, whereas

a 6-methyl group enhances activity and reduces metabolism. Medroxyprogesterone acetate is a particularly potent example (Table 23-2).

Duax and coworkers^{19, 20} have studied the structural requirements of the progesterone receptor in detail. They conclude that the progesterone 4-en-3-one ring A is a key to binding but only when it is in a conformation quite different from that of testosterone or the glucocorticoids. Their reviews contain stereo drawings that show the required conformations in three dimensions. Structural features modifying the steroid D ring are also important for optimal interactions with the progesterone receptor.

Two important discoveries led to the development of the nortestosterone derivatives. One was the discovery that 19-norprogesterone still maintained significant progestational activity. The second was that 17 α -alkynyl testosterone (ethisterone) had greater progestational than androgenic activity. Although the 19-nortestosterones do have androgenic side effects, their primary activity, nevertheless, is progestational. In addition to causing a marked increase in progestational activity, the 17 α -alkynyl group also blocks metabolic or bacterial oxidation to the corresponding 17-ones. Thus, by adding a 17 α -ethinyl group to testosterone, one can simultaneously decrease androgenic activity, promote good progestational activity, and have an orally active compound as well. Table 23-2 illustrates the relative progestational activity of a number of progestins. A further modification to the nortestosterones yields progestins with minimal androgenic activities. Changing the alkyl group at C13 from a methyl to an ethyl group, as in levonorgestrel, reduces the androgenic effects, while maintaining the progestational effects.

THERAPEUTIC USES OF PROGESTINS

Progestin therapy may cause menstrual irregularities, such as spotting or amenorrhea. Weight gain and acne have been associated with testosterone and 19-nortestosterone analogues, in part because of their slight androgenic effects.

TABLE 23-2 Comparative Progestational Activity of Selected Progestins

	Relative Oral Activity	Activity SC
Progesterone	(nil)	1
17 α -Ethinyltestosterone (ethisterone)	1	0.1
17 α -Ethinyl-19-nortestosterone (noretthidrone)	5-10	0.5-1
Norethynodrel	0.5-1	0.05-1
17 α -Hydroxyprogesterone caproate	2-10	4-10
Medroxyprogesterone acetate	12-25	50
19-Norprogesterone		5-10
Norgestrel		3
Dimethisterone	12

Birth Control. A significant use of the progestins, as of the estrogens, is inhibition of ovulation. Steroidal birth control agents are discussed in the following section on chemical contraception.

Reduction of the Risk of Endometrial Cancer From Postmenopausal Estrogens. As discussed in the section on therapeutic uses of estrogens, several studies have suggested that the combination of a progestin with an estrogen may significantly reduce the risk of endometrial cancer in women taking postmenopausal estrogens. Because of this, a progestin is often included in HRT.

Primary and Secondary Amenorrhea and Functional Uterine Bleeding Caused by Insufficient Progesterone Production or Estrogen–Progesterone Imbalance. Progestins have been used very effectively to treat primary and secondary amenorrhea, functional uterine bleeding, and

related menstrual disorders caused by hormonal deficiency or imbalance.

Breast or Endometrial Carcinoma. Progestins can be used for palliative treatment of advanced carcinoma of the breast or endometrium. These agents should not be used in place of surgery, radiation, or chemotherapy.

Progestins for Premenstrual Syndrome (PMS).

There have been claims that progesterone may reduce the effects of PMS. Continued analyses of various studies indicate, however, that progestins are not effective for this use.⁷⁴

PROGESTIN PRODUCTS

The progestins are primarily used in oral contraceptive products and in hormone replacement regimens for women. They are also used to treat several gynecological disorders: dys-

Figure 23-20 ■ Continued.

menorrhea, endometriosis, amenorrhea, and dysfunctional uterine bleeding. Estrogens are given simultaneously in most of these situations.

Progesterone, USP. Progesterone, pregn-4-en-3,20-dione is so rapidly metabolized that it is not particularly effective orally, being only one-twelfth as active as intramuscularly. An oral formulation of micronized progesterone (Prometrium) is available. Progesterone given intramuscularly can be very irritating. A vaginal gel containing 4 or 8% progesterone offers an alternative dosage form. Progesterone was originally obtained from animal ovaries but is now prepared synthetically from plant sterol precursors. The discovery of 19-nortestosterones with progesterone activity made synthetically modified progestins of tremendous therapeutic importance.

Progesterone (and all other steroid 4-ene-3-ones) is light sensitive and should be protected from light.

Hydroxyprogesterone Caproate, USP. Hydroxyprogesterone caproate, 17-hydroxypregn-4-ene-3,20-dione hexanoate, is much more active and longer acting than progesterone (see Table 23-2), probably because the 17 α ester hinders reduction to the 20-ol. In contrast, hydroxyprogesterone itself lacks progestational activity. The caproate ester is given only intramuscularly. The ester greatly increases oil

solubility, allowing it to be slowly released from depot preparations, as one would predict from Figure 23-6.

Medroxyprogesterone Acetate, USP. Medroxyprogesterone acetate, 17-acetyloxy-6 α -methylpregn-4-ene-3,20-dione (Provera), adds a 6 α -methyl group to the basic 17 α -hydroxyprogesterone structure to greatly decrease the rate of reduction of the 4-ene-3-one system. The 17 α -acetate group also decreases reduction of the 20-one, similar to the 17 α -caproate. Medroxyprogesterone acetate (MPA) is very active orally (see Table 23-2) and has such a long duration of action intramuscularly that it cannot be routinely used intramuscularly for treating many menstrual disorders. The intramuscular formulation is useful in the palliative treatment of advanced endometrial, breast, and renal carcinomas. MPA also has an important role in several birth control products (Depo-Provera, Lunelle).

Megestrol Acetate, USP. Megestrol acetate, 17-hydroxy-6-methylpregna-4,6-diene-3,20-dione acetate (Megace), is a progestin used primarily for the palliative management of recurrent, inoperable, or metastatic endometrial or breast carcinoma. Megestrol acetate has also been indicated for appetite enhancement in AIDS patients. The biochemical basis for this use of megestrol is unclear.

Norethindrone, USP, and Norethynodrel, USP. Norethindrone, 17 α -ethinyl-19-nortestosterone, and its $\Delta^{5(10)}$ isomer, norethynodrel, might appear at first glance to be subtle copies of each other. One would predict that the $\Delta^{5(10)}$ double bond would isomerize in the stomach's acid to the Δ^4 position. In fact, however, the two drugs were developed simultaneously and independently; hence, neither can be considered a copy of the other. Furthermore, norethindrone is about 10 times more active than norethynodrel (see Table 23-2), indicating that isomerization is not as facile *in vivo* as one might predict. Although they are less active than progesterone when given subcutaneously, they have the important advantage of being orally active. The discovery of the potent progestin activity of 17 α -ethinyltestosterone (ethisterone) and 19-norprogesterone preceded the development of these potent progestins. Both are orally active, with the 17 α -ethinyl group blocking oxidation to the less active 17-one. The rich electron density of the ethinyl group and the absence of the 19-methyl group greatly enhance progestin activity. Both compounds were of great importance as progestin components of oral contraceptives, although currently, use of norethynodrel is minimal. Norethindrone, USP, and norethindrone acetate, USP, are widely used for all the usual indications of the progestins, as well as being components of oral contraceptives. Because these compounds retain key features of the testosterone structure, including the 17 β -OH, it is not surprising that they possess some androgenic side effects.

Ethinodiol Diacetate, USP. Ethinodiol diacetate, 19-norpregn-4-en-20-yne-3 β ,17 α -diol diacetate, is a prodrug of norethindrone. A combination of hydrolysis of both esters and oxidation of the C3 alcohol to the ketone is necessary to provide the fully active progestin.⁷⁵

Norgestrel, USP, and Levonorgestrel, USP. Norgestrel, (17 α)-(±)-13-ethyl-17-hydroxy-18,19-dinorpregn-4-en-20-yn-3-one, and levonorgestrel, (17 α)-(-)-13-ethyl-17-hydroxy-18,19-dinorpregn-4-en-20-yn-3-one, have a C13 ethyl group instead of the C13 methyl but have progestational properties similar to those of norethindrone, with decreased androgenic effects. The ethyl group apparently provides unfavorable steric interactions with the androgen receptor that reduce the affinity compared with that with the progesterone receptors. Norgestrel is a racemic mixture, while levonorgestrel is the single active levorotatory enantiomer. Norgestrel is used only in oral contraceptives. Levonorgestrel is used in both oral combination birth control products and polymeric implants that provide contraception for up to 5 years.

Desogestrel, USP. Desogestrel, (17 α)-13-ethyl-11-methylene-18,19-dinorpregn-4-en-20-yn-17-ol (Desogen), is a 19-nortestosterone analogue with good progestin activity. Like the other progestins, it is orally active and used in combination with an estrogen in oral contraceptives. Desogestrel is a prodrug that must be oxidized to the 3-one *in vivo* to have progestational action. CYPs 2C9 and 2C19 have been implicated in the initial hydroxylation of desogestrel at C3.⁷⁶

Norgestimate, USP. Norgestimate, (17 α)-17-acetyloxy-13-ethyl-18,19-dinor-pregn-4-en-20-yn-3-one oxime (Cyclen, Tri-Cyclen), is a 19-nortestosterone, 3-oxime prodrug that is orally active and used with an estrogen in oral contraceptive products. It has minimal androgenic action. Norgestimate is metabolized to 17-deacetylnorgestimate (norgestromin) and norgestrel, which provide the progestational action.⁷⁷

Norelgestromin, USP. Norelgestromin, (17 α)-13-ethyl-17-hydroxy-18,19-dinor-pregn-4-en-20-yn-3-one, oxime, is the progestin component in the contraceptive patch (Ortho-Evra). First-pass metabolism in the liver is avoided by the transdermal application. Hepatic metabolism does occur, however, and norgestrel, an active metabolite, and other hydroxylated and conjugated metabolites are formed.

Etonogestrel, USP. Etonogestrel, 17 α -13-ethyl-17-hydroxy-11-methylene-18,19-dinorpregn-4-en-20-yn-3-one, 3-ketodesogestrel, is the active metabolite of desogestrel. It is the progestin component in a newer implantable contraceptive (Implanon) and in the vaginal contraceptive ring (NuvaRing).

Drospirenone, USP. Drospirenone, 3-oxo-6 β ,7 β ,15 β ,16 β -dimethylene-17 α -pregn-4-en-21,17-carbolactone, differs structurally from all of the other commercially available progestins. Its structure is similar to that of spironolactone, a mineralocorticoid receptor antagonist, and drospirenone does have antimineralocorticoid activity as well as progestational activity. It is also reported to have some antiandrogenic effects. The spirolactone at C17 and the two cyclopropyl groups at C6-C7 and C15-C16 contribute to these unique actions. Drospirenone is the progestin component in a new oral contraceptive, Yasmin.

Trimegestone. Trimegestone, 17 β -(S)-lactoyl-17-methyl-estra-4,9-dien-3-one, is a highly modified norprogesterone derivative that is being investigated for its use in HRT and as a component of oral contraceptives. The key structural differences are a 17 β -lactoyl group in place of the typical acetyl group, a 17 α -methyl, and a C9-C10 double bond. Trimegestone lacks androgenic action and has little to no affinity for the estrogen and glucocorticoid receptors.⁷⁸

CHEMICAL CONTRACEPTIVE AGENTS

Political, cultural, and research-cost barriers have enormously complicated the development of contraceptive agents in modern times. The reviews by Djerassi,⁷⁹ inventor of norethindrone, and by Lednicher⁸⁰ are important reading. (Their "insider's viewpoint" of the research competition during the 1950s and 1960s to develop steroid products is especially interesting.) More recent reviews provide a slightly different perspective on the overall development of oral contraceptives.^{81, 82}

The most notable achievement in chemical contraception came in the late 1950s and early 1960s with the development of oral contraceptive agents—"the pill." Since then, a vari-

ety of contraceptive products have been introduced, including hormone-releasing intrauterine devices, polymer implants, injectable formulations, and a transdermal patch. Additionally, postcoital contraceptives and abortifacients have been developed. Despite the advances in chemical contraceptive agents for women, no hormonal male contraceptives are currently available, although limited research in this area has been conducted. In the following pages, each of these approaches to chemical contraception is discussed. Individual compounds are discussed above with the estrogens and progestins.

Ovulation Inhibitors and Related Hormonal Contraceptives

HISTORY^{79, 80, 83}

In the 1930s, several research groups found that injections of progesterone inhibited ovulation in rats, rabbits, and guinea pigs.⁸⁴⁻⁸⁶ Kurzrok, Albright, and Sturgis, in the early 1940s, are generally credited with the concept that estrogens, progesterone, or both could be used to prevent ovulation in women.^{87, 88} In 1965, Pincus⁸⁹ reported that progesterone given from day 5 to day 25 of the menstrual cycle would inhibit ovulation in women. During this time, Djerassi et al.⁹⁰ of Syntex, and Colton⁹¹ of G. D. Searle and Co. reported the synthesis of norethindrone and norethynodrel. These progestins possessed very high progestational and ovulation-inhibiting activity.

Extensive animal and clinical trials conducted by Pincus, Rock, and Garcia confirmed, in 1956, that Searle's norethynodrel and Syntex's norethindrone were effective ovulation inhibitors in women. In 1960, Searle marketed Enovid (a mixture of norethynodrel and mestranol), and in 1962, Ortho marketed Ortho Novum (a mixture of norethindrone and mestranol) under contract with Syntex. Norethindrone has remained the most extensively used progestin in oral contraceptives, but several other useful agents have been developed. These are discussed in the sections below.

THERAPEUTIC CLASSES AND MECHANISM OF ACTION

The modern hormonal contraceptives fall into several major categories (Table 23-3), each with its own mechanism of contraceptive action. Individual compounds are discussed with the estrogens and progestins in the section above.

Combination Tablets: Mechanism of Action. Although, as noted above, Sturgis and Albright recognized in the early 1940s that either estrogens or progestins could inhibit ovulation, it was subsequently found that combinations were highly effective. Some problems, such as breakthrough (midcycle) bleeding, were also reduced by the use of a combination of progestin and estrogen.

Although all the details of the process are still not completely understood, it is now believed that the combination tablets suppress the production of LH, FSH, or both by a feedback-inhibition process (see Fig. 23-9). Without FSH or LH, ovulation is prevented. The process is similar to the natural inhibition of ovulation during pregnancy, caused by the release of estrogens and progesterone from the placenta and ovaries. An additional effect comes from the progestin causing the cervical mucus to become very thick, providing a

barrier for the passage of sperm through the cervix. Because pregnancy is impossible without ovulation, however, the contraceptive effects of thick cervical mucus or alterations in the lining of the uterus (to decrease the probability of implantation of a fertilized ovum) would appear to be quite secondary. Nevertheless, occasional ovulation may occur, and thus the alterations of the cervical mucus and the endometrium may actually serve an important contraceptive function (especially, perhaps, when the patient forgets to take one of the tablets). During combination drug treatment, the endometrial lining develops enough for withdrawal bleeding to occur about 4 or 5 days after taking the last active tablet of the series (see Table 23-3).

MONOPHASIC (FIXED) COMBINATIONS. The monophasic combinations of a progestin and estrogen contain the same amount of drug in each active tablet (see Table 23-3). As discussed below in this chapter, the trend in prescribing has been toward lower doses of estrogen. As estrogen levels are reduced, however, breakthrough bleeding (or "spotting") becomes an annoying side effect for some patients at early to midcycle. Spotting after midcycle or amenorrhea appears to be related to too little progestin relative to the estrogen. The biphasic and triphasic combinations were developed to solve these breakthrough-bleeding problems in some patients.

BIPHASIC AND TRIPHASIC (VARIABLE) COMBINATIONS. In the natural menstrual cycle, progesterone plasma concentrations peak late in the cycle. The higher estrogen/progesterone ratio early in the cycle is believed to assist in development of the endometrium. The higher progesterone concentration later contributes to proliferation of the endometrium and a resultant "normal" volume of menstrual flow. The biphasic and triphasic combinations attempt to mimic this variation in estrogen/progestin levels, and thereby to reduce the incidence of spotting associated with low-dose monophasic combinations. With proper selection of patients, the goal has been achieved; but in other patients, the incidence of spotting has not decreased appreciably.

EXTENDED ORAL CONTRACEPTIVE THERAPY. Clinical trials are currently in progress that use a 91-day cycle as opposed to the current 28-day cycles typically used for oral contraceptives. The monophasic combinations in testing have levonorgestrel and ethinyl estradiol as the progestin and estrogen, respectively. Instead of 21 days of hormones, followed by a week of inert tablets, these regimens have 84 days of hormones, followed by a week of inert tablets. The key difference with this approach is that the number of menstrual cycles during the year would be reduced from 12 to 4. If shown to be effective and safe, this type of product could allow women to reduce the frequency of cramps and anemia associated with menstruation.

HOW SAFE?

The safety of the "pill" has been investigated extensively because of the widespread use of these drugs in healthy young women. Overall, oral contraceptives have an excellent safety profile in healthy, nonsmoking women of child-bearing age.⁹² Early studies, based largely on the earlier products that contained high doses of estrogen, showed an alarming

TABLE 23–3 Comparison of Steroid Contraceptive Regimens

1. Combination—Monophasic		
Products are available in 21- or 28-day dispensers and refills. The 28-day dispensers contain several inert (or Fe ²⁺ -containing) tablets of a different color, taken daily after the 21 days of active tablets. Doses of active tablets are shown		
Brand	Progestin	Estrogen
Necon 1/50	Norethindrone, 1 mg	Mestranol, 50 µg
Norinyl 1 + 50	Norethindrone, 1 mg	Mestranol, 50 µg
Ortho-Novum 1/50	Norethindrone, 1 mg	Mestranol, 50 µg
Ovcon 50	Norethindrone, 1 mg	Ethinyl estradiol, 50 µg
Demulen 1/50	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 50 µg
Zovia 1/50E	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 50 µg
Ovral-28	Norgestrel, 0.5 mg	Ethinyl estradiol, 50 µg
Ogestrel	Norgestrel, 0.5 mg	Ethinyl estradiol, 50 µg
Necon 1/35	Norethindrone, 1 mg	Ethinyl estradiol, 35 µg
Norinyl 1 + 35	Norethindrone, 1 mg	Ethinyl estradiol, 35 µg
Nortrel 1/35	Norethindrone, 1 mg	Ethinyl estradiol, 35 µg
Ortho-Novum 1/35	Norethindrone, 1 mg	Ethinyl estradiol, 35 µg
Modicon	Norethindrone, 0.5 mg	Ethinyl estradiol, 35 µg
Necon 0.5/35	Norethindrone, 0.5 mg	Ethinyl estradiol, 35 µg
Nortrel 0.5/35	Norethindrone, 0.5 mg	Ethinyl estradiol, 35 µg
Ovcon-35	Norethindrone, 0.4 mg	Ethinyl estradiol, 35 µg
Ortho-Cyclen	Norgestimate, 0.25 mg	Ethinyl estradiol, 35 µg
Demulen 1/35	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 35 µg
Zovia 1/35E	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 35 µg
Yasmin	Drospirenone, 3 mg	Ethinyl estradiol, 30 µg
Loestrin 21 1.5/30	Norethindrone acetate, 1.5 mg	Ethinyl estradiol, 30 µg
Loestrin Fe 1.5/30	Norethindrone acetate, 1.5 mg	Ethinyl estradiol, 30 µg
Microgestin Fe 1.5/30	Norethindrone acetate, 1.5 mg	Ethinyl estradiol, 30 µg
Lo/Ovral	Norgestrel, 0.3 mg	Ethinyl estradiol, 30 µg
Low-Ogestrel	Norgestrel, 0.3 mg	Ethinyl estradiol, 30 µg
Desogen	Desogestrel, 0.15 mg	Ethinyl estradiol, 30 µg
Ortho-Cept	Desogestrel, 0.15 mg	Ethinyl estradiol, 30 µg
Apri	Desogestrel, 0.15 mg	Ethinyl estradiol, 30 µg
Leven	Levonorgestrel, 0.15 mg	Ethinyl estradiol, 30 µg
Levora	Levonorgestrel, 0.15 mg	Ethinyl estradiol, 30 µg
Nordette	Levonorgestrel, 0.15 mg	Ethinyl estradiol, 30 µg
Alesse	Levonorgestrel, 0.1 mg	Ethinyl estradiol, 20 µg
Aviane	Levonorgestrel, 0.1 mg	Ethinyl estradiol, 20 µg
Levlite	Levonorgestrel, 0.1 mg	Ethinyl estradiol, 20 µg
Loestrin 21 1/20	Norethindrone acetate, 1 mg	Ethinyl estradiol, 20 µg
Loestrin Fe 1/20	Norethindrone acetate, 1 mg	Ethinyl estradiol, 20 µg
Microgestin Fe 1/20	Norethindrone acetate, 1 mg	Ethinyl estradiol, 20 µg
2. Combination—Biphasic		
Products are available in 21- or 28-day dispensers and refills. They are taken on the same schedule of 21 days plus 7 days of no (or inert) tablets as the monophasics above, except Mircette. Doses of active tablets are shown.		
Brand	Progestin and Estrogen	
Jenest-28	7 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 µg 14 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 µg	
Necon 10/11	10 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 µg 11 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 µg	
Ortho-Novum	10 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 µg	
(Continued)		

TABLE 23-3 Comparison of Steroid Contraceptive Regimens—Continued

Brand	Progestin and Estrogen
10/11 21	11 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 µg
Mircette	21 days: Desogestrel, 0.15 mg, and ethinyl estradiol, 20 µg
	5 days: Ethinyl estradiol, 10 µg
	2 days: Inert

3. Combination—Triphasic

Products are available in 21- or 28-day dispensers and refills. They are taken on the same schedule of 21 days plus 7 days of no (or inert) tablets as the monophasics above. Doses of active tablets are shown.

Brand	Progestin and Estrogen
Ortho-Novum 7/7/7	7 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 µg
	7 days: Norethindrone, 0.75 mg, and ethinyl estradiol, 35 µg
	7 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 µg
Ortho-Tri-Cyclen	7 days: Norgestimate, 0.18 mg, and ethinyl estradiol, 35 µg
	7 days: Norgestimate, 0.215 mg, and ethinyl estradiol, 35 µg
	7 days: Norgestimate, 0.25 mg, and ethinyl estradiol, 35 µg
Trinormyl	7 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 µg
	9 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 µg
	5 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 µg
Tri-Levlen	6 days: Levonorgestrel, 0.05 mg, and ethinyl estradiol, 30 µg
	5 days: Levonorgestrel, 0.075 mg, and ethinyl estradiol, 40 µg
	10 days: Levonorgestrel, 0.125 mg, and ethinyl estradiol, 30 µg
Tri-Phasil	6 days: Levonorgestrel, 0.05 mg, and ethinyl estradiol, 30 µg
	5 days: Levonorgestrel, 0.075 mg, and ethinyl estradiol, 40 µg
	10 days: Levonorgestrel, 0.125 mg, and ethinyl estradiol, 30 µg
Trivora	6 days: Levonorgestrel, 0.05 mg, and ethinyl estradiol, 30 µg
	5 days: Levonorgestrel, 0.075 mg, and ethinyl estradiol, 40 µg
	10 days: Levonorgestrel, 0.125 mg, and ethinyl estradiol, 30 µg
Estrostep	5 days: Norethindrone acetate, 1 mg, and ethinyl estradiol, 20 µg
	7 days: Norethindrone acetate, 1 mg, and ethinyl estradiol, 30 µg
	9 days: Norethindrone acetate, 1 mg, and ethinyl estradiol, 35 µg

4. Progestin Only

An active tablet is taken each day of the year.

Brand	Progestin	Dose
Micronor	Norethindrone	0.35 mg
Nor-Q.D.	Norethindrone	0.35 mg
Ovrette	Norgestrel	0.075 mg

5. Injectable Depot Hormonal Contraceptives

Brand	Drug	Dosage Cycle
Depo-Provera	Medroxyprogesterone acetate alone	150 mg/month
		150 mg every 3 months
Lunelle	Medroxyprogesterone acetate (MPA), 25 mg, and estradiol cypionate (E2C), 5 mg/0.5 mL	0.5-mL IM injection once in deltoid, gluteus maximus, or anterior thigh every 28 to 30 days

6. Transdermal Contraceptive Patch

Brand	Release Rate	Total Hormone Content	Dosage Cycle
Ortho-Evra	0.15 mg norelgestromin, 0.02 mg, ethinyl estradiol/24 hours	6 mg norelgestromin, 0.075 mg, ethinyl estradiol	One patch each week for 3 weeks, 1 week no patch.

TABLE 23-3—Continued

7. Hormone-Releasing Implants, IUDs, and Vaginal Rings		
Brand	Drug	Dosage Cycle
Progestasert	Progesterone-releasing IUD	38-mg dose in IUD lasts 1 year
Mirena	Levonorgestrel-releasing intrauterine system (LIRS)	52-mg dose in LIRS provides contraception for up to 5 years
Norplant	6 Silastic capsules with 36 mg levonorgestrel; all 6 capsules are inserted subdermally in the middle upper arm	Contraceptive efficacy lasts for 5 years if the implants are not removed
Implanon	One polymeric rod with 68 mg etonorgestrel, released at a rate of ~40 µg/day.	Contraceptive efficacy lasts up to 3 years if the implant is not removed
NuvaRing	11.7 mg etonorgestrel, 2.7 mg ethinyl estradiol in a flexible, polymeric vaginal ring	Vaginal ring is inserted for 3 weeks duration, then 1 week off before insertion of a new ring
8. Emergency Contraceptives		
Brand	Drug	Dosage
Plan B	0.75 mg levonorgestrel	The first dose (1 tablet) should be taken as soon as possible within 72 hours of intercourse; the second dose (1 tablet) must be taken 12 hours later
Preven	0.25 mg levonorgestrel, 0.05 mg ethinyl estradiol	The first dose (2 tablets) should be taken as soon as possible within 72 hours of intercourse; the second dose (2 tablets) must be taken 12 hours later

incidence of thromboembolic disease (blood clots). More recent studies have shown a greatly reduced risk of cardiovascular effects with lower estrogen doses. Another concern has been an association between estrogens and increased cancer risk. Recent reanalysis of clinical data supports a slightly increased risk of breast cancer in women taking oral contraceptives, but the risk subsides within 10 years of discontinuation of use.⁹³ This small increase in incidence of breast cancer is not greatly affected by duration of use, dose, age at first use, or progestin component. Additionally, use of oral contraceptives has shown a decreased risk for endometrial and ovarian cancers.⁹³

The overall results of these studies have been that (a) the sequential contraceptive products with their high doses of estrogen have been removed from American markets; (b) most combination contraceptives now marketed contain less than 0.050 mg of estrogen per dose (see Table 23-3); (c) progestin-only or minipill products are available (see Table 23-3); and (d) a few groups of women have been identified who should definitely not take oral contraceptives (e.g., women with a history of thromboembolic disease or other cardiovascular disease, women who are heavy smokers over the age of 35, and women with a history of breast cancer in their immediate family). The actual incidence of "pill-induced" cardiovascular death for nonsmoking young women is quite small, and there is not a widespread link between oral contraceptive use and cancer. Cigarette smoking increases the risk of thromboembolic disorders associated with oral contraceptive use, so women should be counseled to abstain from smoking while using oral contraceptives.

Progestin Only (Minipill). The estrogen component of sequential and combination oral contraceptive agents has been related to some side effects, with thromboembolism being a concern. One solution to this problem has been to develop new products with decreased estrogen content. The minipill contains no estrogen at all.

Although higher doses of progestin are known to suppress ovulation, minipill doses of progestin do not suffice to suppress ovulation in all women. Some studies have indicated that increased viscosity of the cervical mucus (or sperm barrier) could account for much of the contraceptive effect. Low doses of progestin have also been found to increase the rate of ovum transport and to disrupt implantation. There is a good probability that most, or all, of these factors contribute to the overall contraceptive effect of the minipill. The incidence of pregnancy with the minipill is slightly higher than with combination products, although still very low when the minipill is used as directed.

Depo-Provera. Medroxyprogesterone acetate intramuscular (IM) injection (Depo-Provera) provides contraception for 3 months after a single 150-mg IM dose. Most women experience some irregular bleeding or spotting and often experience small weight gain. Fertility returns for most women within the first 12 months after discontinuance of Depo-Provera. Contraception typically continues for a few weeks beyond the 3-month term, giving patients a short grace period if the subsequent IM dose is delayed.

Lunelle. Lunelle is a newer injectable contraceptive formulation that combines the effects of a progestin, medroxy-

progesterone acetate (MPA), and an estrogen, estradiol cypionate (E2C). This product is also referred to as MPA/E2C. The cypionate ester at C17 provides a lipophilic prodrug that is slowly released from the injection site, providing sustained action of the estrogen component. The progestin is also slowly released from the injection site. The MPA/E2C injection is given once a month in the deltoid, gluteus maximus, or anterior thigh.

Transdermal Contraceptives. In 2001, the Food and Drug Administration (FDA) approved the first transdermal contraceptive patch, Ortho-Evra. The product contains norelgestromin and ethinyl estradiol. A patch is applied once a week for 3 weeks, followed by a week with no patch. The pregnancy rate for this product is 1 in 100, a rate similar to that often observed with oral contraceptives.

Progesterone IUD. The low progestin doses of the mini-pill seem to have a direct effect on the uterus and associated reproductive tract. Therefore, it would seem possible to lower the progestin dose even more if the drug were released in the reproductive tract itself.

The Progestasert IUD (Progesterone Intrauterine Contraceptive System, USP) has 38 mg of microcrystalline progesterone dispersed in silicone oil. The dispersion is contained in a flexible polymer in the approximate shape of a T. The polymer acts as a membrane to permit 65 μg of progesterone to be released slowly into the uterus each day for 1 year. The progesterone-containing IUD has had some of the therapeutic problems of other IUDs, including a relatively low patient continuation rate, some septic abortions, and some perforations of uterus and cervix.

Levonorgestrel-Releasing Intrauterine System (LRIS). Because the Progestasert system provided evidence that a progestin-releasing intrauterine device was an effective contraceptive, another intrauterine system has been developed with use of a different progestin. Mirena is a plastic T-shaped frame, with the stem of the "T" containing 52 mg of levonorgestrel. The levonorgestrel is released slowly, at a dose lower than in a pill (approximately one-seventh strength), directly to the lining of the uterus. This local release and absorption of the hormone helps to reduce systemic progesterone-type side effects. The contraceptive effectiveness of this device lasts up to 5 years.

Mirena acts as a contraceptive in two ways: it thickens the mucus at the cervix, preventing sperm from getting through, and it also thins the lining of the uterus, preventing implantation. In some women it also prevents ovulation. An additional feature of the LRIS is that menstrual periods are typically lighter than usual. The LRIS may be useful to alleviate the difficulties associated with heavy periods, even in patients who do not need contraception.

There is a small chance that the device may dislodge in the early months of use. Although the LRIS releases a reduced amount of progestin, it does slightly increase progesterone levels in the bloodstream. This increased progesterone can cause side effects including headache, water retention, breast tenderness, or acne, although these are typically mild. Bleeding problems are the most common side effect, but this effect usually ceases after 3 to 6 months of use.

Intrauterine Ring. A new entry into the contraceptive market is a flexible polymeric ring, approximately 2.1 inches in diameter, that contains etonogestrel and ethinyl estradiol (NuvaRing). The ring is inserted into the vagina by the woman herself and remains inserted for 3 weeks. The spent ring is removed for 1 week to allow the menstrual period. A new ring is inserted 1 week after removal of the prior ring. The ring contains 11.7 mg of etonogestrel and 2.7 mg of ethinyl estradiol, with a release rate of 0.12 mg etonogestrel/day and 0.015 mg of ethinyl estradiol/day. Unlike a diaphragm, the placement of the vaginal ring contraceptive device is not critical. Clinical trials suggest a 1 to 2% pregnancy rate for women using the ring as indicated. Like other hormone-based contraceptives, the ring should not be used by women who have cardiovascular disease, blood clots, or hormone-dependent breast cancer. Women should also abstain from smoking while using the ring.

CONTRACEPTIVE IMPLANTS

Norplant. The first implantable contraceptive was Norplant, a set of six flexible Silastic (dimethylsiloxane/methylvinylsiloxane copolymer) capsules that contain levonorgestrel. The capsules implanted in the midportion of the upper arm provided contraception for up to 5 years. Contraceptive efficacy was very high. Most women experienced changes in menstrual bleeding, ranging from irregular cycles to prolonged bleeding or amenorrhea. A problem that arose with Norplant was that removal of the product, either at the end of 5 years, or earlier in patients who wished to stop using contraception, often entailed a sometimes painful surgical procedure. The insertion and removal procedures required extra training of physicians, another feature that reduced the desirability of this product. Although Norplant was extremely effective as a contraceptive, a variety of legal issues, public concerns, and production issues led the manufacturer to discontinue production of Norplant. Norplant II, a two-rod implantable system that had reduced problems with insertion and removal, was approved by the FDA but was never marketed in the United States.

A new implantable system may be available soon in the United States. Implanon is a single-rod system (40 \times 2 mm) that releases etonogestrel (3-ketodesogestrel) rather than the levonorgestrel in Norplant. The contraceptive efficacy is up to 3 years. With a single rod and a specially designed applicator system, the insertion/removal difficulties with Norplant should be avoided. The Implanon system has been used successfully in Europe for several years.

Other Methods of Chemical Contraception

POSTCOITAL CONTRACEPTIVES

Two products specifically designated for postcoital or emergency contraception have been approved. Plan B uses a high-dose progestin-only approach, whereas Preven combines a progestin and an estrogen. Both must be taken within 72 hours of unprotected intercourse, followed by another dose 12 hours later. Some monophasic oral contraceptives must also be used in a similar fashion. A specific drug that has been used in this manner is Ovral, which combines norgestrel (0.5 mg) and ethinyl estradiol (50 μg). Two Ovral tablets

are taken within 72 hours of unprotected intercourse or failure of other method, followed by another two tablets 12 hours later. Some patients experience nausea, which is usually mild. The treatment successfully prevents pregnancy with about 90% of patients. This treatment is intended, however, only for use in short-term emergency situations.

ABORTIFACIENTS

History records many different compounds that have been tried as abortifacients, but many of these compounds also are toxic or mutagenic or cause severe hemorrhaging along with the abortion. Several therapeutically acceptable abortifacients, however, are currently available. Two prostaglandins have been approved by the FDA to induce second-trimester abortions, and mifepristone (Mifeprex), a progesterone receptor antagonist, is available for use in the first 49 days of pregnancy (Fig. 23-21).

Prostaglandins $F_{2\alpha}$ ($PGF_{2\alpha}$) and E_2 (PGE_2) concentrations increase significantly in amniotic fluid before normal labor and childbirth and are involved in stimulating uterine contractions. In a similar fashion, the prostaglandin drugs stimulate the uterus to contract. These contractions usually suffice to expel the fetus from the uterus. Good surgical support is

essential with carboprost and dinoprostone because some clinicians report a high incidence of incomplete abortions that require additional treatment. Carboprost is approved only for intramuscular injection, while dinoprostone (prostaglandin E_2) is available as a vaginal suppository. Both products are used for second-trimester abortions. Carboprost is a $PGF_{2\alpha}$ analogue.

Mifepristone acts directly by antagonizing the effects of progesterone at progesterone receptors, as well as indirectly by causing a decrease in progesterone secretion from the corpus luteum. These combined effects lead to an increase in the level of prostaglandins, which stimulates uterine contractions. Mifepristone also causes a softening of the cervix, which aids in expulsion of the fertilized ovum. Mifepristone treatment is followed by the use of misoprostol, a prostaglandin E_2 analogue, to ensure a complete abortion. Mifepristone also has antagonist action at glucocorticoid receptors.

Relative Contraceptive Effectiveness of Various Methods

Some caution is required in interpreting data on the effectiveness of contraceptive methods. Even the "best" method can lead to pregnancy if not used consistently and correctly. Even the generally least effective method is better than no contraceptive at all. Table 23-4 presents some data on numbers of pregnancies per method.

TABLE 23-4 Failure Rate of Contraceptive Methods

Method	Pregnancies/100 Woman Years
Tubal ligation	0.5
Vasectomy	0.15
Norplant	0.05
Implanon	(0.05)*
Depo-Provera injection	0.3
MPA/E2C injection	<1
Combination oral contraceptives	0.1-3
Progestin only minipill (oral)	0.5-3
Progestasert IUD	1.5-2
Copper T IUD	0.6-0.8
Levonorgestrel-releasing intrauterine system	0.1
NuvaRing	1-2
Transdermal combination contraceptive	1
Diaphragm (with spermicide)	6-20
Condom (female)	5-21
Condom (male)	3-14
Withdrawal	4-19
Spermicides	6-26
Periodic abstinence	9-25
No contraceptive method	85

Modified from Trussel, J.: Contraceptive Efficacy. In Hatcher, R. A., Trussel, J., Stewart, F., et al. Contraceptive Technology, 17th rev. ed. New York, Irvington Publishers, 1998.

*The failure rate for Implanon is estimated to be similar to that of Norplant. Several thousand women have used Implanon, and as of the end of 2001, no pregnancies were reported with proper use.

Figure 23-21 ■ Abortifacients.

Combined Estrogen/Progestin Hormone Replacement Therapy

Similar to the combined estrogen and progestin oral contraceptives, combination estrogen/progestin products are available for use in HRT in women. In contrast to the oral contraceptives, in which the estrogen component is almost always ethinyl estradiol, the estrogen component of HRT products is typically conjugated estrogens or estradiol. The progestin component for HRT is often medroxyprogesterone acetate or norethindrone acetate. Table 23-5 lists the currently available combination products. Both oral tablets and a transdermal patch are used.

TREATMENT OF VASOMOTOR SYMPTOMS OF MENOPAUSE AND ATROPHIC VAGINITIS

Estragens have been very useful in treating the "hot flashes" associated with early menopause, as well as atrophic vaginitis and other vaginal symptoms of inadequate estrogen production. The evidence that they result in enhanced mood and improved cognitive function in postmenopausal women is less clear, however, and more studies are needed to sort out the competing claims in these areas.⁹⁴⁻⁹⁶

OSTEOPOROSIS PREVENTION AND TREATMENT⁹⁷⁻⁹⁹

Osteoporosis is an enormous public health problem, responsible for approximately 1.5 million fractures in the United States each year. Because of the prevalence of osteoporosis, especially in older women, the prevention and treatment of this condition have received much attention. Prior to menopause, a good diet and exercise are essential for young women, to decrease the risk of osteoporosis later in life. After menopause, supplemental estrogens can have a positive effect relative to osteoporosis. Estrogens mainly act by decreasing bone resorption, so estrogens are better at preventing bone loss than restoring bone mass. Estrogens taken after menopause (often with a supplemental progestin) have been unequivocally shown to greatly decrease the incidence and severity of osteoporosis, especially when combined with good nutrition and exercise. The long-term use of estrogens plus a progestin for preventing osteoporosis should be carefully considered in light of the recent results of a study examining HRT for lowering the risk of heart disease (see below). Alternatives to estrogens for the prevention of osteoporosis, such as raloxifene, should also be considered.

POSTMENOPAUSAL ESTROGENS IN LOWERING RISK OF HEART DISEASE¹⁰⁰

After years of general recommendations for the beneficial use of estrogens after menopause for lowering the risk of heart disease, the results of a long-term study with conjugated estrogens supplemented with a progestin have indicated that the risks of this approach outweigh the benefits. The Women's Health Initiative (WHI) trial, which enrolled over 16,000 postmenopausal women between 1993 and 1998, was terminated early in 2002 because of an unacceptably high level of adverse effects relative to the benefits gained. With long-term use (average follow-up of 5.2 years), there was a slight increase in the incidence of coronary heart disease, as well as an increase in breast cancer risk. Although there was a slight decrease in the risk of colorectal cancer and fewer hip fractures, the effects on the heart and breast argue against the use of estrogens plus a progestin for the prevention of coronary heart disease in postmenopausal women. Another WHI trial with estrogen alone in postmenopausal women without a uterus is still in progress. The estrogen-plus-progestin trial used, however, only one drug regimen (0.625 mg of conjugated equine estrogens and 2.5 mg of medroxyprogesterone acetate), so care should be taken in extending these results to other regimens and products. Also, the short-term use in the management of hot flashes and other postmenopausal symptoms is still appropriate.

An alternative to a combination estrogen/progestin drug for HRT would be a single compound that has both estrogenic and progestogenic actions. Tibolone (17 α -hydroxy-7 α -methyl-19-norpregn-5(10)-en-20-yn-3-one) is such a compound. It is a synthetic steroid that has diverse actions and is used alone in HRT in Europe as an alternative to standard estrogen or estrogen-plus-progestin therapy. Tibolone is awaiting FDA approval for use in HRT and for treating osteoporosis. It has been described as a tissue-specific compound with beneficial actions on bone, vagina, climacteric symptoms, mood, and sexual well-being but without stimulation of breast and endometrial tissue.^{101, 102} Tibolone has estrogenic, progestogenic, and weak androgenic actions. This range of actions has been attributed to metabolites of tibolone (Fig. 23-22). Tibolone is rapidly converted to 3 α - and 3 β -hydroxy metabolites as well as a Δ^4 metabolite.¹⁰² Despite the lack of an A-ring phenol, the hydroxy metabolites bind to the ER, while the Δ^4 metabolite binds to the progesterone and androgen receptors. The absence of stimu-

TABLE 23-5 Combined Progestin/Estrogen Hormone Replacement Therapy Products (Available in Tablets or a Transdermal Patch)

Brand	Progestin	Estrogen
Prempro	Medroxyprogesterone acetate, 2.5 or 5 mg	Conjugated estrogens, 0.625 mg
Premphase ^a	Medroxyprogesterone acetate, 5 mg	Conjugated estrogens, 0.625 mg
Femhrt	Norethindrone acetate, 1 mg	Ethinyl estradiol, 5 μ g
Activella	Norethindrone acetate, 0.5 mg	Estradiol, 1 mg
Ortho-Prefest ^b	Norgestimate, 0.09 mg	Estradiol, 1 mg
CombiPatch	Norethindrone acetate, 0.14 or 0.25 mg	Estradiol, 50 μ g

^aPremphase is dosed 14 days of estrogen-only tablets (0.625 mg conjugated estrogens), followed by 14 days of combined progestin/estrogen.
^bOrtho-Prefest is dosed 15 days of estradiol (1 mg) alone, then 15 days of the combined progestin/estrogen.

Figure 23-22 ■ Tibolone and its active metabolites.

lation of endometrial tissue has been attributed to progestational action of the Δ^4 metabolite. Tibolone and the 3 β -hydroxy metabolite inhibit estrone sulfatase, which may partly explain the lack of breast tissue stimulation (the decreased amount of estrone that would be available for conversion to estradiol).¹⁰³ Although tibolone reduces high-density lipoprotein (HDL) levels, it has other positive effects on the cardiovascular system that may be beneficial.¹⁰⁴

rapidly converted to testosterone in many tissues. Testosterone levels in the plasma of men are 5 to 100 times higher than those in the plasma of women.

Testosterone is produced in the testes in response to LH release by the anterior pituitary, as shown in Figure 23-10. Testosterone and DHT inhibit the production of LH and FSH by a feedback-inhibition process. This is quite similar to the feedback inhibition by estrogens and progestins in FSH and LH production.

ANDROGENS¹⁰⁵

Endogenous Androgens

Testosterone and its more potent reduction product 5 α -DHT are produced in significantly greater amounts in males than in females, but females also produce low amounts of these "male" sex hormones. These endogenous compounds have two important activities: androgenic activity (promoting male sex characteristics) and anabolic activity (muscle-building).

DHEA and androstenedione are referred to as *adrenal androgens*, although this nomenclature is somewhat misleading. DHEA and androstenedione are biosynthetic precursors to the androgens but have only low affinity for the androgen receptors themselves.^{106, 107} Therefore, DHEA or androstenedione can have androgenic actions, but only after a *vivo* conversion to testosterone and DHT. DHEA and androstenedione are, however, also precursors to the estrogens, so estrogenic actions may also occur.

Biosynthesis

As shown in Figure 23-5, testosterone can be synthesized through pregnenolone, DHEA, and androstenedione. About 7 mg/day is synthesized by young human adult males. Labeling experiments have also shown that it can be biosynthesized from androst-5-ene-3 β ,17 β -diol, a reduction product of DHEA.

Testosterone is primarily produced by the interstitial cells of the testes, synthesized largely from cholesterol made in Leydig cells. DHT is also secreted by the testes, as well as being produced in other tissues. The ovaries and adrenal cortex synthesize androstenedione and DHEA, which can be

Metabolism of Androgens

Testosterone is rapidly converted to 5 α -DHT in many tissues by the action of 5 α -reductase. Depending on the tissue, this is either to activate testosterone to the more potent androgen, DHT (e.g., in the prostate), or a step in the metabolic inactivation of this androgen. The primary route for metabolic inactivation of testosterone and DHT is oxidation to the 17-one. The 3-one group is also reduced to the 3 α - (major) and 3 β -ols (minor). The metabolites are shown in Figure 23-23. Androsterone is the major urinary metabolite and was the first "androgenic" steroid isolated. These metabolites are excreted mainly as the corresponding glucuronides. Other minor metabolites have also been detected.¹⁰⁵

Biological Activities of Androgens

Testosterone and DHT cause pronounced masculinizing effects, even in the male fetus. They induce the development of the prostate, penis, and related sexual tissues. At puberty, the secretion of testosterone by the testes increases greatly, leading to an increase in facial and body hair, deepening of the voice, increased protein anabolic activity and muscle mass, rapid growth of long bones, and loss of some subcutaneous fat. Spermatogenesis begins, and the prostate and seminal vesicles increase in activity. Sexual organs increase in size. The skin becomes thicker, and sebaceous glands increase in number, leading to acne in many young people. The androgens also play important roles in male psychology and behavior. In women, testosterone plays a role in libido, mood, muscle mass and strength, as well as bone density.^{108, 109}

Figure 23-23 ■ Metabolism of testosterone and 5 α -DHT (conjugates of the metabolites are also formed; HSD, hydroxysteroid dehydrogenase).

Structural Classes—Anabolic Androgenic Steroids

The androgens, also known as anabolic androgenic steroids (AAS), include all of the therapeutic agents whose main actions are mediated by the androgen receptors. The inclusion of both *anabolic* and *androgenic* in referring to these compounds reflects the fact that no products are available in which the anabolic properties of androgens can be separated from the androgenic properties. The commonly used AAS are shown in Figure 23-24. Several recent reviews on AAS have been published.^{105, 110}

SEMISYNTHETIC ANALOGUES

Because bacterial and hepatic oxidation of the 17 β -hydroxyl to the 17-one is a key component of metabolic inactivation, 17 α -alkyl groups have been added to prevent oxidation of the alcohol. Even though 17 α -methyltestosterone is only about half as active as testosterone, it can be taken orally because its half-life is longer than that of testosterone. 17 α -Ethyltestosterone has greatly reduced activity, as shown in Table 23-6.¹¹¹ As mentioned above, addition of an α -alkynyl group provides more progestogenic action than androgenic action, although some activity at androgen receptors is retained. A disadvantage of the 17 α -methyl testosterone is hepatotoxicity. Hepatic disturbances, jaundice (occasionally), and death (in rare cases) may occur, particularly in the high doses often used by athletes (see next section).

Table 23-6 illustrates some structure–activity effects of the androgens, such as the greatly decreased activity of the 17 α -ol isomer of testosterone (epitestosterone). Hundreds

TABLE 23-6 Androgenic Activities of Some Androgens

Compound	μg Equivalent to an International Unit
Testosterone (17 β -ol)	15
Epitestosterone (17 α -ol)	400
17 α -Methyltestosterone	25–30
17 α -Ethyltestosterone	70–100
17 α -Methylandrosterone-3 α , 17 β -diol	35
17 α -Methylandrosterone-3-one-17 β -ol	15
Androsterone	100
Epiandrosterone	700
Androstane-3 α , 17 β -diol	20–25
Androstane-3 α , 17 α -diol	350
Androstane-3 β , 17 β -diol	500
Androstane-17 β -ol-3-one	20
Androstane-17 α -ol-3-one	300
Δ^5 -Androstene-3 α , 17 β -diol	35
Δ^5 -Androstene-3 β , 17 β -diol	500
Androstenedione-3, 17	120–130
Δ^4 -Androstenedione	120

Figure 23–24 ■ Testosterone and synthetic anabolic androgenic steroids.

of different AAS have been synthesized and studied. The goal of many synthetic programs was to make a compound that possessed the anabolic properties of testosterone but lacked its androgenic actions. While numerous compounds were prepared that did display improved anabolic/androgenic ratios in vitro, no compounds completely lacked androgenic action.¹¹⁰ Also, the high anabolic/androgenic ratios did not appear to be maintained when these drugs were used in humans. Despite the many compounds that have been examined, the structure–activity relationships of these drugs are not well delineated. Many hypotheses have been made in an attempt to summarize the structure–activity relationships of all the known androgens.¹⁰⁵ As with other compounds that have been discussed, hydroxyl groups in the testosterone are often converted to the corresponding esters to prolong activity or to provide some protection from oxidation.

Therapeutic Uses of Anabolic Androgenic Steroids

The primary use of AAS is in androgen replacement therapy in men, either at maturity or in adolescence. The cause of

testosterone deficiency may be either hypogonadism or hypopituitarism.

The use of the AAS for their anabolic activity or for uses other than androgen replacement has been limited because of their masculinizing actions. This has greatly limited their use in women and children. Although anabolic activity is often needed clinically, none of the products presently available is free of significant androgenic side effects.

The masculinizing (androgenic) side effects in females include hirsutism, acne, deepening of the voice, clitoral enlargement, and depression of the menstrual cycle. Furthermore, AAS generally alter serum lipid levels and increase the probability of atherosclerosis, characteristically a disease of men and postmenopausal women.

The masculinizing effects of the AAS preclude their use in most circumstances in women. Secondary treatment of advanced or metastatic breast carcinoma in selected patients is generally considered to be the only indication for large-dose, long-term androgen therapy in women. In lower doses, androgen replacement therapy is more often being considered for use in menopausal and postmenopausal women for the positive effects on libido, mood, vasomotor symptoms,

and muscle mass, all areas negatively affected by decreased testosterone levels in aging women.¹¹²

Androgens are also used to relieve bone pain associated with osteoporosis and to treat certain anemias, although this use has greatly decreased because of the availability of erythropoietin. In all cases, use of these agents requires caution.

Androgens and Sports

The use of androgens for their anabolic effects (hence the term *anabolic steroids*) by athletes began in the late 1940s and has, at times, been widespread.¹¹³ Prior to urine testing requirements, it was estimated that up to 80% of competitive weight lifters and about 75% of professional football players used these drugs, along with a variety of other athletes. International awareness of the abuse of steroids by athletes, however, was limited until the 1988 Olympics when Canada's Ben Johnson was disqualified as the winner of the gold medal in the 100-yard dash for having traces of stanozolol in his urine. The shocking disqualification brought the international misuse of AAS to headlines worldwide. Unfortunately, abuse of steroids is still a problem at all levels of competitive sports.

Although numerous "anabolic" steroids have been synthesized and used/abused by athletes, most likely all of the androgens have been used by athletes in an attempt to improve strength and increase muscle mass. In the early years, the 17 α -alkylated steroids with high anabolic/androgenic ratios *in vitro* were used with the belief that the anabolic properties of these drugs were greater than those of other androgens such as testosterone. With the ban on the use of steroids in most sports and the prevalence of drug testing, however, the 17 α -alkylated steroids have fallen out of favor because of the ease of detecting these compounds by mass spectrometry. This has led to a greater use of testosterone and its esters, as well as the androgen precursors androstenedione ("andro"), androstenediol, androstenediol, and DHEA. The belief is that because these steroids all occur naturally, detecting them will be much more difficult. While it is true that assays for the endogenous steroids must now discriminate deviations from normal ratios, it is possible to detect the abuse of these compounds. Externally supplied testosterone, for example, can be detected by a urine test examining the ratio of testosterone glucuronide to epitestosterone glucuronide. A ratio greater than 6:1 usually indicates abuse.¹¹⁴

Many studies have attempted to determine if taking anabolic steroids improves athletic performance.^{110, 115} Some failed to use controls (athletes who trained in an identical manner but did not take anabolic steroids). Others failed to use placebos in at least a single-blind research design (neither the treated nor control groups knowing which they were taking). An additional problem with many of the studies has been that typical therapeutic doses have been tested for their anabolic properties in clinical settings, whereas athletes typically use much higher doses.^{110, 116} Of the studies using at least a single-blind protocol, some have reported that anabolic steroids did increase athletic performance, whereas others found they did not. It would be fair to say, therefore, that the benefit of anabolic steroids to athletic performance is uncertain. The risks of using these drugs appear to outweigh their uncertain benefits.

As summarized by the FDA,¹¹⁷ the side effects include

In both sexes

- Increased risk of coronary heart disease, stroke, or obstructed blood vessels
- Increased aggression and antisocial behavior (known as "steroid rage")
- Liver tumors, peliosis hepatis (blood-filled cysts), and jaundice (for 17 α -alkylated androgens only)

In men

- Testicular atrophy with consequent sterility or decreased sperm count and abnormal motility and morphology
- Impotence
- Enlarged prostate
- Breast enlargement

In women

- Clitoral enlargement
- Beard growth
- Baldness
- Deepened voice
- Breast diminution

Because of these risks, the International Olympic Committee, numerous professional sports organizations, and the National Collegiate Athletic Association (NCAA) banned all anabolic drugs. Testing of elite athletes for performance-enhancing drugs of all types is commonplace. Despite the known problems with the use of AAS, however, some professional sports have been slow to enact testing for performance-enhancing drugs. As of the summer of 2002, Major League Baseball was finalizing a testing policy for its athletes, while the National Hockey League still lacked a policy on the use of anabolic steroids.

An additional risk is associated with self-injection of long-lasting anabolic steroid preparations. The risk of contracting hepatitis A, hepatitis C, and human immunodeficiency virus (HIV) is increased if needles used for injecting steroids are shared.¹¹⁸

Anabolic Androgenic Steroid Products

Therapeutic uses of the androgens are discussed above. 17 β -Esters and 17 α -alkyl products are available for a complete range of therapeutic uses. These drugs are contraindicated in men with prostatic cancer; in men or women with heart, kidney, or liver disease; and in pregnancy. Diabetics using the androgens should be carefully monitored. Androgens potentiate the action of oral anticoagulants, causing bleeding in some patients, and they may also interfere with some laboratory tests. Female patients may develop virilization side effects, and doctors should be warned that some of these effects may be irreversible (e.g., voice changes). All of the "anabolic" agents currently commercially available (methyl- androstenedione, oxymetholone, oxandrolone, stanozolol, nandrolone) have significant androgenic activity; hence, virilization is a potential problem for all women patients. Many of the anabolic agents are orally active, as one would predict by noting a 17 α -alkyl group in many of them (see Fig. 23-24). Those without the 17 α -alkyl (nandrolone decanoate and nandrolone phenpropionate) are active only intramuscularly. The 17 α -alkyl products may induce liver toxicity in some patients.

All steroid 4-en-3-ones are light sensitive and should be kept in light-resistant containers.

Testosterone, USP. Testosterone, 17 β -hydroxyandrost-4-en-3-one, is a naturally occurring androgen in men

In women, it mainly serves as a biosynthetic precursor to estradiol but also has other hormonal effects. It is rapidly metabolized to relatively inactive 17-ones (see Fig. 23-23), however, preventing significant oral activity. Testosterone is available in a transdermal delivery system (patch), a gel formulation, and as implantable pellets. Testosterone 17 β -esters are available in long-acting intramuscular depot preparations illustrated in Figure 23-24, including the following:

- Testosterone cypionate, USP: Testosterone 17 β -cyclopentylpropionate
- Testosterone enanthate, USP: Testosterone 17 β -heptanoate
- Testosterone propionate, USP: Testosterone 17 β -propionate

Methyltestosterone, USP. Methyltestosterone, 17 β -hydroxy-17-methylandrosta-4-en-3-one, is only about half as active as testosterone (intramuscularly), but it has the great advantage of being orally active.

Fluoxymesterone, USP. Fluoxymesterone, 9 α -fluoro-11 β ,17 β -dihydroxy-17-methylandrosta-4-en-3-one, is a highly potent, orally active androgen, about 5 to 10 times more potent than testosterone. It can be used for all the indications discussed above, but its great androgenic activity has made it useful primarily for treatment of the androgen-deficient male.

Methandrostenolone, USP. Methandrostenolone, 17 β -hydroxy-17-methylandrosta-1,4-dien-3-one, is orally active and about equal in potency to testosterone.

Oxymetholone, USP. Oxymetholone, 17 β -hydroxy-2-(hydroxymethylene)-17-methylandrostan-3-one, is approved for the treatment of a variety of anemias.

Oxandrolone, USP. Oxandrolone, 17 β -hydroxy-17-methyl-2-oxaandrostan-3-one, is approved to aid in the promotion of weight gain after weight loss following surgery, chronic infections, or severe trauma and to offset protein catabolism associated with long-term corticosteroid use. Oxandrolone is also used to relieve bone pain accompanying osteoporosis. It has been used to treat alcoholic hepatitis and HIV wasting syndrome.

Stanozolol, USP. Stanozolol, 17-methyl-2'*H*-5 α -androsta-2-en-3-one[3,2,*c*]-pyrazol-17 β -ol, is used prophylactically in the management of hereditary angioedema to reduce the frequency and severity of attacks.

Handrolone Decanoate, USP, and Nandrolone Phenpropionate, USP. Nandrolone decanoate, 17 β -hydroxyestr-4-en-3-one 17-decanoate, has been used in the management of certain anemias, but the availability of erythropoietin has greatly reduced this use. Nandrolone phenpropionate is 17 β -hydroxyestr-4-en-3-one 17-(3'-phenyl)propionate.

Danazol and Endometriosis

Danazol, USP. Danazol, 17 α -pregna-2,4-dien-20-yno-13-dioxazol-17-ol (Danocrine), is a weak androgen that,

in spite of the 17 α -ethinyl group, has little estrogenic or progestogenic activity. Danazol has been called a synthetic steroid with diverse biological effects.¹¹⁹ Danazol binds to sex-hormone-binding globulin (SHBG) and decreases the hepatic synthesis of this estradiol and testosterone carrier. Free testosterone thus increases. Danazol inhibits FSH and LH production by the hypothalamus and pituitary. It binds to progesterone receptors, glucocorticoid receptors, androgen receptors, and ERs. Although the exact mechanism of action is unclear, danazol alters endometrial tissue so that it becomes inactive and atrophic, which allows danazol to be an effective treatment for endometriosis. Danazol is also used to treat hereditary angioedema and fibrocystic breast disease.

Antiandrogens

A variety of compounds (Fig. 23-25) have been intensively studied as androgen receptor antagonists, or antiandrogens.^{120, 121} Antiandrogens are of therapeutic use in treating conditions of hyperandrogenism (e.g., hirsutism, acute acne, and premature baldness) or androgen-stimulated cancers (e.g., prostatic carcinoma). The ideal antiandrogen would be nontoxic, highly active, and devoid of any hormonal activity. Both steroidal and nonsteroidal antiandrogens have been investigated, but only nonsteroidal antiandrogens have been approved for use in the United States. Cyproterone acetate, a steroidal antiandrogen, is used in Europe. The steroidal antiandrogens typically have actions at other steroid receptors that limit their use. The nonsteroidal antiandrogens, while lacking hormonal activity, bind with lower affinity to the androgen receptor than the endogenous hormones.

FLUTAMIDE, BICALUTAMIDE, AND NILUTAMIDE

Three nonsteroidal antiandrogens are in clinical use in the United States—flutamide, bicalutamide, and nilutamide (Fig. 23-25). They are mainly used in the management of prostate cancer. Flutamide was the first of these compounds approved for use by the FDA, but liver toxicity and thrice-daily dosing offered room for improvement. It was also determined that a metabolite of flutamide, hydroxyflutamide, had greater antiandrogen action than the parent. Bicalutamide, which has greater potency than flutamide, incorporates a hydroxyl into its structure at the same relative position as in hydroxyflutamide. Bicalutamide is dosed once a day and has less toxicity than flutamide and nilutamide, making it a preferred choice when initiating therapy.

Prostate cancer is strongly androgen sensitive, so by blocking androgen receptors, the cancer can be inhibited or slowed. Studies have shown that these drugs completely inhibit the action of testosterone and other androgens by binding to androgen receptors. In clinical trials when given as a single agent for prostate cancer, serum testosterone and estradiol increase. But when given in combination with a GnRH agonist, such as goserelin or leuprolide, bicalutamide and flutamide do not affect testosterone suppression, which is the result of GnRH. GnRH agonists greatly decrease gonadal function—the medical equivalent of castration in men. Thus, the combination of GnRH with bicalutamide or flutamide blocks the production of testosterone in the testes and androgen receptors in the prostate.

Figure 23-25 ■ Antiandrogens

Antiandrogen Products

Flutamide, USP. Flutamide, 2-methyl-*N*-[4-nitro-3-(trifluoromethyl)phenyl]propanamide (Eulexin), is dosed 3 times daily (250-mg dose; 750-mg total daily dose). A major metabolite of flutamide, hydroxyflutamide, is a more potent androgen receptor antagonist than the parent compound. This metabolite, which is present at a much higher steady-state concentration than is flutamide, contributes a significant amount of the antiandrogen action of this drug. A limiting factor in the use of flutamide is hepatotoxicity in from 1 to 5% of patients. Although the hepatotoxicity usually is reversible following cessation of treatment, rare cases of death associated with hepatic failure have been reported to be associated with flutamide therapy. Diarrhea is also a limiting side effect with flutamide therapy for some patients.

Bicalutamide, USP. Bicalutamide, *N*-4-cyano-3-(trifluoromethyl)phenyl-3-[(4-fluorophenyl)sulfonyl]-2-hydroxy-2-methyl-propanamide (Casodex), is more potent than flutamide and has a much longer half-life (5.9 days versus 6 hours for hydroxyflutamide). Because of the longer half-life, bicalutamide is used for once-a-day (50 mg) treatment of advanced prostate cancer. Bicalutamide is available as a racemic mixture, but both animal and human studies with the androgen receptor show that the *R* enantiomer has higher affinity for the androgen receptor than the *S* enantiomer.¹²²

Nilutamide, USP. Nilutamide, 5,5-dimethyl-3-[4-nitro-3-(trifluoromethyl)phenyl]-2,4-imidazolidinedione, is used in combination with surgical castration for the treatment of metastatic prostate cancer. Nilutamide, which has an elimination half-life of approximately 40 hours, can also be used in once-daily dosing, but it has side effects that limit its use—visual disturbances, alcohol intolerance, and allergic pneumonitis.

Inhibition of 5 α -Reductase

5 α -DHT is important for maintaining prostate function in men. The formation of DHT is mediated by 5 α -reductase, an enzyme that has two distinct forms, type I and type II.¹²³ The type I enzyme is located in the liver and some periph-

eral tissues and is involved mainly in the metabolism of testosterone and other A-ring enones. The type II enzyme is located in the prostate gland and testes and is responsible for the conversion of testosterone to DHT for androgen action. Blocking this enzyme is one approach for controlling androgen action. The 1997 review by Harris and Kozancopoulos provides an excellent background and details the development of finasteride, the first 5 α -reductase inhibitor approved for use in the United States (Fig. 23-26).¹²⁵

DHT also plays a major role in the pathogenesis of benign prostatic hyperplasia (BPH). Finasteride, (5 α ,17 β)-*N*-(4,4-dimethylethyl)-3-oxo-4-azaandrost-1-ene-17-carboxamide (Proscar, Propecia), is a potent, slow, tight-binding inhibitor of 5 α -reductase that functions by a unique mechanism. Finasteride is activated by the enzyme and irreversibly binds to the NADP cofactor, yielding a finasteride-NADP complex that is only slowly released from the enzyme active site, producing essentially irreversible inhibition of the enzyme (Fig. 23-27).¹²⁶ The turnover from the finasteride-5 α -reductase complex is very slow (*t*_{1/2} ~30 days).

Figure 23-26 ■ Steroid 5 α -reductase inhibitors

Figure 23-27 ■ Comparison of 5 α -reductase action on testosterone and finasteride. This scheme is an oversimplification of the exact mechanisms, but it indicates that when finasteride is bound at the active site of 5 α -reductase, NADPH is positioned closer to C1 of finasteride than to the normal C5 of testosterone, leading to essentially irreversible inhibition.

Finasteride is a relatively selective inhibitor of type II 5 α -reductase. This enzyme is present in high levels in the prostate and at lower levels in other tissues. Because of the strong connection to the formation of DHT in the prostate, it was theorized that specific inhibition of this isoform would yield the greatest therapeutic effect. More recent studies suggest, however, that the type I isoform may also play a role in the progression of hormone-dependent prostate cancer.¹²⁷ Because of this, dual 5 α -reductase inhibitors have been developed. Dutasteride, a compound recently approved for treating BPH, inhibits both isoforms of the enzyme and may be found to have superior therapeutic effects once it is broadly used (Fig. 23-26). Dutasteride bears an aromatic amide at C17, rather than the *t*-butyl amide seen in finasteride.

A second use of finasteride is in the treatment of male pattern baldness. The conversion of testosterone to DHT in advancing years leads to thinning of hair in men. Inhibition of this conversion was envisioned as a possible baldness treatment. After finasteride was shown to be safe and effective

in the treatment of BPH, a lower dose formulation was studied for treating male pattern baldness. The trials were a success, and Propecia (1 mg/day) was the result. Although finasteride preferentially inhibits the type II enzyme, it is believed to be the peripheral type-I 5 α -reductase that is being targeted for the baldness treatment. Dutasteride is also being investigated for use as a baldness treatment.

Saw palmetto (*Serenoa repens*) extract is an herbal product used to treat BPH, and it has been suggested that the effects can be attributed to a constituent of the extract with 5 α -reductase inhibition, but other mechanisms have also been proposed.¹²⁸ Further studies and identification of a specific component that inhibits 5 α -reductase are necessary.

ADRENAL CORTEX HORMONES

Endogenous Corticosteroids

The adrenal glands (which lie just above the kidneys) secrete over 50 different steroids, including precursors for other ste-

roid hormones. The most important hormonal steroids produced by the adrenal cortex, however, are aldosterone and hydrocortisone. Aldosterone is the primary *mineralocorticoid* in humans (i.e., it causes significant salt retention). Hydrocortisone is the primary *glucocorticoid* in humans (i.e., it has its primary effects on intermediary metabolism). The glucocorticoids have become very important in modern medicine, especially for their anti-inflammatory effects.

Aldosterone and, to a lesser extent, other mineralocorticoids maintain a constant electrolyte balance and blood vol-

ume. The glucocorticoids have key roles in controlling carbohydrate, protein, and lipid metabolism.

Biosynthesis

As shown in the scheme in Figure 23-28, aldosterone and hydrocortisone are biosynthesized from pregnenolone through a series of steps involving hydroxylations at C17, C11, and C21 that convert pregnenolone to hydrocortisone. Deficiencies in any of the enzymes cause congenital adrenal

Figure 23-28 ■ Biosynthesis of hydrocortisone and aldosterone.

hyperplasia. Defects in the gene regulation, as well as the enzymes that catalyze the hydroxylation have been studied intensively.^{129–131} Investigators have linked defects in particular genes or steroid-binding sites to the pathophysiology of patients with the corresponding metabolic diseases.¹³¹

These disorders are usually caused by an inability of the adrenal glands to carry out 11 β -, 17 α -, or 21-hydroxylations. The most common is a lack of 21-hydroxylase activity, which will result in decreased production of hydrocortisone and a compensatory increase in adrenocorticotrophic hormone (ACTH) production. Furthermore, the resultant buildup of 17 α -hydroxyprogesterone will lead to an increase of testosterone. The 21-hydroxylase is important for the synthesis of both mineralocorticoids and glucocorticoids. When 11 β -hydroxylase activity is low, large amounts of 11-deoxycorticosterone will be produced. Because 11-deoxycorticosterone is a potent mineralocorticoid, there will be symptoms of mineralocorticoid excess, including hypertension. When 17 α -hydroxylase activity is low, there will be decreased production of testosterone and estrogens as well as hydrocortisone.

Although the details are not completely known, the 39-amino acid peptide ACTH (corticotropin) produced by the anterior pituitary is necessary for the conversion of cholesterol to pregnenolone. ACTH acts at the ACTH receptor, a G-protein-coupled receptor that activates adenylyl cyclase, leading to increased cAMP levels. Activation of the ACTH receptors has short- and long-term effects on steroidogenesis. The short-term phase involves an increase in the supply of cholesterol for use by cytochrome P-450_{sc} in the formation of pregnenolone. The long-term effects are due to increased transcription of steroidogenic enzymes.¹³² An overall result of ACTH action is increased synthesis and release of hydrocortisone. Hydrocortisone then acts by feedback inhibition to suppress the formation of additional ACTH. (ACTH is discussed in more detail in Chapter 25.)

The release of the primary mineralocorticoid aldosterone depends only slightly on ACTH. Aldosterone is an active part of the angiotensin–renin–blood pressure cycle that controls blood volume. A decrease in blood volume stimulates the kidneys to secrete the enzyme renin. Renin, in turn, converts angiotensinogen to angiotensin, which stimulates the adrenal cortex to release aldosterone. Aldosterone then causes the kidneys to retain sodium, and blood volume increases. When the blood volume has increased sufficiently, renin production decreases, until blood volume drops again.

Metabolism of Hydrocortisone

Hydrocortisone and cortisone are enzymatically interconvertible, and thus one finds metabolites with both the 11-keto and the 11 β -hydroxy functionality. Most of the metabolic processes occur in the liver, with the metabolites excreted primarily in the urine. Although many metabolites have been isolated, the primary routes of catabolism are (a) reduction of the C4,5 double bond to yield 5 β -pregnanes, (b) reduction of the 3-one to give 3 α -ols, and (c) reduction of the 20-one to the corresponding 20 α - and 20 β -ols. These are the same steps that are involved in progesterone metabolism. The two primary metabolites are tetrahydrocortisol and tetrahydrocortisone and their conjugates. The cortols (20 α and 20 β),

Figure 23–29 ■ Metabolites of cortisone and hydrocortisone.

cortolones (20 α and 20 β), and 11 β -hydroxyetiocholanolone are some of the minor metabolites of hydrocortisone (Fig. 23–29).

Biological Activities of Mineralocorticoids and Glucocorticoids

The adrenocortical steroids permit the body to adjust to environmental changes, to stress, and to changes in the diet. Aldosterone and, to a lesser extent, other mineralocorticoids maintain a constant electrolyte balance and blood volume, and the glucocorticoids have key roles in controlling carbohydrate, protein, and lipid metabolism.

Aldosterone increases sodium reabsorption in the kidneys. An increase in plasma sodium concentration, in turn, will lead to increased blood volume, because blood volume and urinary excretion of water are directly related to the plasma sodium concentration. Simultaneously, aldosterone increases potassium ion excretion. 11-Deoxycorticosterone also is quite active as a mineralocorticoid. Similar actions are exhibited with hydrocortisone and corticosterone, but to a much smaller degree.

Aldosterone controls the movement of sodium ions in most epithelial structures involved in active sodium transport. Although aldosterone acts primarily on the distal convoluted tubules of the kidneys, it also acts on the proximal convoluted tubules and collecting ducts. Aldosterone controls the transport of sodium in sweat glands, small intestine, salivary glands, and the colon. In all of these tissues, aldosterone enhances the inward flow of sodium ions and promotes the outward flow of potassium ions.

The glucocorticoids have many physiological and pharmacological actions. They control or influence carbohydrate, protein, lipid, and purine metabolism. They also affect the cardiovascular and nervous systems and skeletal muscle. They regulate growth hormone gene expression. In addition, glucocorticoids have anti-inflammatory and immunosuppressive actions that arise through complex mechanisms.

Glucocorticoids stimulate glycogen storage synthesis by inducing the synthesis of glycogen synthase and stimulate gluconeogenesis in the liver. They have a catabolic effect on muscle tissue, stimulating the formation and transamination of amino acids into glucose precursors in the liver. The catabolic actions in Cushing's syndrome are demonstrated by wasting of the tissues, osteoporosis, and reduced muscle mass. Lipid metabolism and synthesis increase significantly in the presence of glucocorticoids, but the actions usually seem to depend on the presence of other hormones or cofactors. A lack of adrenal cortex steroids also causes depression, irritability, and even psychoses, reflecting significant effects on the central nervous system.

ANTI-INFLAMMATORY/IMMUNOSUPPRESSIVE ACTIONS OF GLUCOCORTICOID¹³³⁻¹³⁷

Glucocorticoid-receptor complexes (see Fig. 23-7) may activate or repress the genes to which they associate. Repression in particular may have an important role in glucocorticoid anti-inflammatory actions. Glucocorticoids inhibit the transcription of genes encoding cytokines such as interferon- γ , tumor necrosis factor- α (TNF- α), the interleukins, and granulocyte/monocyte colony-stimulating factor, all factors involved in the immune system and inflammatory responses.¹³² Glucocorticoids inhibit the production and release of other mediators of inflammation, including prostaglandins, leukotrienes, and histamine. In addition, glucocorticoids inhibit the expression of the gene encoding collagenase, an important enzyme involved with inflammation.

RESISTANCE TO GLUCOCORTICOID¹³⁸⁻¹⁴⁰

A few patients with chronic inflammatory illnesses such as asthma, rheumatoid arthritis, and lupus develop resistance to the anti-inflammatory effects of the glucocorticoids. The

mechanism is not fully understood but appears to be a decrease in the binding or activation ability of glucocorticoid receptor complexes and their target or "activator" genes. Disruption of the translocation of the glucocorticoid receptor to the nucleus has also been implicated in glucocorticoid resistance.¹⁴¹

Structural Classes: Mineralocorticoids and Glucocorticoids

Medically important adrenal cortex hormones and synthetic mineralocorticoids and glucocorticoids are shown in Figure 23-30. Because salt retention activity is usually undesirable, the drugs are classified by their salt retention activities. As illustrated in Figure 23-30, the adrenal cortex hormones are classified by their biological activities into three major groups.

MINERALOCORTICOID⁵

The mineralocorticoids are adrenal cortex steroids and analogues with high salt-retaining activity. They are used mainly for treatment of Addison's disease, or primary adrenal insufficiency. The naturally occurring hormone aldosterone has an 11 β -OH and an 18-CHO that naturally bridge to form a hemiacetal (as drawn in Fig. 23-28). Aldosterone is too expensive to produce commercially; therefore other semisynthetic analogues have taken its place for treatment of Addison's disease. Adding a 9 α -fluoro group to hydrocortisone greatly increases both salt retention and anti-inflammatory activity. Deoxycorticosterone (11-deoxy), an intermediate in the biosynthesis of aldosterone, has lower mineralocorticoid activity than aldosterone (~20-fold) but may play a role if the 11 β -hydroxylase is deficient. Deoxycorticosterone is not available for therapeutic uses.

Extensive modifications have been made to the basic hydrocortisone structure to alter the properties of glucocorticoids. Modifications at all sites of the steroid backbone have been tried. Aside from addition of a double bond at C1-C2, the most beneficial changes are made to rings B and D of the steroid skeleton and modification of the C17 side chain. Table 23-7 summarizes the relative effects of various substituents seen in commercially available products on salt retention and glucocorticoid activity. The salt-retaining actions

TABLE 23-7 Effects of Substituents on Glucocorticoid/Mineralocorticoid Activity

Functional Group	Glycogen Deposition	Anti-inflammatory Activity	Effects on Urinary Sodium ^a

^a+, retention; -, excretion.

are approximately additive. For example, the 3+ increase in salt retention of a 9 α -fluoro group can be eliminated by the 3- decrease of a 6 α -methyl.

GLUCOCORTICOIDS WITH MODERATE-TO-LOW SALT RETENTION

The glucocorticoids with moderate-to-low salt retention include cortisone, hydrocortisone, and their 1-enes prednisolone and prednisone. As shown in Table 23-8, an 11 β -OH maintains good topical anti-inflammatory activity, but 11-ones have little or none. The 11 β -hydroxysteroid dehydrogenase in the skin oxidizes an 11 β -hydroxyl to an 11-ketone.¹⁴² For activation of an 11-one glucocorticoid for topical action, reduction at C11 would be necessary. The 1-ene of prednisolone and prednisone increases anti-inflammatory activity about fourfold and somewhat decreases salt retention. Duax and coworkers²⁰ have shown that the increase in

lone and prednisone. As shown in Table 23-8, an 11 β -OH maintains good topical anti-inflammatory activity, but 11-ones have little or none. The 11 β -hydroxysteroid dehydrogenase in the skin oxidizes an 11 β -hydroxyl to an 11-ketone.¹⁴² For activation of an 11-one glucocorticoid for topical action, reduction at C11 would be necessary. Figure 23-30 ■ Natural and synthetic corticosteroids.

Figure 23-30 ■ Continued.

activity may be due to a change in shape of ring A. Specifically, analogues more active than hydrocortisone appear to have their ring A bent underneath the molecule to a much greater extent than hydrocortisone.

The $11\beta\text{-OH}$ of hydrocortisone is of major importance in binding to the receptors. Cortisone is reduced in vivo to yield hydrocortisone as the active agent. The increased activity of 9α -halo derivatives may be due to the electron-withdrawing inductive effect on the $11\beta\text{-OH}$, making it more acidic and, therefore, better able to form hydrogen bonds with the recep-

tor. A 9α -halo substituent also reduces oxidation of the $11\beta\text{-OH}$ to the inactive 11 -one.

GLUCOCORTICOIDS WITH VERY LITTLE OR NO SALT RETENTION

Cortisone and hydrocortisone, and even prednisone and prednisolone, have too much salt-retaining activity in the doses needed for some therapeutic purposes. Over the past several decades, a number of substituents have been discov-

TABLE 23-8 Approximate Relative Activities of Corticosteroids^a

	Anti-Inflammatory Activity	Topical Activity	Salt-Retaining Activity	Equivalent Dose (mg)
Mineralocorticoids				
Aldosterone	0.2	0.2	800	
Deoxycorticosterone	0	0	40

Dexamethasone	30	10–35	0	0.75

^a The data in this table are only approximate. Blanks indicate that comparative data are not available to the author or that the product has only one use (e.g., topical). Data were taken from several sources, and there is an inherent risk in comparing such data. The table should, however, serve as a guide to relative activities.

ered that greatly decrease salt retention. They include 16 α -hydroxy; 16 α ,17 α -ketal; 6 α -methyl; and 16 α - and 16 β -methyl. Other substituents have been found to increase both glucocorticoid and mineralocorticoid activities: 1-ene, 9 α -fluoro, 9 α -chloro, and 21-hydroxy.

As a result of the great economic benefit of having a potent anti-inflammatory product on the market, pharmaceutical manufacturers have made numerous combinations of these various substituents. In almost every case a 16-methyl or a modified 16-hydroxy (to eliminate salt retention) has been combined with another substituent to increase glucocorticoid or anti-inflammatory activity. The number of permutations and combinations has resulted in a redundant array of analogues with very low salt retention and high anti-inflammatory activity.

A primary goal of these highly anti-inflammatory drugs has been to increase topical potency. As shown in Table 23-8, some are as much as 100 times more active topically than hydrocortisone. Relative potency is as follows:

Very high potency

- Augmented betamethasone dipropionate ointment, 0.05%
- Clobetasol propionate, 0.05%
- Diffurasone diacetate ointment, 0.05%

High potency

- Amcinonide, 0.1%
- Betamethasone dipropionate ointment, 0.05%
- Desoximetasone, 0.25%
- Diffurasone diacetate cream, 0.05%
- Fluocinonide, 0.05%
- Halcinonide, 0.1%
- Halobetasol propionate, 0.05%
- Triamcinolone acetonide, 0.5%

Medium potency

- Betamethasone valerate, 0.1%
- Clocortolone pivalate, 0.1%
- Desoximetasone, 0.05%
- Fluocinolone acetonide, 0.025%
- Fluticasone propionate, 0.005%
- Hydrocortisone butyrate, 0.1%
- Hydrocortisone valerate, 0.2%
- Mometasone furoate, 0.1%
- Prednicarbate, 0.1%
- Triamcinolone acetonide, 0.1%

Low potency

- Aclometasone dipropionate, 0.05%
- Desonide, 0.05%
- Fluocinolone acetonide, 0.01%
- Triamcinolone acetonide cream, 0.1%

Lowest potency

- Hydrocortisone, 1.0%
- Hydrocortisone, 2.5%

Although, as shown in Table 23-8, cortisone and prednisone are not active topically, most other glucocorticoids are active. Some compounds, such as clobetasol and betamethasone dipropionate, have striking activity topically. Skin absorption is favored by increased lipid solubility of the drug.

Absorption of topical glucocorticoids can also be greatly affected by the extent of skin damage, concentration of the glucocorticoid, cream or ointment base used, and similar factors. One must not assume, therefore, from a study of Table 23-8 that, for example, a 0.25% cream of prednisolone is necessarily exactly equivalent in anti-inflammatory potency to 1% hydrocortisone. Nevertheless, the table can serve as a preliminary guide. Furthermore, particular patients may seem to respond better to one topical anti-inflammatory

glucocorticoid than to another, irrespective of the relative potencies shown in Table 23-8.

RISK OF SYSTEMIC ABSORPTION

The topical corticosteroids do not typically cause significant absorption effects when used on small areas of intact skin. When these compounds are used on large areas of the body, however, systemic absorption may occur, especially if the skin is damaged or if occlusive dressings are used. Up to 20 to 40% of hydrocortisone given rectally may also be absorbed.

Therapeutic Uses of Adrenal Cortex Hormones

The adrenocortical steroids are used primarily for their glucocorticoid effects, including immunosuppression, anti-inflammatory activity, and antiallergic activity. The mineralocorticoids are used only for treatment of Addison's disease. Addison's disease is caused by chronic adrenocortical insufficiency and may be due to either adrenal or anterior pituitary failure. The glucocorticoids are also used in the treatment of congenital adrenal hyperplasias.

The symptoms of Addison's disease illustrate the great importance of the adrenocortical steroids in the body and, especially, the importance of aldosterone. These symptoms include increased loss of body sodium, decreased loss of potassium, hypoglycemia, weight loss, hypotension, weakness, increased sensitivity to insulin, and decreased lipolysis.

Hydrocortisone is also used during postoperative recovery after surgery for Cushing's syndrome—excessive adrenal secretion of glucocorticoids. Cushing's syndrome can be caused by bilateral adrenal hyperplasia or adrenal tumors and is treated by surgical removal of the tumors or resection of hyperplastic adrenal gland(s).

The use of glucocorticoids during recovery from surgery for Cushing's syndrome illustrates a most important principle of glucocorticoid therapy: abrupt withdrawal of glucocorticoids may result in adrenal insufficiency, showing clinical symptoms similar to those of Addison's disease. For that reason, patients who have been on long-term glucocorticoid therapy must have the dose reduced gradually. Furthermore, prolonged treatment with glucocorticoids can cause adrenal suppression, especially during times of stress. The symptoms are similar to those of Cushing's syndrome, such as rounding of the face, hypertension, edema, hypokalemia, thinning of the skin, osteoporosis, diabetes, and even subcapsular cataracts.

The glucocorticoids are used in the treatment of collagen vascular diseases, including rheumatoid arthritis and disseminated lupus erythematosus. Although there is usually prompt remission of redness, swelling, and tenderness by the glucocorticoids in rheumatoid arthritis, continued long-term use may lead to serious systemic forms of collagen disease. As a result, the glucocorticoids should be used infrequently in rheumatoid arthritis.

The glucocorticoids are used extensively topically, orally, and parenterally to treat inflammatory conditions. They also usually relieve the discomforting symptoms of many allergic conditions—intractable hay fever, exfoliative dermatitis, generalized eczema, and others. The glucocorticoids are also

used to treat asthmatic symptoms unresponsive to bronchodilators. They are especially useful in inhaled formulations (see section below). The glucocorticoids' lymphocytopenic actions make them particularly useful for treatment of chronic lymphocytic leukemia in combination with other antineoplastic drugs.

The adrenocortical steroids are contraindicated or should be used with great caution in patients who have (a) peptic ulcer (in which the steroids may cause hemorrhage), (b) heart disease, (c) infections (the glucocorticoids suppress the body's normal infection-fighting processes), (d) psychoses (since behavioral disturbances may occur during steroid therapy), (e) diabetes (the glucocorticoids increase glucose production, so more insulin may be needed), (f) glaucoma, (g) osteoporosis, or (h) herpes simplex involving the cornea.

When administered topically, the glucocorticoids present relatively infrequent therapeutic problems, but their anti-inflammatory action can mask symptoms of infection. Many physicians prefer not giving a topical anti-inflammatory steroid until after an infection is controlled with topical antibiotics. The immunosuppressive activity of the topical glucocorticoids can also prevent natural processes from curing the infection. Topical steroids actually may also cause dermatoses in some patients.

Finally, as discussed above with the oral contraceptive steroid hormones should not be used during pregnancy. If it is absolutely necessary to use glucocorticoids topically during pregnancy, they should be limited to small areas of intact skin and used for a limited time.

Mineralocorticoid and Glucocorticoid Products

The corticosteroids used in commercial products are shown in Figures 23-30, 23-31, and 23-32. The structures illustrate the usual changes (see Fig. 23-6) made to modify solubility of the products and, therefore, their therapeutic uses. In particular, the 21-hydroxyl can be converted to an ester to make it less water soluble to modify absorption or to a phosphate ester salt or hemisuccinate ester salt to make it more water soluble and appropriate for intravenous use. The products also reflect the structure-activity relationship changes discussed above to increase anti-inflammatory activity or potency or decrease salt retention.

Again, patients who have been on long-term glucocorticoid therapy must have the dose reduced gradually. This "critical rule" and indications are discussed above under the heading, Therapeutic Uses of Adrenal Cortex Hormones. Dosage schedules and gradual dosage reduction can be quite complex and specific for each indication.

Many of the glucocorticoids are available in topical dosage forms, including creams, ointments, aerosols, lotions, and solutions. They are usually applied 3 to 4 times a day to well-cleaned areas of affected skin. Ointments are usually prescribed for dry, scaly dermatoses. Lotions are well suited for weeping dermatoses. Creams are of general use for many other dermatoses. When applied to very large areas of skin or to damaged areas of skin, significant systemic absorption can occur. The use of an occlusive dressing can also greatly increase systemic absorption.

The glucocorticoids that are mainly used for inflammation of the eye are shown in Figure 23-31. These compounds differ structurally from other glucocorticoids, in that the 21-

Figure 23-31 ■ Ophthalmic glucocorticoids.

hydroxyl is missing from medrysone, fluorometholone, and rimexolone, while loteprednol etalbonate has a modified ester at C17 that leads to rapid degradation upon systemic absorption.

MINERALOCORTICOIDS

Fludrocortisone Acetate, USP. Fludrocortisone acetate, 21-acetyloxy-9-fluoro-11 β ,17-dihydroxypregn-4-ene-3,20-dione, 9 α -fluorohydrocortisone (Florinef Acetate), is used only for the treatment of Addison's disease and for inhibition of endogenous adrenocortical secretions. As shown in Table 23-8, it has up to about 800 times the mineralocorticoid activity of hydrocortisone and about 11 times the glucocorticoid activity. Its potent activity stimulated the synthesis and study of the many fluorinated steroids shown in Figure 23-30. Although its great salt-retaining activity limits its use to Addison's disease, it has sufficient glucocorticoid activity that in some cases of the disease, additional glucocorticoids need not be prescribed.

GLUCOCORTICOIDS WITH MODERATE-TO-LOW SALT RETENTION

Hydrocortisone, USP. Hydrocortisone, 11 β ,17,21-trihydroxypregn-4-ene-3,20-dione, is the primary natural glucocorticoid in humans. Despite the large number of synthetic glucocorticoids, hydrocortisone, its esters, and its salts remain a mainstay of modern adrenocortical steroid therapy and the standard for comparison of all other glucocorticoids and mineralocorticoids (see Table 23-8). It is used for all the indications mentioned above. Its esters and salts illustrate the principles of chemical modification to modify pharmacokinetic use shown in Figure 23-6. The commercially available salts and esters (see Fig. 23-30) include

Hydrocortisone acetate, USP (21-acetate)
 Hydrocortisone butyrate, USP (17-butyrate, 21-propionate)
 Hydrocortisone butyrate, USP (17-butyrate)
 Hydrocortisone cypionate, USP (21-cypionate)
 Hydrocortisone sodium phosphate, USP (21-sodium phosphate)
 Hydrocortisone sodium succinate, USP (21-sodium succinate)
 Hydrocortisone valerate, USP (17-valerate)

Cortisone Acetate, USP. Cortisone acetate, 21-(acetyloxy)-17-hydroxypregn-4-ene-3,11,20-trione, is the 21-acetate of naturally occurring cortisone with good systemic anti-inflammatory activity and low-to-moderate salt-retention activity after its *in vivo* conversion to hydrocortisone acetate. This conversion is mediated by 11 β -hydroxysteroid dehydrogenase. It is used for the entire spectrum of uses discussed above under the heading, Therapeutic Uses of Adrenal Cortex Hormones—collagen diseases, Addison's disease, severe shock, allergic conditions, chronic lymphocytic leukemia, and many other indications. Cortisone acetate is relatively ineffective topically, mainly because it must be reduced *in vivo* to hydrocortisone. Its plasma half-life is only about 30 minutes, compared with 90 minutes to 3 hours for hydrocortisone.

Prednisolone, USP. Prednisolone, Δ^1 -hydrocortisone, 11 β ,17,21-trihydroxypregna-1,4-diene-3,20-dione, has less salt-retention activity than hydrocortisone (see Table 23-8), but some patients have more frequently experienced complications such as gastric irritation and peptic ulcers. Because of low mineralocorticoid activity, it cannot be used alone for adrenal insufficiency. Prednisolone is available in a variety of salts and esters to maximize its therapeutic utility (see Fig. 23-30):

Prednisolone acetate, USP (21-acetate)
 Prednisolone sodium phosphate, USP (21-sodium phosphate)
 Prednisolone sodium succinate, USP (21-sodium succinate)
 Prednisolone tebutate, USP (21-tebutate)

Prednisone, USP. Prednisone, Δ^1 -cortisone, 17,21-dihydroxypregna-1,4-diene-3,11,20-trione, has systemic activity very similar to that of prednisolone, and because of its lower salt-retention activity, it is often preferred over cortisone or hydrocortisone. Prednisone must be reduced *in vivo* to prednisolone to provide the active glucocorticoid.

GLUCOCORTICOIDS WITH VERY LITTLE OR NO SALT RETENTION

Most of the key differences between the many glucocorticoids with minimal salt retention (see Fig. 23-30) have been

summarized in Tables 23-7 and 23-8. The tremendous therapeutic and, therefore, commercial importance of these drugs has stimulated the proliferation of new compounds and their products. Many compounds also are available as salts or esters to give the complete range of therapeutic flexibility illustrated in Figure 23-30. When additional pertinent information is available, it is given below. The systemic name for each drug is provided after the common name.

Alclometasone Dipropionate, USP. Alclometasone dipropionate, 7 α -chloro-11 β -hydroxy-16 α -methyl-17,21-bis(1-oxopropoxy)-pregna-1,4-diene-3,20-dione (Aclovate), is one of the few commercially used glucocorticoids that bears a halogen substituent in the 7 α position.

Amcinonide, USP. Amcinonide, 21-(acetyloxy)-16 α ,17-[cyclopentylidenebis(oxy)]-9-fluoro-11 β -hydroxypregna-1,4-diene-3,20-dione (Cyclocort).

Beclomethasone Dipropionate, USP. Beclomethasone dipropionate, 9-chloro-11 β -hydroxy-16 β -methyl-17,21-bis(1-oxopropoxy)-pregna-1,4-diene-3,20-dione (Beconase, Vancenase, Vanceril, QVAR), is used in nasal sprays and aerosol formulations to treat allergic rhinitis and asthma (see section below).

Betamethasone, USP. Betamethasone, 9-fluoro-11 β ,17,21-trihydroxy-16 β -methylpregna-1,4-diene-3,20-dione, is available as a variety of ester derivatives.

Betamethasone valerate, USP (17-valerate)
Betamethasone acetate, USP (21-acetate)
Betamethasone sodium phosphate, USP (21-sodium phosphate)
Betamethasone dipropionate, USP (17-propionate, 21-propionate)

Budesonide, USP. Budesonide, 16 α ,17-[butylidenebis(oxy)]-11 β ,21-dihydroxypregna-1,4-diene-3,20-dione (Entocort), in oral capsules is used to treat Crohn's disease. The affinity for the GR is approximately 200-fold greater than that of hydrocortisone and 15-fold greater than that of prednisolone. Budesonide is a mixture of epimers, with the 22R form having twice the affinity for the GR of the S epimer. This glucocorticoid is metabolized by CYP 3A4, and its levels can be increased in the presence of potent CYP 3A4 inhibitors. Budesonide is also used in an inhaled formulation for the treatment of asthma (see below).

Clobetasol Propionate, USP. Clobetasol propionate, 21-chloro-9-fluoro-11 β -hydroxy-16 β -methyl-17-(1-oxopropoxy)-pregna-1,4-diene-3,20-dione (Temovate).

Clocortolone Pivalate, USP. Clocortolone pivalate, 9-chloro-21-(2,2-dimethyl-1-oxopropoxy)-6 α -fluoro-11 β -hydroxy-16 α -methylpregna-1,4-diene-3,20-dione (Cloderm), along with desoximetasone, lacks the C17 α oxygen functionality that is present in other glucocorticoids but still retains good glucocorticoid activity.

Desonide, USP. Desonide, 11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione (DesOwen, Tridesiol).

Desoximetasone, USP. Desoximetasone, 9-fluoro-11 β ,21-dihydroxy-16 α -methylpregna-1,4-diene-3,20-dione, like clocortolone pivalate, lacks a C17 α hydroxyl group in its structure.

Dexamethasone, USP. Dexamethasone, 9-fluoro-11 β ,17,21-trihydroxy-16 α -methylpregna-1,4-diene-3,20-dione, is the 16 α isomer of betamethasone.

Dexamethasone acetate, USP (21-acetate)
Dexamethasone sodium phosphate, USP (21-sodium phosphate)

Diflorasone Diacetate, USP. Diflorasone diacetate, 17,21-bis(acetyloxy)-6 α ,9-difluoro-11 β -hydroxy-16 α -methylpregna-1,4-diene-3,20-dione.

Flunisolide, USP. Flunisolide, 6 α -fluoro-11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione. (See following section for use of flunisolide in the treatment of asthma.)

Fluocinolone Acetonide, USP. Fluocinolone acetonide, 6 α ,9-difluoro-11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione, also known as 6 α -fluorotriamcinolone acetonide, is the 21-acetate derivative of fluocinolone acetonide and is about 5 times more potent than fluocinolone acetonide in at least one topical activity assay.

Fluorometholone, USP. Fluorometholone, 9-fluoro-11 β ,17-dihydroxy-6 α -methylpregn-4-ene-3,20-dione (FluorOp, FML), lacks the typical C21 hydroxyl group of glucocorticoids and is used exclusively in ophthalmic products. The 17-acetate of fluorometholone is also used as an ophthalmic suspension (Flarex).

Flurandrenolide, USP. Flurandrenolide, 6 α -fluoro-11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregn-4-ene-3,20-dione, although available as a tape product, can stick to and remove damaged skin, so it should be avoided with vesicular or weeping dermatoses.

Fluticasone Propionate, USP. Fluticasone propionate, 5-(fluoromethyl)-6 α ,9-difluoro-11 β -hydroxy-16 α -methyl-3-oxo-17 α -(1-oxopropoxy)androsta-1,4-diene-17-carbaldehyde (Cutivate), is 3- to 5-fold more potent than dexamethasone in receptor binding assays. (See also the following section on inhaled corticosteroids.)

Halcinonide. Halcinonide, 21-chloro-9-fluoro-11 β -hydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregn-4-ene-3,20-dione, was the first chloroglucocorticoid marketed. Like many of the other potent glucocorticoids, it is used only topically.

Halobetasol Propionate, USP. Halobetasol propionate, 21-chloro-6 α ,9-difluoro-11 β -hydroxy-16 β -methyl-17-(1-oxopropoxy)pregna-1,4-diene-3,20-dione.

Loteprednol Etabonate, USP. Loteprednol etabonate, chloromethyl 17 α -(ethoxycarbonyloxy)-11 β -hydroxy-3-oxoandrost-1,4-diene-17-carboxylate (Alrex, Lotemax), has a modified carboxylate at the C17 position rather than the typical ketone functionality. This modification maintains affinity for the glucocorticoid receptor but allows facile metabolism to inactive metabolites. This limits the systemic action of the drug. Loteprednol etabonate is used as an ophthalmic suspension that has greatly reduced systemic action due to rapid metabolism to the inactive carboxylate (Fig. 23-31).

Medrysone, USP. Medrysone, 11 β -hydroxy-6 α -methylpregn-4-ene-3,20-dione, is unique among the corticosteroids, in that it lacks the usual 17 α ,21-diol system of the others (Fig. 23-31). Currently, it is used only for treatment of inflammation of the eyes.

Methylprednisolone, USP. Methylprednisolone, 11 β , 17,21-trihydroxy-6 α -methyl-1,4-pregnadiene-3,20-dione, is available unmodified or as ester derivatives.

Methylprednisolone acetate, USP
Methylprednisolone sodium succinate, USP

Mometasone Furoate, USP. Mometasone furoate, 9,21-dichloro-17 α -(2-furanylcarbonyloxy)-11 β -hydroxy-16 α -methylpregna-1,4-diene-3,20-dione (Elocon), is a high-potency glucocorticoid available in cream, lotion, or ointment formulations for topical use. In addition, mometasone furoate monohydrate is formulated in a nasal spray for treating allergic rhinitis (see following section).

Prednicarbate, USP. Prednicarbate, 17-(ethoxycarbonyloxy)-11 β -hydroxy-21-(1-oxopropoxy)pregna-1,4-diene-3,20-dione, is a prednisolone derivative with a C21 propionate ester and a C17 ethyl carbonate group. It is available for use only in a 0.1% topical cream. Prednicarbate is a medium-potency glucocorticoid.

Rimexolone, USP. Rimexolone, 11 β -hydroxy-16 α ,17 α -dimethyl-17-(1-oxopropyl)androst-1,4-diene-3-one, like medrysone and fluorometholone, lacks the C21 hydroxyl group. In addition, rimexolone has an additional methyl group in the 17 α position, a site where a hydroxyl group is typically found. Rimexolone is available as a suspension for ophthalmic use (Fig. 23-31).

Triamcinolone, USP. Triamcinolone, 9-fluoro-11 β ,16 α , 17,21-tetrahydropregna-1,4-diene-3,20-dione.

Triamcinolone acetonide, USP: Triamcinolone-16 α ,17-acetonide
Triamcinolone hexacetonide, USP: Triamcinolone acetonide 21-[3-(3,3-dimethyl)butyrate]
Triamcinolone diacetate, USP: 16,21-Diacetate

Triamcinolone acetonide is approximately 8 times more potent than prednisone in animal inflammation models. Topically applied triamcinolone acetonide is a potent anti-inflammatory agent (see Table 23-8), about 10 times more so

than triamcinolone. The plasma half-life is approximately 90 minutes, although the plasma half-life and biological half-lives for glucocorticoids do not correlate well. The hexacetonide is slowly converted to the acetonide in vivo and is given only by intra-articular injection. Only triamcinolone and the diacetate are given orally. The acetonide and diacetate may be given by intra-articular or intrasynovial injection; additionally, the acetonide may be given by intrabursal or, sometimes, intramuscular or subcutaneous injection. A single intramuscular dose of the diacetate or acetonide may last up to 3 or 4 weeks. Plasma levels with intramuscular doses of the acetonide are significantly higher than with triamcinolone itself. The acetonide is also used to treat asthma and allergic rhinitis (see following section).

INHALED CORTICOSTEROIDS FOR ASTHMA AND ALLERGIC RHINITIS

The National Asthma Education and Prevention Program has provided recent recommendations on the treatment of asthma, including a strong recommendation for the first-line use of inhaled corticosteroids for severe and moderate persistent asthma in all age groups. The corticosteroids currently used in inhaled formulations are all relatively potent topical corticosteroids that have the advantage of rapid deactivation/inactivation for the portion of the dose that is swallowed. The development of glucocorticoids that are efficiently inactivated metabolically when swallowed has greatly reduced the systemic side effects associated with the use of steroids in asthma treatment. The older corticosteroids that are used orally (e.g., methylprednisolone, prednisolone, and prednisone) have much greater systemic side effects, and their use should be limited, if possible. Although systemic side effects are reduced, they are not completely eliminated. The side effects can vary with the steroid used and the frequency of administration.

The five glucocorticoids that are currently approved for use in the United States for asthma as inhaled formulations are beclomethasone dipropionate, budesonide, flunisolide, fluticasone propionate, and triamcinolone acetonide (Fig. 23-32). Mometasone furoate will likely be added soon for an asthma indication. Ciclesonide is the newest glucocorticoid being pursued for use in the treatment of asthma. Ciclesonide is in phase III clinical trials and may be available in the United States within a few years. Clinical trials suggest that it may have better tolerability than some of the currently available inhaled steroids.

The following agents are also available in nasal inhalers for the treatment of allergic rhinitis. Details are provided below for the mode of metabolic inactivation involved for each of these products. Although all of these agents have much lower systemic effects than the oral steroids, some systemic effects, as measured by suppression of the hypothalamic–pituitary–adrenal (HPA) axis, have been observed for these products.

GLUCOCORTICOIDS FOR ASTHMA AND ALLERGIC RHINITIS

Beclomethasone Dipropionate. Beclomethasone dipropionate (Beclivent, Beconase, Vanceryl, Vancenase) (BDP) is rapidly converted in the lungs to beclomethasone

Figure 23-32 ■ Glucocorticoids used to treat asthma and allergic rhinitis (some are also used topically)

17-monopropionate (17-BMP), the metabolite that provides the bulk of the anti-inflammatory activity. The monopropionate also has higher affinity for the GR than either the dipropionate or beclomethasone. The portion of BDP that is swallowed is rapidly hydrolyzed to 17-BMP, 21-BMP (which arises by a transesterification reaction from 17-BMP), and beclomethasone itself.¹⁴³ Beclomethasone has much less glucocorticoid activity than the monopropionate.¹⁴⁴

Budesonide. Budesonide (Pulmicort Turbuhaler, Rhinocort) is extensively metabolized in the liver, with 85 to 95% of the orally absorbed drug metabolized by the first-pass effect. The major metabolites are 6 β -hydroxybudesonide and 16 α -hydroxyprednisolone, both with less than 1% of the activity of the parent compound. Metabolism involves the CYP 3A4 enzyme, so coadministration of budesonide with a known CYP 3A4 inhibitor should be monitored carefully.

Flunisolide. The portion of a flunisolide (AeroBid, Nasarel) dose that is swallowed is rapidly converted to the 6 β -hydroxy metabolite after first-pass metabolism in the liver. The 6 β -hydroxy metabolite is approximately as active as hydrocortisone itself, but the small amount produced usually has limited systemic effects. Water-soluble conjugates are inactive.

Fluticasone Propionate. The main metabolite of fluticasone propionate (Flovent, Flonase) found in circulation in

humans is the 17 β -carboxylate derivative. As expected, a charged carboxylate in place of the normal acetol functionality at C17 greatly reduces affinity for the glucocorticoid receptor (2,000-fold less than the parent), and this metabolite is essentially inactive. The metabolite is formed via the CYP 3A4 system, so care should be taken if fluticasone propionate is coadministered with a CYP 3A4 inhibitor such as ketoconazole or ritonavir. Clinically induced Cushing's syndrome has been observed when inhaled fluticasone propionate was administered concurrently with ritonavir.¹⁴⁵

Fluticasone is also available in an inhaled formulation in combination with the long-acting β_2 -agonist salmeterol (Advair Diskus).

Mometasone Furoate. Mometasone furoate (Nasonex) undergoes extensive metabolism to multiple metabolites. No major metabolites are detectable in human plasma after oral administration, but the 6 β -hydroxy metabolite is detectable by use of human liver microsomes. This metabolite is formed via the CYP 3A4 pathway.

Triamcinolone Acetonide. The three main metabolites of triamcinolone acetonide (Azmecort, Nasacort) are 6 β -hydroxytriamcinolone acetonide, 21-carboxytriamcinolone acetonide, and 6 β -hydroxy-21-carboxytriamcinolone acetonide. All are much less active than the parent compound. The 6 β -hydroxyl group and the 21-carboxy group are both structural features that greatly reduce glucocorticoid action. The increased water solubility of these metabolites also facilitates more rapid excretion.

Spironolactone (Aldolactone)

Eplerenone (Inspra)

Figure 23-33 • Aldosterone receptor antagonists.

Mineralocorticoid Receptor Antagonists (Aldosterone Antagonists)

Antagonism of the mineralocorticoid receptor can have profound effects on the renin-angiotensin system, thus having significant cardiac effects. Structurally, these compounds have an A-ring enone, essential for recognition by the receptor, but the 7 α substituent and the D-ring spiro-lactone provide structural elements that lead to antagonism (Fig. 23-33).

Spironolactone, USP. Spironolactone, 7 α -(acetylthio)-17 α -hydroxy-3-oxopregn-4-ene-3-one-21-carboxylic acid γ -lactone (Aldactone), is an aldosterone antagonist of great medical importance because of its diuretic activity. Spironolactone is discussed in Chapter 18.

Eplerenone, USP. Eplerenone, 9,11 α -epoxy-17 α -hydroxy-3-oxopregn-4-ene-7 α ,21-dicarboxylic acid, γ -lactone, methyl ester (Inspra), is a new aldosterone antagonist that was approved by the FDA in 2002 for the treatment of hypertension.

Acknowledgment

I would like to thank Debra Peters for assistance with the illustration of several figures. I would also like to express my appreciation to the authors of various review articles on the steroids. Without the dedication and hard work of these individuals, the assembly of this chapter would have been a much more challenging task.

Prostaglandins, Leukotrienes, and Other Eicosanoids

THOMAS J. HOLMES, JR.

The prostaglandins (PGA through PGJ) are one group of naturally occurring 20-carbon fatty acid derivatives produced by the oxidative metabolism of 5,8,11,14-eicosatetraenoic acid, also called *arachidonic acid*. Other so-called eicosanoids produced in the complex biological oxidation scheme called the arachidonic acid cascade (Figs. 24-1 and 24-2) are thromboxane A₂ (TXA₂), the leukotrienes (LKTs A to F), and the highly potent antithrombotic agent prostacyclin (PGI₂). The naming and the numbering of these 20-carbon acids are included in Figures 24-1 to 24-3. Although eicosanoid-derived agents in current human clinical therapy are few, the promise of future contributions from this area is presumed to be very great. This promise stems from the fact that intermediates of arachidonic acid metabolism play an essential modulatory role in many normal and disease-related cellular processes. In fact, much of the pain, fever, swelling, nausea, and vomiting associated with "illness," in general, probably results from excessive prostaglandin production in damaged tissues.

HISTORY OF DISCOVERY

Early in the past century (1931), Kurzrok and Lieb noted that human seminal fluid could increase or decrease spontaneous muscle contractions of uterine tissue under controlled conditions.¹ This observed effect on uterine musculature was believed to be induced by an acidic vasoactive substance formed in the prostate gland, which was later (1936) termed *prostaglandin* by von Euler.² Much later (1950s), it was found that the acidic extract contained not one but several structurally related prostaglandin substances.³ These materials subsequently were separated, purified, and characterized as the prostaglandins (PGA through PGJ), varying somewhat in degree of oxygenation and dehydrogenation and markedly in biological activity (Table 24-1). Specific stereochemical syntheses of the prostaglandins provided access to sufficient purified material for wide-scale biological evaluation and confirmed the structural characterization of these complex substances.⁴

Although many scientists have contributed to refined characterization of the eicosanoid biosynthetic pathways and the biological consequences of this cascade, the discerning and persistent pioneering efforts of Sune Bergstrom, Bengt Samuelsson, and John R. Vane were recognized by the award of a shared Nobel Prize in Medicine in 1982. These scientists not only dedicated themselves to the chemical and biological

characterization of the eicosanoid substances but also were the first to realize the profound significance of the arachidonic acid cascade in disease processes, particularly inflammation. These individuals first proved that the mechanism of the anti-inflammatory action of aspirin and related nonsteroidal anti-inflammatory drugs (NSAIDs) was directly due to their inhibitory effect on prostaglandin formation. It was shown subsequently that the analgesic and antipyretic effects of these NSAIDs, as well as their proulcerative and anticoagulant side effects, also result from their effect on eicosanoid metabolism (e.g., inhibition of cyclooxygenases 1 and 2 [COX-1 and COX-2]).

Many books have been published describing the role of eicosanoids in the inflammatory process, the immune system, carcinogenesis, the cardiovascular system, reproductive processes, gastric ulceration, and the central nervous system (see Selected Reading). An annual update of research results in this area has been published since 1975, *Advances in Prostaglandins, Thromboxanes, and Leukotriene Research*. Recent research findings in this area may appear in a variety of biochemical and clinical journals but are the primary concern of two specific journals: *Prostaglandins and Other Lipid Mediators* and *Prostaglandins, Leukotrienes, and Essential Fatty Acids*.

EICOSANOID BIOSYNTHESIS

Prostaglandins and other eicosanoids are produced by the oxidative metabolism of free arachidonic acid. Under normal circumstances, arachidonic acid is not available for metabolism as it is present as a conjugated component of the phospholipid matrix of most cellular membranes. Release of free arachidonic acid, which subsequently may be oxidatively metabolized, occurs by stimulation of phospholipase (PLA₂) enzyme activity in response to some traumatic event (e.g., tissue damage, toxin exposure, or hormonal stimulation). It is believed that the clinical anti-inflammatory effect of glucocorticoid steroids (i.e., hydrocortisone) is due to their ability to suppress PLA₂ activity via lipocortins and thus prevent the release of free arachidonic acid.⁵ Modulation of PLA₂ activity by alkali metal ions, toxins, and various therapeutic agents has become a major focus of biological research because of the changes in eicosanoid production and the dramatic biological effects accompanying PLA₂ stimulation or suppression. Although initially it was believed that the inflammatory response (swelling, redness, pain) was princi-

Figure 24-1 ■ Cyclooxygenase pathway

pally due to PGE₂, recent interest has focused on the interrelationships of PGE-type eicosanoids with PGI₂ and cytokines, such as interleukin-1 and interleukin-2, in the modulation of inflammatory reactions.⁶

Two different routes for oxygenation of arachidonic acid have been defined: the cyclooxygenase pathway (Fig. 24-1) and the lipoxygenase pathway (Fig. 24-2). The relative significance of each of these pathways may vary in a particular tissue or disease state. The cyclooxygenase pathway, so named because of the unusual bicyclic endoperoxide (PGG₂) produced in the first step of the sequence, involves the highly stereospecific addition of two molecules of oxygen to the arachidonic acid substrate, followed by subsequent enzyme-

controlled rearrangements to produce an array of oxygenated eicosanoids with diverse biological activities (see Table 24-1). The first enzyme in this pathway, PGH synthase, is a hemoprotein that catalyzes both the addition of oxygen (to form PGG₂) and the subsequent reduction (peroxidase activity) of the 15-position hydroperoxide to the 15-(S)-configuration alcohol (PGH₂).⁷ PGH synthase (also called *cyclooxygenase-1* [COX-1] or *cyclooxygenase-2* [COX-2], and formerly *PG synthetase*) has been the focus of intense investigation because of its key role as the first enzyme in the arachidonic acid cascade.⁸ It is this enzyme in constitutive (COX-1) or inducible (COX-2) form that is susceptible to inhibition by NSAIDs, leading to relief of pain, fever, and

Figure 24-2 ■ Lipoxygenase pathway.

inflammation.^{6, 9} This enzyme is also inhibited by the ω -3 (omega-3) fatty acids (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) found in certain cold-water fish and provided commercially as nutritional supplements, leading to beneficial cardiovascular effects.¹⁰ This enzyme will metabolize 20-carbon fatty acids with one more or one less double bond than arachidonic acid, leading to prostaglandins of varied degrees of unsaturation (e.g., PGE₁ or PGE₃, for which the subscript number indicates the number of double bonds in the molecule).

Prostaglandin H₂ serves as a branch-point substrate for specific enzymes, leading to the production of the various prostaglandins, TXA₂, and PGI₂. Even though most tissues can produce PGH₂, the relative production of each of these derived eicosanoids is highly tissue specific and may be subject to secondary modulation by a variety of cofactors. The complete characterization of enzymes involved in branches of the cyclooxygenase pathway is currently under way.

Specific cellular or tissue responses to the eicosanoids are apparently a function of available surface receptor recognition sites.¹¹ The variety of tissue responses observed on eicosanoid exposure is outlined in Table 24-1. Non-tissue-selective inhibitors of the cyclooxygenase pathway, such as aspirin, thus may exert a diversity of therapeutic effects or side effects (e.g., decreased uterine muscle contraction and platelet aggregation, gastric ulceration, lowering of elevated

body temperature, central and peripheral pain relief, and decreased vascular perfusion) based on their tissue distributions.

The lipoxygenase pathway of arachidonic acid metabolism (Fig. 24-2) produces a variety of acyclic lipid peroxides (hydroperoxyeicosatetraenoic acids [HPETEs]) and derived alcohols (hydroxyeicosatetraenoic acids [HETEs]).¹² Although the specific biological function of each of these lipoxygenase-derived products is not completely known, they are believed to play a major role as chemotactic factors that promote cellular mobilization toward sites of tissue injury. In addition, the glutathione (GSH) conjugates LKT-C₄ and LKT-D₄ are potent, long-acting bronchoconstrictors that are released in the lungs during severe hypersensitivity episodes (leading to their initial designation as the "slow-reacting substances of anaphylaxis" [SRSAs]). Because of the presumed benefit of preventing formation of LKTs in asthmatic patients, much research effort is being dedicated to the design and discovery of drugs that might selectively inhibit the lipoxygenase pathway of arachidonic acid metabolism without affecting the cyclooxygenase pathway.¹³ Zileuton (Zyflo by Abbott Laboratories) specifically inhibits the lipoxygenase pathway. It has been proposed that aspirin hypersensitivity in susceptible individuals may result from effectively "shutting down" the cyclooxygenase metabolic route, allowing only the biosynthesis of lipoxygenase path-

Prostaglandins

Figure 24-3 ■ Eicosanoid degradation.

TABLE 24-1 Biological Activities Observed with the Eicosanoids

Substance	Observed Biological Activity
PGD ₂	Weak inhibitor of platelet aggregation
PGE ₁	Vasodilation Inhibitor of lipolysis Inhibitor of platelet aggregation Bronchodilation Stimulates contraction of gastrointestinal smooth muscle
PGE ₂	Stimulates hyperalgesic response Renal vasodilatation Stimulates uterine smooth muscle contraction Protects gastrointestinal epithelia from acid degradation Reduces secretion of stomach acid
PGF ₂	Elevates thermoregulatory set point in anterior hypothalamus Stimulates breakdown of corpus luteum (luteolysis) in animals Stimulates uterine smooth muscle contraction
PGI ₂	Potent inhibitor of platelet aggregation Potent vasodilator Increases cAMP levels in platelets
PGJ ₂	Stimulates osteogenesis Inhibits cell proliferation
TXA ₂	Potent inducer of platelet aggregation Potent vasoconstrictor Decreases cAMP levels in platelets Stimulates release of ADP and serotonin from platelets
LTB ₄	Increases leukocyte chemotaxis and aggregation
LTCD ₄	Slow-reacting substances of anaphylaxis Potent and prolonged contraction of guinea pig ileum smooth muscle Contracts guinea pig lung parenchymal strips Bronchoconstrictive in humans Increased vascular permeability in guinea pig skin (augmented by PGEs)
5- or 12-HPETE	Vasodilatation of rat and rabbit gastric circulation Inhibits induced platelet aggregation
5- or 12-HETE	Aggregates human leukocytes Promotes leukocyte chemotaxis

way intermediates, including the bronchoconstrictive LKTS.¹⁴

DRUG ACTION MEDIATED BY EICOSANOIDS

The ubiquitous nature of the eicosanoid-producing enzymes implies their significance in a variety of essential cellular processes. Additionally, the sensitivity of these enzymes to structurally varied hydrophobic materials, particularly car-

boxylic acids and phenolic antioxidants, implies their susceptibility to influence by a variety of exogenously administered agents. Because most aromatic drug molecules undergo hepatic hydroxylation, phenolic derivatives of administered drugs become readily available *in vivo*. Even more directly, aromatic molecules on *in vitro* incubation with microsomal PGH synthase will become hydroxylated directly during arachidonic acid metabolism, in a process labeled *cooxidation*.¹⁵ This cooxidative process presumably occurs during the peroxidase conversion of PGG₂ to PGH₂, which effectively makes available a nonspecific oxidizing equivalent. The cooxidation process has been implicated in the activation of polycyclic aromatic hydrocarbons to form proximate carcinogens.¹⁶

The only group of drugs that has been thoroughly characterized for its effect on arachidonic acid metabolism is the NSAIDs. This large group of acidic, aromatic molecules exerts a diverse spectrum of activities (mentioned above) by inhibition of the first enzyme in the arachidonic acid cascade, PGH synthase (also called *COX-1* and *COX-2*). Such agents as salicylic acid, phenylbutazone, naproxen, sulindac, and ibuprofen presumably act by a competitive, reversible inhibition of arachidonic acid oxygenation.¹⁷ Aspirin and certain halogenated aromatics (including indomethacin, flurbiprofen, and Meclomen) appear to inhibit PGH synthase in a time-dependent, irreversible manner.¹⁸ Since this irreversible inhibition appears critical for aspirin's significant effect on platelet aggregation and, therefore, prolongation of bleeding time,¹⁹ this discovery has led clinicians to recommend the daily consumption of low doses of aspirin (81 mg) by patients at risk for myocardial infarction (MI, heart attack), particularly a second MI.

Interestingly, aspirin's primary competitor in the commercial analgesic marketplace, acetaminophen, is a rather weak inhibitor of arachidonic acid oxygenation *in vitro*.²⁰ This, in fact, is a characteristic of reversible, noncompetitive, phenolic antioxidant inhibitors in general.²¹ This determination, in concert with its lack of *in vitro* anti-inflammatory activity (while maintaining analgesic and antipyretic activity equivalent to that of the salicylates) has led to the proposal that acetaminophen is more active as an inhibitor of cyclooxygenases in the brain, where peroxide levels (which stimulate cyclooxygenase activity) are lower than in inflamed peripheral joints, where lipid peroxide levels are high.¹⁷ In fact, when *in vitro* experimental conditions are modified to reduce the so-called peroxide tone, acetaminophen becomes as effective as aspirin in reducing arachidonic acid metabolism.²²

COX-2 INHIBITORS

The newer anti-inflammatory COX-2 inhibitors (e.g., celecoxib, rofecoxib, and valdecoxib) are claimed to show greater inhibitory selectivity for the inducible form of cyclooxygenase.²² Although not absolute, this selectivity provides a potential therapeutic advantage by reducing side effects, particularly gastric irritation and ulceration.²³ Unfortunately, this altered profile of activity is not totally risk free. The manufacturer of rofecoxib (Vioxx) has recently (April 2002) issued a warning regarding the use of this product in patients with a medical history of ischemic heart disease

COX-2 inhibitors do not share the beneficial effects of aspirin in preventing cardiovascular thrombotic events.

DESIGN OF ECOSANOID DRUGS

The ability to capitalize successfully on the highly potent biological effects of the various eicosanoids to develop new therapeutic agents currently seems an unfulfilled promise to medicinal chemists. Although these natural substances are highly potent effectors of various biological functions, their use as drugs has been hampered by several factors: (a) their chemical complexity and relative instability, which have limited, to some extent, their large-scale production and formulation for clinical testing; (b) their susceptibility to rapid degradation (Fig. 24-3), which limits their effective bioactive half-life; and (c) their ability to affect diverse tissues (particularly the gastrointestinal tract, which may lead to severe nausea and vomiting) if they enter the systemic circulation, even in small amounts. Caution is always recommended with the use of prostaglandin analogues in females of childbearing age because of their potential for inducing dramatic contraction of uterine muscles, possibly leading to miscarriage.

Several approaches have been used to overcome these difficulties. First, structural analogues of particular eicosanoids have been synthesized that are more resistant to chemical and metabolic degradation but maintain, to a large extent, a desirable biological activity. Although commercial production and formulation may be facilitated by this approach, biological potency of these analogues is usually reduced by several orders of magnitude. Also, systemic side effects may become troublesome because of broader tissue distribution as a result of the increased biological half-life.

Structural alterations of the eicosanoids have been aimed primarily at reducing or eliminating the very rapid metabolism of these potent substances to relatively inactive metabolites (see Fig. 24-3). Several analogues are presented in Table 24-2 to illustrate approaches that have led to potentially useful eicosanoid drugs. Methylation at the 15 or 16 position will eliminate or reduce oxidation of the essential 15-(S)-alcohol moiety. Esterification of the carboxylic acid function may affect formulation or absorption characteristics of the eicosanoid, whereas esterase enzymes in the bloodstream or tissues would be expected to regenerate the active therapeutic agent quickly. Somewhat surprisingly, considering the restrictive configurational requirements at the naturally asymmetric centers, a variety of hydrophobic substituents (including phenyl rings) may replace the saturated alkyl chains, with retention of bioactivity.

A second major approach has been aimed at delivering the desired agent, either a natural eicosanoid or a modified analogue, to a localized site of action by a controlled delivery method. The exact method of delivery may vary according to the desired site of action (e.g., uterus, stomach, lung) but has included aerosols and locally applied suppository, gel formulations, or cyclodextrin complexes. The recent commercial development of PGF-type derivatives for use in the eye to lower intraocular pressure (IOP) in glaucoma (discussed below under the heading, Prostaglandins for Ophthalmic Use) relies on their potent therapeutic effects coupled

with their limited distribution from this site of administration.²⁴

DEVELOPMENT OF PROSTACYCLIN-DERIVED PRODUCTS

The ongoing development of potent, effective, and long-acting forms of naturally occurring PGI₂ is an excellent illustration of strategies that capitalize on the beneficial but short-lived biological effects of eicosanoid derivatives. PGI₂ itself is currently marketed as the sodium salt (epoprostenol; Flolan by GlaxoSmithKline) for continuous intravenous infusion in patients suffering from primary pulmonary hypertension (PPH). The solution for infusion is prepared within 48 hours of expected use because of its limited chemical stability. The potent vasodilatory, platelet antiaggregatory effect and vascular smooth muscle antiproliferative effect of this naturally occurring eicosanoid produce a dramatic but short-lived (half-life less than 6 minutes) therapeutic effect in PPH patients. Continuous, uninterrupted administration of the drug by portable infusion pump is necessary, however, to prevent symptoms of rebound pulmonary hypertension. To ensure proper use of this therapy, its distribution is relatively restricted.²⁵

Three more-stable derivatives of PGI₂ are being developed to extend the duration of action of this drug to improve the safety and convenience of PPH therapy and, perhaps, broaden the therapeutic indications for its use. Treprostinil (Remodulin) with an extended half-life has been developed for continuous subcutaneous injection for PPH patients. This

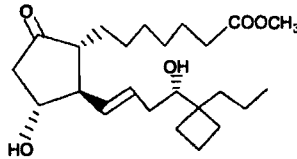

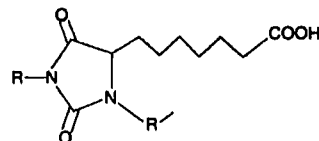

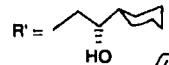

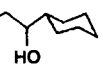

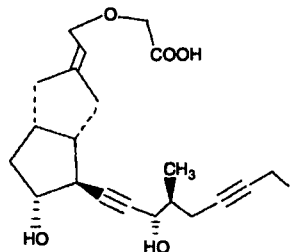

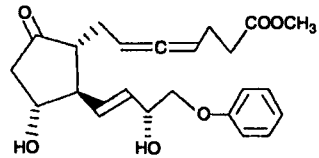

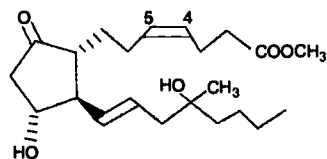

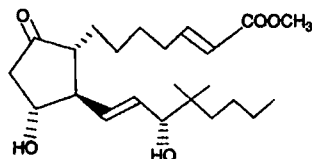

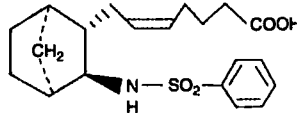

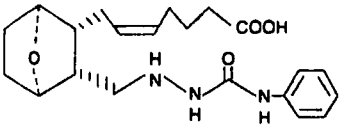

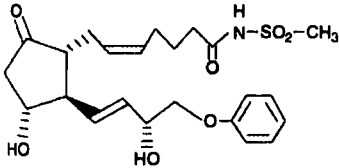

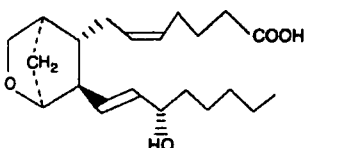

TABLE 24-2 Prostaglandin Analogues under Investigation as Receptor Ligands and Future Drug Candidates

	Butaprost	EP ₂ -receptor ligand
	BW245C: R = H R' =  BWA 868C: R = CH ₂ -  R' = HN- 	DP-receptor ligands

	U-46619	TP-receptor ligand

method of administration and longer half-life would markedly improve the convenience and safety of "prostaacyclin" therapy in PPH patients. Localized intermittent subcutaneous administration of Uniprost is proposed for the treatment of critical limb ischemia.

Another stable derivative of PGI₂, iloprost, is intended for nasal inhalation to provide a direct vasodilatory effect on pulmonary blood vessels and thus decrease vascular resistance. Currently available in Europe, patients inhale 6 to 8 puffs of aerosolized iloprost every 2 to 3 hours. Side effects such as coughing, headaches, and jaw pain have been reported.

An even more chemically and biologically stable derivative of PGI₂ is beraprost, which is being evaluated in an oral formulation for the treatment of early-stage pulmonary arterial hypertension^{26,27} and peripheral vascular disease.²⁸ This prostacyclin has been approved for use in Japan but not yet in the United States.

EICOSANOID RECEPTORS

Another approach to developing new therapies based on the known biological activities of the prostaglandins and leukotrienes requires characterization of the naturally occurring tissue receptors for these agents. A thorough knowledge of the tissue distribution (localization) of such receptors and their binding characteristics would allow the design of receptor-specific agonists or antagonists that might not possess the same limitations as the natural eicosanoids but could affect tissue function nonetheless.

An excellent historical description of prostanoid receptor isolation and characterization has been published,²⁹ and a more recent review of developments in this field is available.¹¹ Basically, prostanoid receptors are identified by their primary eicosanoid agonist (e.g., DP, EP, IP, and TP), although subclassification of PGE receptors has been neces-

sary (e.g., EP₁, EP₂, EP₃, and EP₄). In fact, the existence of subtypes of the EP₁ receptor (EP_{1A}, EP_{1B}, EP_{1C}, EP_{1D}) and TP receptor (TP_α, TP_β) has been proposed. Complete characterization of receptors (and subtypes) includes tissue localization, biological effect produced, cellular signal transduction mechanism, inhibitor sensitivity, protein structure, and genetic origin. Not all receptors or subtypes have been completely characterized in this way, but significant progress toward this goal has occurred recently. Table 24-3 indicates characteristics of the prostanoid receptors identified thus far.

Although receptor studies have required the use of nonhuman species (principally the mouse but also the rat, cow, sheep, and rabbit), a high correlation of structural homology of receptor subtypes between species (~80 to 90%) has been observed, while structural homology among receptor sub-

types is relatively low (30 to 50%). All prostanoid receptors, however, are believed belong to a "rhodopsin-type" superfamily of receptors that function via G-protein-coupled transduction mechanisms. Three general classes of prostanoid receptors are proposed¹¹: (a) relaxant, including DP, EP₂, EP₃, and IP, which promote smooth muscle relaxation by raising intracellular cyclic adenosine monophosphate (cAMP) levels; (b) contractile, including EP₁, FP, and TP, which promote smooth muscle contraction via calcium ion mobilization; and (c) inhibitory, such as EP₄, which prevents smooth muscle contraction by lowering intracellular cAMP levels. Although structural and functional characterization of prostanoid receptors has permitted the identification and differentiation of selective receptor ligands (Table 24-3, both agonists and antagonists), overlapping tissue distribution

TABLE 24-3 Prostanoid Receptor Characteristics

Receptor	Principle Ligands	Tissue/Action	Transduction	Gene Knockout Effect

and common signal transduction mechanisms present formidable obstacles to the development of specific pharmacological therapies.

EICOSANOIDS APPROVED FOR HUMAN CLINICAL USE

Prostaglandin $F_{2\alpha}$. $\text{PGF}_{2\alpha}$, dinoprost (Prostin F_2 Alpha), is a naturally occurring prostaglandin that was administered intra-amniotically to induce labor or abortion within the first trimester.

This product, which was supplied as a solution of the tromethamine salt (5 mg/mL) for direct administration, is no longer available in the United States for human use but is still formulated for veterinary use as described elsewhere in this chapter.

Prostaglandin E_2 . PGE_2 , dinoprostone (Prostin E_2 , Cervidil), is a naturally occurring prostaglandin that is administered in a single dose of 20 mg by vaginal suppository to induce labor or abortion.

Carboprost Tromethamine. Carboprost tromethamine, 15-(*S*)-methyl- $\text{PGF}_{2\alpha}$ (Hemabate), is a prostaglandin derivative that has been modified to prevent metabolic oxidation of the 15-position alcohol function.

This derivative is administered in a dose of 250 μg by deep intramuscular injection to induce abortion or to ameliorate severe postpartum hemorrhage.

Prostaglandin E_1 , USP. PGE_1 , alprostadil (Prostin VR Pediatric), is a naturally occurring prostaglandin that has found particular use in maintaining a patent (opened) ductus arteriosus in infants with congenital defects that restrict pulmonary or systemic blood flow.

Alprostadil must be administered intravenously continually at a rate of approximately 0.1 $\mu\text{g}/\text{kg}$ per minute to temporarily maintain the patency of the ductus arteriosus until corrective surgery can be performed. Up to 80% of circulating alprostadil may be metabolized in a single pass through the lungs. Because apnea occurs in 10 to 12% of neonates with congenital heart defects, this product should be administered only when ventilatory assistance is immediately available. Other commonly observed side effects include decreased arterial blood pressure (which should be monitored during infusion), inhibited platelet aggregation (which might aggravate bleeding tendencies), and diarrhea. Prostin VR Pediatric is provided as a sterile solution in absolute alcohol (0.5 mg/mL) that must be diluted in saline or dextrose solution before intravenous administration. A liposomal preparation is available (Liposome Company) to extend the biological half-life of the active prostaglandin.

Alprostadil (Caverject) is also available in glass vials for reconstitution to provide 1.0 mL of solution containing either 10 or 20 $\mu\text{g}/\text{mL}$ for intercavernosal penile injection to diagnose or correct erectile dysfunction in certain cases of impotence. A urethral suppository is also available; this therapeutic use has been all but eliminated, however, by the availability of orally administered Viagra.

Prostaglandin E_1 Cyclodextrin. The cyclic polysaccharide complex of PGE_1 (Vasoprost) is available as an orphan drug for the treatment of severe peripheral arterial occlusive disease when grafts or angioplasty are not indicated. Cyclodextrin complexation is used to enhance water solubility and reduce rapid metabolic inactivation.

Misoprostol. Misoprostol, 16-(*R,S*)-methyl-16-hydroxy- PGE_1 methyl ester (Cytotec), is a modified prostaglandin analogue that shows potent gastric antisecretory and gastroprotective effects when administered orally.

Misoprostol is administered orally in tablet form in a dose

of 100 to 200 μg 4 times a day to prevent gastric ulceration in susceptible individuals who are taking NSAIDs. Misoprostol is combined with the NSAID diclofenac in an analgesic product (Arthrotec by Pharmacia) that is potentially safe for long-term antiarthritic therapy. This prostaglandin derivative should be avoided by pregnant women because of its potential to induce abortion. In fact, the combined use of intramuscular methotrexate and intravaginal misoprostol has been claimed to be a safe and effective, noninvasive method for the termination of early pregnancy.³⁰

PROSTAGLANDINS FOR OPHTHALMIC USE

Several prostaglandin analogues have recently come to market for the treatment of open-angle glaucoma or ocular hypertension in patients who have not benefited from other available therapies. These products are marketed as sterile solutions for use in the eye (as indicated below). Each of these agents is presumed to lower IOP by stimulation of FP receptors to open the uveoscleral pathway, thus increasing aqueous humor outflow. Commonly occurring side effects reported for this product group include conjunctival hyperemia, increased pigmentation and growth of eyelashes, ocular pruritus, and increased pigmentation of the iris and eyelid. Contact lenses should be removed during and after (15 minutes) administration of these products.

Bimatoprost. Bimatoprost (Lumigan) is supplied as a sterile 0.03% ophthalmic solution in 2.5- and 5.0-mL sizes. The recommended dosage of bimatoprost is limited to one drop into the affected eye once daily in the evening. Increased use may decrease its beneficial effect. If used concurrently with other IOP-lowering drugs, a waiting period of 5 minutes should separate administrations.

Latanoprost. Latanoprost (Xalatan) is available as a 0.005% sterile ophthalmic solution in a 2.5-mL dispenser bottle. Latanoprost is also marketed as a combination ophthalmic product with the β -adrenergic blocking agent timolol, which apparently enhances IOP-lowering by decreasing the production of aqueous humor. Cautions and side effects are similar to those for other ophthalmic prostanoids.

Travoprost. Travoprost (Travatan) is supplied as a 2.5-mL sterile 0.004% ophthalmic solution in a 3.5-mL container. Travoprost is claimed to be the most potent and FP-specific analogue in this product category.³¹ Cautions and side effects are similar to those given above.

Unoprostone. Unoprostone (Rescula) is supplied as a 0.15% sterile ophthalmic solution. Unoprostone is somewhat unusual, in that it is a docosanoid (22-carbon atom) PGF₂ analogue marketed as the isopropyl ester. The natural 15-position alcohol is oxidized to the ketone, as would be expected to occur in vivo. Cautions and side effects are similar to those given above.

VETERINARY USES OF PROSTANOIDS

Since McCracken and coworkers demonstrated that PGF₂ acts as a hormone in sheep to induce disintegration of the corpus luteum (luteolysis),³² salts of this prostaglandin and a variety of analogues have been marketed to induce or synchronize estrus in breed animals. This procedure allows artificial insemination of many animals during one insemination period. The following two products are currently available for this purpose.

Cloprostenol Sodium. Cloprostenol sodium (Estrumate) is available as the sodium salt from Bayer Agricultural Division or Bayvet Division of Miles Laboratory as an aqueous solution containing 250 mg/mL.

Dinoprost Trimethamine. Dinoprost trimethamine (Lutalyse) marketed by Upjohn (veterinary) is a pH-balanced aqueous solution of the trimethylammonium salt of PGF_{2α} (5.0 mg/mL).

EICOSANOIDS IN CLINICAL DEVELOPMENT FOR HUMAN TREATMENT

Numerous prostaglandin analogues are under investigation for the treatment of human diseases (see Table 24-2). Efforts are being focused on the areas of gastroprotection for antiulcer therapy, fertility control, the development of thrombolytics (e.g., prostacyclin or thromboxane synthetase inhibitors) to treat cerebrovascular or coronary artery diseases, and the development of antiasthmatics through modulation of the lipoxygenase pathway. Future application of eicosanoids to the treatment of cancer, hypertension, or immune system disorders cannot be ruled out, however. Thus, although progress has been slow, the expanded use of eicosanoids or eicosanoid analogues as therapeutic agents in the future is almost ensured.

Proteins, Enzymes, and Peptide Hormones

STEPHEN J. CUTLER AND HORACE G. CUTLER

Proteins are essential to all living matter and perform numerous functions as cellular components. Fundamental cellular events are catalyzed by proteins called enzymes, while other proteins serve as architectural constituents of protoplasm and cell membranes. Most important are the classes of hormones that are characterized as proteins or protein-like compounds because of their polypeptidic structure.

Protein chemistry, essential in understanding the mechanisms of molecular biology and how cellular components participate in physiology, is also key to certain aspects of medicinal chemistry. An examination of the chemical nature of proteins explains the action of those medicinal agents that are proteins or protein-like compounds and elucidates their physicochemical and biochemical properties. This, in turn, relates to their mechanisms of action. Furthermore, in medicinal chemistry, drug-receptor interactions are directly related to structure-activity relationships (SARs) and aid in the process of rational drug design. Drug receptors are considered to be macromolecules, some of which appear to be proteins or protein-like.

Recombinant DNA (rDNA) technology¹ has had a dramatic impact on our ability to produce complex proteins and polypeptides structurally identical with those found *in vivo*. Many of the endogenous proteins or polypeptides have exhibited neurotransmitter and hormonal properties that regulate a variety of important physiological processes. rDNA-derived technology products currently being used are discussed below in this chapter.

Although this chapter reviews the medicinal chemistry of proteins, it includes some enzymology, not only because many drugs affect enzyme systems and vice versa but also because basic discoveries in enzymology have been practically applied to the study of drug-receptor interactions. Hence, a basic introduction to enzymes is included.

PROTEIN HYDROLYSATES

In therapeutics, agents affecting volume and composition of body fluids include various classes of parenteral products. Ideally, it would be desirable to have available parenteral fluids that provide adequate calories and important proteins and lipids to mimic, as closely as possible, an appropriate diet. Unfortunately, this is not the case. Usually, sufficient carbohydrate is administered intravenously to prevent ketosis, and in some cases, it is necessary to give further sources of carbohydrate by vein to reduce protein waste. Sources of

protein are made available in the form of protein hydrolysates, and these can be administered to induce a favorable balance.

Protein deficiencies in human nutrition are sometimes treated with protein hydrolysates. The lack of adequate protein may result from several conditions, but the problem is not always easy to diagnose. The deficiency may be due to insufficient dietary intake, temporarily increased demands (as in pregnancy), impaired digestion or absorption, liver malfunction, increased catabolism, or loss of proteins and amino acids (e.g., in fevers, leukemia, hemorrhage, surgery, burns, fractures, or shock).

Protein Hydrolysate. Protein hydrolysate is a solution of amino acids and short-chain oligopeptides that represent the approximate nutritive equivalent of the casein, lactalbumin, plasma, fibrin, or other suitable protein from which it is derived by acid, enzymatic, or other hydrolytic methods. It may be modified by partial removal, and restoration or addition of one or more amino acids. It may contain dextrose or another carbohydrate suitable for intravenous infusion. Not less than 50% of the total nitrogen present is in the form of α -amino nitrogen. It is a yellowish to red-amber transparent liquid with a pH of 4 to 7.

Parenteral preparations are used to maintain a positive nitrogen balance in patients who exhibit interference with ingestion, digestion, or absorption of food. For such patients, the material to be injected must be nonantigenic and must not contain pyrogens or peptides of high molecular weight. Injection may result in untoward effects such as nausea, vomiting, fever, vasodilatation, abdominal pain, twitching and convulsions, edema at the site of injection, phlebitis, and thrombosis. Sometimes, these reactions are due to inadequate cleanliness or too-rapid administration.

AMINO ACID SOLUTIONS

Amino acid solutions contain a mixture of essential and non-essential crystalline amino acids, with or without electrolytes (e.g., Aminosyn, ProCalamine, Travasol, Novamine). Although oral studies have shown a comparison between protein hydrolysates and free amino acid diets,² protein hydrolysates are being replaced by crystalline amino acid solutions for parenteral administration because the free amino acids

are used more efficiently than the peptides produced by the enzymatic cleavage of protein hydrolysates.³

PROTEINS AND PROTEIN-LIKE COMPOUNDS

The chemistry of proteins is complex, with many facets not completely understood. Protein structure is usually studied in basic organic chemistry and, to a greater extent, in biochemistry, but for the purposes of this chapter some of the more important topics are summarized, with emphasis on relationships to medicinal chemistry. Much progress has been made in understanding the more sophisticated features of protein structure⁴ and its correlation with physicochemical and biological properties. With the total synthesis of ribonuclease in 1969, new approaches to the study of SARs among proteins have involved the synthesis of modified proteins.

Many types of compounds important in medicinal chemistry are classified structurally as proteins, including enzymes, antigens, and antibodies. Numerous hormones are low relative-molecular-mass proteins and so are called *simple proteins*. Fundamentally, all proteins are composed of one or more polypeptide chains; that is, the primary organizational level of protein structure is the polypeptide (polyamide) chain composed of naturally occurring amino acids bonded to one another by amide linkages (Fig. 25-1). The specific physicochemical and biological properties of proteins depend not only on the nature of the specific amino acids and their sequence within the polypeptide chain but also on conformational characteristics.

Conformational Features of Protein Structure

As stated, the polypeptide chain is considered to be the primary level of protein structure, and the folding of the polypeptide chains into a specific coiled structure is maintained through hydrogen-bonding interactions (intramolecular) (Fig. 25-2). The folding pattern is the secondary level of protein structure. The intramolecular hydrogen bonds involve the partially negative oxygens of amide carbonyl groups and the partially positive hydrogens of the amide -NH. Additional factors, such as ionic bonding between positively and negatively charged groups and disulfide bonds, help stabilize such folded structures.

The arrangement and interfolding of the coiled chains into layers determine the tertiary and higher levels of protein structure. Such final conformational character is determined by various types of interaction, primarily hydrophobic forces and, to some extent, hydrogen bonding and ion pairing.^{4,5} Hydrophobic forces are implicated in many biological phenomena associated with protein structure and interactions.⁶ The side chains (R groups) of various amino acids have hydrocarbon moieties that are hydrophobic, and they have minimal tendency to associate with water molecules, whereas water molecules are strongly associated through hydrogen bonding. Such hydrophobic R groups tend to get close to one another, with exclusion of water molecules, to form "bonds" between different segments of the chain or

Figure 25-1 ■ Diagrammatic representation of a fully extended polypeptide chain with the bond lengths and the bond angles derived from crystal structures and other experimental evidence. (From Corey, R. B., and Pauling, L.: *Proc. R. Soc. Lond. Ser. B* 141:10, 1953.)

between different chains. These are often termed *hydrophobic bonds*, *hydrophobic forces*, or *hydrophobic interactions*.

The study of protein structure has required several physicochemical methods of analysis.⁴ Ultraviolet spectrophotometry has been applied to the assessment of conformational changes that proteins undergo. Conformational changes can be investigated by the direct plotting of the difference in absorption of the protein under various sets of conditions. X-ray analysis has been most useful in the elucidation of the structures of several proteins (e.g., myoglobin and lysozyme). Absolute determinations of conformation and helical content can be made by x-ray diffraction analysis. Optical rotation of proteins has also been studied

Figure 25-2 ■ Left-handed and right-handed α helices. The R and H groups on the α -carbon atom are in the correct position corresponding to the known configuration of the L-amino acids in proteins. (From Pauling, L., and Corey, R. B.: unpublished drawings.)

fruitfully. The specific rotations of proteins are always negative, and extreme changes in pH (when the protein is in solution) and conditions that promote denaturation (urea solutions, increased temperatures) tend to augment the negative optical rotation. Accordingly, it is thought that the changes in rotation are due to conformational changes (i.e., changes in protein structure at the secondary and higher levels of organization). Optical rotatory dispersion has also been used to study conformational alterations and differences among globular proteins. Additionally, circular dichroism methodology has been involved in structural studies. The shape and the magnitude of rotatory dispersion curves and circular dichroism spectra are very sensitive to conformational alterations; thus, the effects of enzyme inhibitors on conformation can be analyzed. Structural studies have included the investigation of the tertiary structures of proteins in high-frequency nuclear magnetic resonance

(NMR).^{7,8} NMR spectroscopy has been of some use in the study of interactions between drug molecules and proteins such as enzymes, proteolipids, and others. NMR has been applied to the study of binding of atropine analogues to a tyrosinesterase⁹ and interactions involving cholinergic ligands and housefly brain and torpedo electroplax.¹⁰ NMR was also used in the determination of the tertiary structure of the capsid protein of the human immunodeficiency virus (HIV).¹¹

Factors Affecting Protein Structure

Conditions that promote the hydrolysis of amide linkages affect protein structure (see under the heading, Protein Hydrolysis, above). The highly ordered conformation of a protein can be disorganized (without hydrolysis of the amide linkages), and in the process, the protein's biological activity is lost.

is lost. This process, customarily called *denaturation*, involves unfolding of the polypeptide chains, loss of the native conformation of the protein, and disorganization of the uniquely ordered structure, without the cleavage of covalent bonds (e.g., cooked egg albumin). The rupture of native disulfide bonds is usually considered a more extensive and drastic change than denaturation. Criteria for the detection of denaturation involve detection of previously masked $-SH$, imidazole, and $-NH_2$ groups; decreased solubility; increased susceptibility to the action of proteolytic enzymes; decreased diffusion constant and increased viscosity of protein solution; loss of enzymatic activity if the protein is an enzyme; and modification of antigenic properties.

Purification and Classification

It might be said that it is old-fashioned to classify proteins according to the following system, since so much progress has been made in understanding protein structure. Nevertheless, an outline of this system of classification is given because the terms used are still found in the pharmaceutical and medical literature. Table 25-1 includes the classification and characterization of simple proteins. Before classification, the protein material must be purified as much as possible, which is a very challenging task. Several criteria are used to determine homogeneity, including crystallinity, constant solubility at a given temperature, osmotic pressure in different solvents, diffusion rate, electrophoretic mobility, dielectric constant, chemical assay, spectrophotometry, and quantification of antigenicity. The methodology of purification is complex; procedures can involve various techniques of chromatography (column), electrophoresis, ultracentrifugation, and others. High-performance liquid chromatography (HPLC) has been applied to the separation of peptides (e.g., the purification of some hypothalamic peptides by a combination of chromatographic methods including HPLC).^{12, 13}

Conjugated proteins contain a nonprotein structural component in addition to the protein moiety, whereas simple proteins contain only the polypeptide chain of amino acid units. Nucleoproteins are conjugated proteins containing nucleic acids as structural components. Glycoproteins are car-

bohydrate-containing conjugated proteins (e.g., thyroglobulin). Phosphoproteins contain phosphate moieties (e.g., casein). Lipoproteins are lipid bearing. Metalloproteins have some bound metal. Chromoproteins, such as hemoglobin or cytochrome, have some chromophoric moiety.

Properties of Proteins

The classification in Table 25-1 is based on solubility properties. Fibrous proteins are water insoluble and highly resistant to hydrolysis by proteolytic enzymes; the collagens, elastins, and keratins are in this class. Globular proteins (albumins, globulins, histones, and protamines) are relatively water soluble; they are also soluble in aqueous solutions containing salts, acids, bases, or ethanol. Enzymes, oxygen-carrying proteins, and protein hormones are globular proteins.

Another important characteristic of proteins is their amphoteric behavior. In solution, proteins migrate in an electric field, and the direction and rate of migration are a function of the net electrical charge of the protein molecule, which in turn depends on the pH of the solution. The isoelectric point is the pH value at which a given protein does not migrate in an electric field; it is a constant for any given protein and can be used as an index of characterization. Proteins differ in rate of migration and in their isoelectric points. Electrophoretic analysis is used to determine purity and for quantitative estimation because proteins differ in electrophoretic mobility at any given pH.⁴

Because they are ionic in solution, proteins bind with cations and anions depending on the pH of the environment. Sometimes, complex salts are formed, and precipitation takes place (e.g., trichloroacetic acid is a precipitating agent for proteins and is used for deproteinizing solutions).

Proteins possess chemical properties characteristic of their component functional groups, but in the native state, some of these groups are "buried" within the tertiary protein structure and may not react readily. Certain denaturation procedures can expose these functions and allow them to respond to the usual chemical reagents (e.g., an exposed $-NH_2$ group can be acetylated by ketene; $-CO_2H$ can be esterified with diazomethane).

TABLE 25-1 Simple (True) Proteins

Class	Characteristics	Occurrence
Albumins	Soluble in water, coagulable by heat and reagents	Egg albumin, lactalbumin, serum albumin, leucosin of wheat, legumelin of legumes
Globulins	Insoluble in water, soluble in dilute salt solution, coagulable	Bdestin of plants, vitelline of egg, serum globulin, lactoglobulin, amandin of almonds, myosin of muscles
Protamines	Insoluble in water or alcohol, soluble in 60–80% alcohol, not coagulable	Found only in plants (e.g., gliadin of wheat, hordein of barley, zein of corn, and secalin of rye)
Glutelins	Soluble only in dilute acids or bases, coagulable	Found only in plants (e.g., glutenin of wheat and oryzenin of rice)
Protamines	Soluble in water or ammonia, strongly alkaline, not coagulable	Found only in the sperm of fish (e.g., salmine from salmon)
Histones	Soluble in water, but not in ammonia, predominantly basic, not coagulable	Globin of hemoglobin, nucleolastone from nucleoprotein
Albuminoids	Insoluble in all solvents	In keratin of hair, nails, and feathers; collagen of connective tissue; chondrin of cartilage; fibroin of silk; and spongin of sponges

Color Tests and Miscellaneous Separation and Identification Methods

Proteins respond to the following color tests: (a) biuret, pink to purple with an excess of alkali and a small amount of copper sulfate; (b) ninhydrin, a blue color when boiled with ninhydrin (triketohydrindene hydrate), which is intensified by the presence of pyridine; (c) Millon's test for tyrosine, a brick-red color or precipitate when boiled with mercuric nitrate in an excess of nitric acid; (d) Hopkins-Cole test for tryptophan, a violet zone with a salt of glyoxylic acid and stratified over sulfuric acid; and (e) xanthoproteic test, a brilliant orange zone when a solution in concentrated nitric acid is stratified under ammonia. Almost all so-called alkaloidal reagents will precipitate proteins in slightly acid solution.

The qualitative identification of the amino acids found in proteins and other substances has been simplified greatly by the application of paper chromatographic techniques to the proper hydrolysate of proteins and related substances. End-member degradation techniques for the detection of the sequential arrangements of the amino acid residues in polypeptides (proteins, hormones, enzymes, etc.) have been developed to such a high degree with the aid of paper chromatography that very small samples of the polypeptides can be used. These techniques, together with statistical methods, have led to the elucidation of the amino acid sequences in oxytocin, vasopressin, insulin, hypertensin, glucagon, corticotropins, and others.

Ion exchange chromatography has been applied to protein analysis and to the separation of amino acids. The principles of ion exchange chromatography can be applied to the design of automatic amino acid analyzers with appropriate recording instrumentation.⁴ One- or two-dimensional thin-layer chromatography has been used to accomplish separations not possible with paper chromatography. Another method for separating amino acids and proteins involves a two-dimensional analytical procedure that uses electrophoresis in one dimension and partition chromatography in the other. The applicability of HPLC was noted above.^{12, 13}

Products

Gelatin, NF. Gelatin, NF, is a protein obtained by the partial hydrolysis of collagen, an albuminoid found in bones, skin, tendons, cartilage, hoofs, and other animal tissues. The products seem to be of great variety, and from a technical standpoint, the raw material must be selected according to the purpose intended (Table 25-2). This is because collagen

is usually accompanied in nature by elastin and, especially, mucoids such as chondromucoid, which enter into the product in a small amount. The raw materials for official gelatin, and that used generally for food, are skins of calf or swine and bones. The bones are first treated with hydrochloric acid to remove the calcium compounds and then are digested with lime for a prolonged period, which solubilizes most other impurities. The fairly pure collagen is extracted with hot water at a pH of about 5.5, and the aqueous solution of gelatin is concentrated, filtered, and cooled to a stiff gel. Calf skins are treated in about the same way, but those from hogs are not given any lime treatment. The product derived from an acid-treated precursor is known as type A and exhibits an isoelectric point between pH 7 and 9; that for which alkali is used is known as type B and exhibits an isoelectric point between pH 4.7 and 5. The minimum gel strength officially is that a 1% solution kept at 0°C for 6 hours must show no perceptible flow when the container is inverted.

Gelatin occurs in sheets, shreds, flakes, or coarse powder. It is white or yellowish, has a slight but characteristic odor and taste, and is stable in dry air but subject to microbial decomposition when moist or in solution. It is insoluble in cold water but swells and softens when immersed and gradually absorbs 5 to 10 times its own weight of water. It dissolves in hot water to form a colloidal solution; it also dissolves in acetic acid and in hot dilute glycerin. Gelatin commonly is bleached with sulfur dioxide, but the medicinal product must not have over 40 parts per million of sulfur dioxide. A proviso is made, however, for the manufacture of capsules or pills, which may have certified colors added, may contain as much as 0.15% sulfur dioxide, and may have a lower gel strength.

Gelatin is used in the preparation of capsules, in the coating of tablets, and, with glycerin, as a vehicle for suppositories. It has also been used as a vehicle when slow absorption is desired for drugs. When dissolved in water, the solution becomes somewhat viscous, and in cases of shock, these solutions may be used to replace the loss in blood volume. Presently, this replacement is accomplished more efficiently with blood plasma, which is safer to use. In hemorrhagic conditions, it is sometimes administered intravenously to increase the clotting of blood or is applied locally for the treatment of wounds.

The most important value in therapy is as an easily digested and adjuvant food. Notably, it fails to provide any tryptophan and is lacking in adequate amounts of other essential amino acids; approximately 60% of the total amino acids consist of glycine and the prolines. Nevertheless, when supplemented, it is very useful in various forms of malnutrition, gastric hyperacidity or ulcer, convalescence, and general diets of the sick. It is especially useful in the preparation of modified milk formulas for feeding infants.

Gelatin Film, Absorbable, USP. Gelatin film, absorbable (Gelfilm), is a sterile, nonantigenic, absorbable, water-insoluble gelatin film. The gelatin films are prepared from a solution of specially prepared gelatin-formaldehyde combination, by spreading on plates and drying under controlled humidity and temperature. The film is available as light yellow, transparent, brittle sheets 0.076 to 0.228 mm thick. Although insoluble in water, they become rubbery after being in water for a few minutes.

TABLE 25-2 Pharmaceutically Important Protein Products

Name Proprietary Name	Category
Gelatin, NF	Pharmaceutical acid (encapsulating agent; suspending agent; tablet binder and coating agent)
Gelatin film, absorbable. USP <i>Gelfilm</i>	Local hemostatic
Gelatin sponge, absorbable. USP <i>Gelfoam</i> , <i>Surgiform</i>	Local hemostatic

Gelatin Sponge, Absorbable, USP. Gelatin sponge absorbable (Gelfoam, Surgifoam) is a sterile, absorbable, water-insoluble, gelatin-based sponge that is a light, nearly white, nonelastic, tough, porous matrix. It is stable to dry heat at 150°C for 4 hours. It absorbs 50 times its own weight of water or 45 times oxalated whole blood.

It is absorbed in 4 to 6 weeks when used as a surgical sponge. When applied topically to control capillary bleeding, it should be moistened with sterile isotonic sodium chloride solution or thrombin solution.

Venoms. Cobra (*Naja*) venom solution, from which the hemotoxic and proteolytic principles have been removed, has been credited with virtues because of its toxins and has been injected intramuscularly as a nonnarcotic analgesic in doses of 1 mL/day. Snake venom solution of the water moccasin is used subcutaneously in doses of 0.4 to 1.0 mL as a hemostatic in recurrent epistaxis and thrombocytopenic purpura and as a prophylactic before tooth extraction and minor surgical procedures. Stypven, from the Russell viper, is used topically as a hemostatic and as a thromboplastic agent in Quick's modified clotting-time test. Ven-Apis, the purified and standardized venom from bees, is furnished in graduated strengths of 32, 50, and 100 bee-sting units. It is administered topically in acute and chronic arthritis, myositis, and neuritis.

The frog venom, caerulein, isolated from the red-eyed tree frog *Agalychnis callidryas* mimics the effects of cholecystokinin and has been used in radiography procedures to contract the gallbladder. In addition, sauvagine, an anxiolytic, has been isolated from *A. callidryas*. Finally, bombesin, a 14-amino acid peptide that also possesses anxiolytic properties, has been isolated from the European fire-bellied frog. Although not a complete list of the peptides isolated from frogs, these provide an insight into the ancient defense mechanisms these reptiles possess and the possibility of exploitation for such uses as analgetics, antimicrobials (especially against resistant organisms), and cardiovascular agents.

Nucleoproteins. The nucleoproteins mentioned above are found in the nuclei and cytoplasm of all cells. They can be deproteinized by several methods. The compounds that occur in yeast are usually treated by grinding with a very dilute solution of potassium hydroxide, adding picric acid in excess, and precipitating the nucleic acids with hydrochloric acid, leaving the protein in solution. The nucleic acids are purified by dissolving in dilute potassium hydroxide, filtering, acidifying with acetic acid, and finally precipitating with a large excess of ethanol.

The nucleoproteins found in the nucleus of eukaryotic cells include a variety of enzymes, such as DNA and RNA polymerases (involved in nucleic acid synthesis), nucleases (involved in the hydrolytic cleavage of nucleotide bonds), isomerases, and others. The nucleus of eukaryotic cells also contains specialized proteins, such as tubulin (involved in the formation of mitotic spindle before mitosis) and histones. Histones are proteins rich in the basic amino acids arginine and lysine, which together make up one fourth of the amino acid residues. Histones combine with negatively charged double-helical DNA to form complexes that are held together by electrostatic interactions. Histones package and

order the DNA into structural units called *nucleosomes*. Because of the enormous amount of research on histones, the reader is encouraged to evaluate the Selected Reading list provided at the end of this chapter.

ENZYMES

Proteins that have catalytic properties are called *enzymes* (i.e., enzymes are biological catalysts of protein nature). Some enzymes have full catalytic reactivity per se; these are considered to be simple proteins because they do not have a nonprotein moiety. Other enzymes are conjugated proteins, and the nonprotein structural components are necessary for reactivity. Occasionally, enzymes require metallic ions. Because enzymes are proteins or conjugated proteins, the general review of protein structural studies presented above in this chapter (e.g., protein conformation and denaturation) is fundamental to the following topics. Conditions that affect denaturation of proteins usually have an adverse effect on the activity of the enzyme.

General enzymology is discussed effectively in numerous standard treatises, and one of the most concise discussions appears in the classic work by Ferdinand,¹⁴ who includes reviews of enzyme structure and function, bioenergetics, and kinetics and appropriate illustrations with a total of 37 enzymes selected from the six major classes. For additional basic studies of enzymology, the reader should refer to this classic monograph and to a comprehensive review of this topic.¹⁵

Relation of Structure and Function

Koshland¹⁶ has reviewed concepts concerning correlations of protein conformation and conformational flexibility of enzymes with enzyme catalysis. Enzymes do not exist initially in a conformation complementary to that of the substrate. The substrate induces the enzyme to assume a complementary conformation. This is the so-called induced-fit theory. There is proof that proteins do possess conformational flexibility and undergo conformational changes under the influence of small molecules. This does not mean that all proteins must be flexible; nor does it mean that conformationally flexible enzymes must undergo conformational changes when interacting with all compounds. Furthermore, a regulatory compound that is not directly involved in the reaction can exert control on the reactivity of the enzyme by inducing conformational changes (i.e., by inducing the enzyme to assume the specific conformation complementary to the substrate). (Conceivably, hormones as regulators function according to the foregoing mechanism of affecting protein structure.) So-called flexible enzymes can be distorted conformationally by molecules classically called *inhibitors*. Such inhibitors can induce the protein to undergo conformational changes, disrupting the catalytic functions or the binding function of the enzyme. In this connection, it is noteworthy how the work of Belcau¹⁷ and the molecular perturbation theory of drug action relate to Koshland's studies presented above in this textbook.

Evidence continues to support the explanation of enzyme catalysis on the basis of the active site (reactive center) of amino acid residues, which is considered to be that relatively small region of the enzyme's macromolecular surface involved in catalysis. Within this site, the enzyme has strategically positioned functional groups (from the side chains of amino acid units) that participate cooperatively in the catalytic action.¹⁸

Some enzymes have absolute specificity for a single substrate; others catalyze a particular type of reaction that various compounds undergo. In the latter, the enzyme is said to have *relative specificity*. Nevertheless, compared with other catalysts, enzymes are outstanding in their specificity for certain substrates.¹⁹ The physical, chemical, conformational, and configurational properties of the substrate determine its complementarity to the enzyme's reactive center. These factors, therefore, determine whether a given compound satisfies the specificity of a particular enzyme. Enzyme specificity must be a function of the nature, including conformational and chemical reactivity, of the reactive center, but when the enzyme is a conjugated protein with a coenzyme moiety, the nature of the coenzyme also contributes to specificity characteristics.

In some instances, the active center of the enzyme is apparently complementary to the substrate molecule in a strained configuration, corresponding to the "activated" complex for the reaction catalyzed by the enzyme. The substrate molecule is attracted to the enzyme, and the forces of attraction cause it to assume the strained state, with conformational changes that favor the chemical reaction; that is, the enzyme decreases the activation energy requirement of the reaction to such an extent that the reaction proceeds ap-

preciably faster than it would in the absence of the enzyme. If enzymes were always completely complementary in structure to the substrates, then no other molecule would be expected to compete successfully with the substrate in combination with the enzyme, which in this respect would be similar in behavior to antibodies. Occasionally, however, an enzyme complementary to a strained substrate molecule attracts a molecule resembling the strained substrate molecule more strongly; for example, the hydrolysis of benzoyl-L-tyrosylglycineamide is practically inhibited by an equal amount of benzoyl-D-tyrosylglycineamide. This example illustrates a type of antimetabolite activity.

Several types of interaction contribute to the formation of enzyme-substrate complexes: attractions between charged (ionic) groups on the protein and the substrate, hydrogen bonding, hydrophobic forces (the tendency of hydrocarbon moieties of side chains of amino acid residues to associate with the nonpolar groups of the substrate in a water environment), and London forces (induced dipole interactions).

Many studies of enzyme specificity have involved proteolytic enzymes (proteases). Configurational specificity can be exemplified by the aminopeptidase that cleaves L-leucylglycylglycine but does not affect D-leucylglycylglycine. D-Alanyl-glycylglycine is cleaved slowly by this enzyme. These phenomena illustrate the significance of steric factors; at the active center of aminopeptidase, the closeness of approach affects the kinetics of the reaction.

One can easily imagine how difficult it is to study the reactivity of enzymes on a functional group basis because the mechanism of enzyme action is so complex.¹⁶ Nevertheless, the -SH group probably is found in more enzymes as a functional group than are the other polar groups. In some

Figure 25-3 ■ Proposed generalized mechanism for enzyme-catalyzed hydrolysis of $R-C(=O)-X$.

Figure 25-4 ■ Generalized mechanism of protease catalysis. (Adapted from Chem. Eng. News, Apr. 16, 1979, p. 23.)

enzymes (e.g., urease), the less readily available SH groups are necessary for biological activity and cannot be detected by the nitroprusside test, which is used to detect freely reactive SH groups.

A free -OH group of the tyrosyl residue is necessary for the activity of pepsin. Both the -OH of serine and the imidazole portion of histidine appear to be necessary parts of the active center of certain hydrolytic enzymes, such as trypsin and chymotrypsin, and furnish the electrostatic forces involved in a proposed mechanism (Fig. 25-3), in which E denotes enzyme and the other symbols are self-evident. (Alternative mechanisms have been proposed;¹⁵ esterification and hydrolysis were studied extensively by M. L. Bender [see *Journal of the American Chemical Society* 79:1258, 1957; 80:5338, 1958; 82:1900, 1960; 86:3704, 5330, 1964]. D. M. Blow reviewed studies concerning the structure and mechanism of chymotrypsin [see *Accounts of Chemical Research* 9:145, 1976].)

These two groups (i.e., -OH and $=\text{NH}$) could be located on separate peptide chains in the enzyme as long as the specific three-dimensional structure formed during activation of the zymogen brought them near enough to form a hydrogen bond. The polarization of the resulting structure would cause the serine oxygen to be the nucleophilic agent that attacks the carbonyl function of the substrate. The com-

plex is stabilized by the simultaneous "exchange" of the hydrogen bond from the serine oxygen to the carbonyl oxygen of the substrate.

The intermediate acylated enzyme is written with the proton on the imidazole nitrogen. The deacylation reaction involves the loss of this positive charge simultaneously with the attack of the nucleophilic reagent (abbreviated Nu:H).

Roberts²⁰ used nitrogen-15 (^{15}N) NMR to study the mechanism of protease catalysis. A schematic summary of the generalized mechanism is represented in Figure 25-4. It is concluded that the tertiary N-1 nitrogen of the histidine unit within the reactive center of the enzyme deprotonates the hydroxyl of the neighboring serine unit and simultaneously the hydroxyl oxygen exerts a nucleophilic attack on the carbonyl carbon of the amide substrate, as depicted in the scheme. A tetrahedral intermediate is implicated, and the carboxylate group of the aspartate unit (the third functional group within the reactive center) stabilizes the developing imidazolium ion by hydrogen bonding to the N-3 hydrogen. Finally, decomposition of the anionic tetrahedral intermediate toward product formation (amine and acylated serine) is promoted by prior protonation of the amide nitrogen by the imidazolium group.

A possible alternative route to deacylation would involve the nucleophilic attack of the imidazole nitrogen on the newly formed ester linkage of the postulated acyl internediate, leading to the formation of the acyl imidazole. The latter is unstable in water, hydrolyzing rapidly to give the product and regenerated active enzyme.

The reaction of an alkyl phosphate in such a scheme may be written in an entirely analogous fashion, except that the resulting phosphorylated enzyme would be less susceptible to deacylation through nucleophilic attack. The diagrammatic scheme in Figure 25-5 has been proposed to explain the function of the active thiol ester site of papain. This ester site is formed and maintained by the folding energy of the enzyme (protein) molecule.

Zymogens (Proenzymes)

Zymogens, also called *proenzymes*, are enzyme precursors. These proenzymes are said to be activated when they are transformed to the enzyme. Activation usually involves catalytic action by some proteolytic enzyme. Occasionally, the activators merely effect a reorganization of the tertiary structure (conformation) of the protein so that the groups involved within the reactive center become functional (i.e., unmasked).

Synthesis and Secretion of Enzymes

Exportable proteins (enzymes), such as amylase, ribonuclease, chymotrypsin(ogen), trypsin(ogen), and insulin,

Figure 25-5 ■ Proposed scheme for the action of papain.

are synthesized on the ribosomes. They pass across the membrane of the endoplasmic reticulum into the cisternae and directly into a smooth vesicular structure, which effects further transportation. They are finally stored in highly concentrated form within membrane-bound granules called *zymogen granules*. The exportable protein content of zymogen granules may reach a value of 40% of the total protein of the gland cell. In the enzyme sequences above, the newly synthesized exportable protein (enzyme) is not free in the cell sap. The stored exportable digestive enzymes are released into the extracellular milieu and the hormones into adjacent capillaries. Release of these proteins is initiated by specific inducers. For example, cholinergic agents (but not epinephrine) and Ca^{2+} effect a discharge of amylase, lipase, or others into the medium, increased glucose levels stimulate the secretion of insulin, and so on. This release of the reserve enzymes and hormones is completely independent of the synthetic process, as long as the stores in the granules are not depleted. Energy oxidative phosphorylation does not play an important role in these releases. Electron microscope studies indicate a fusion of the zymogen granule membrane with the cell membrane so that the granule opens directly into the extracellular lumen of the gland.

Classification

There are various systems for the classification of enzymes. The International Union of Biochemistry system includes some of the terminology used in the literature of medicinal chemistry, and in many instances the terms are self-explanatory. For example, transferases catalyze transfer of a group (e.g., methyltransferase); hydrolases catalyze hydrolysis reactions (e.g., esterases and amidases); and lyases catalyze nonhydrolytic removal of groups, leaving double bonds. There are also oxidoreductases, isomerases, and ligases. Other systems are sometimes used to classify and characterize enzymes, and the following terms are frequently encountered: *lipase, peptidase, protease, phosphatase, kinase, synthetase, dehydrogenase, oxidase, and reductase*.

Products

Pharmaceutically important enzyme products are listed in Table 25-3.

Pancreatin, USP. Pancreatin (Panteric) is a substance obtained from the fresh pancreas of the hog or the ox and contains a mixture of enzymes, principally pancreatic amylase (amyllopsin), protease, and pancreatic lipase (steapsin). It converts not less than 25 times its weight of USP Potato Starch Reference Standard into soluble carbohydrates and not less than 25 times its weight of casein into proteoses. Pancreatin of higher digestive power may be brought to this standard by admixture with lactose, sucrose containing not more than 3.25% of starch, or pancreatin of lower digestive power. Pancreatin is a cream-colored amorphous powder with a faint, characteristic, but not offensive, odor. It dissolves slowly but incompletely in water and is insoluble in alcohol. It acts best in neutral or faintly alkaline media, and excessive acid or alkali renders it inert. Pancreatin can be prepared by extracting the fresh gland with 25% alcohol or with water and subsequently precipitating with alcohol.

Besides the enzymes mentioned, it contains some trypsinogen, which can be activated by intestinal enterokinase; chymotrypsinogen, which is converted by trypsin to chymotrypsin; and carboxypeptidase.

Pancreatin is used largely for predigestion of food and for the preparation of hydrolysates. The value of its enzymes orally must be very small because they are digested by pepsin and acid in the stomach, although some of them may escape into the intestines without change. Even if they are protected by enteric coatings, it is doubtful they could be of great assistance in digestion.

Trypsin Crystallized, USP. Trypsin crystallized is a proteolytic enzyme crystallized from an extract of the pancreas gland of the ox, *Bos taurus*. It occurs as a white to yellowish white, odorless, crystalline or amorphous powder, and 500,000 USP trypsin units are soluble in 10 mL of water or saline TS.

Trypsin has been used for several conditions in which its proteolytic activities relieve certain inflammatory states, liquefy tenacious sputum, and so forth. Many side reactions are encountered, however, particularly when it is used parenterally, which mitigate against its use.

Pancrelipase, USP. Pancrelipase (Cotazym) has a greater lipolytic action than other pancreatic enzyme preparations. Hence, it is used to help control steatorrhea and in other conditions in which pancreatic insufficiency impair the digestion of fats in the diet.

Chymotrypsin, USP. Chymotrypsin (Chymar) is extracted from mammalian pancreas and is used in cataract surgery. A dilute solution is used to irrigate the posterior chamber of the eye to dissolve the fine filaments that hold the lens.

Dornase Alpha, USP. Dornase alpha (Pulmozyme) is a highly purified solution of recombinant human deoxyribonuclease I (rhDNase). It is indicated for use in cystic fibrosis because of its ability to liquefy secretions from the lung effectively. It accomplishes this by cleaving the extracellular DNA in purulent sputum and reducing the viscosity and elasticity of the secretion.

Hyaluronidase for Injection, USP. Hyaluronidase for injection (Alidase, Wydase) is a sterile, dry, soluble enzyme product prepared from mammalian testes and capable of hydrolyzing the mucopolysaccharide hyaluronic acid. It contains not more than 0.25 μg of tyrosine for each USP hyaluronidase unit. Hyaluronidase in solution must be stored in a refrigerator. Hyaluronic acid, an essential component of tissues, limits the spread of fluids and other extracellular material, and because the enzyme destroys this acid, injected fluids and other substances tend to spread farther and faster than normal when administered with this enzyme. Hyaluronidase may be used to increase the spread and consequent absorption of hypodermoclytic solutions; to diffuse local anesthetics, especially in nerve blocking; and to increase diffusion and absorption of other injected materials, such as penicillin. It also enhances local anesthesia in surgery of the eye.

TABLE 25-3 Pharmaceutically Important Enzyme Products

Name Proprietary Name	Preparations	Category	Application	Usual Adult Dose*	Usual Dose Range*
Pancreatin, USP <i>Panteric</i>	Pancreatin capsules, USP Pancreatin tablets, USP	Digestive aid		325 mg–1 g	
Trypsin crystallized, USP	Trypsin crystallized for aerosol, USP	Proteolytic enzyme		Aerosol, 125,000 USP units in 3 mL of saline daily	
Pancrelipase, USP <i>Cotazym</i>	Pancrelipase capsules, USP Pancrelipase tablets, USP	Digestive aid			An amount of pancrelipase equivalent to 8,000–24,000 USP units of lipolytic activity before each meal or snack, or to be determined by the practitioner according to the needs of the patient
Chymotrypsin, USP <i>Chymar</i>	Chymotrypsin for ophthalmic solution, USP	Proteolytic enzyme (for zonule lysis)	1–2 mL by irrigation to the posterior chamber of the eye, under the iris, as a solution containing 75–150 U/mL		
Dornase Alfa <i>Pulmozyme</i>	Aerosol	Proteolytic enzyme	Nebulizer		
Hyaluronidase for injection, USP <i>Alidase, Wydase</i>	Hyaluronidase injection, USP	Spreading agent		Hypodermoclysis, 150 USP hyaluronidase units	
Imiglucerase <i>Cerezyme</i>	Injection	Proteolytic enzyme			Dose based on body weight: range is 15–60 U/kg IV over 1–2 hours
Suttilains, USP <i>Travase</i>	Suttilains ointment, USP	Proteolytic enzyme	Topical, ointment, b.i.d. to q.i.d.		

*See USP DI for complete dosage information

and is useful in glaucoma because it causes a temporary drop in intraocular pressure.

Hyaluronidase is practically nontoxic, but caution must be exercised in the presence of infection because the enzyme may cause a local infection to spread, through the same mechanism. It should never be injected in an infected area. Sensitivity to the drug is rare.

The activity of hyaluronidase is determined by measuring the reduction in turbidity of a substrate of native hyaluronidate and certain proteins or by measuring the reduction in viscosity of a buffered solution of sodium or potassium hyaluronidate. Each manufacturer defines its product in turbidity or viscosity units, but values are not the same because they measure different properties of the enzyme.

Imiglucerase Injection. Imiglucerase injection (Cerezyme) is a form of human placental glucocerebrosidase from which the terminal mannose residues have been removed. This product is produced through recombinant technology

and is used to treat type-I Gaucher's disease because its ability to hydrolyze glucocerebroside prevents the accumulation of this lipid in organs and tissues.

Suttilains, USP. Suttilains (Travase) is a proteolytic enzyme obtained from cultures of *Bacillus subtilis* and used to dissolve necrotic tissue occurring in second- and third-degree burns as well as bed sores and ulcerated wounds.

Many substances are contraindicated during the topical use of suttilains. These include detergents and anti-infectives that denature the enzyme preparation. The antibiotics penicillin, streptomycin, and neomycin do not inactivate suttilains. Mafenide acetate is also compatible with the enzyme.

Streptokinase. Streptokinase (Kabikinase, Streptase) is a catabolic 47,000-Da protein secreted by group C β -hemolytic streptococci. It is a protein with no intrinsic enzymatic activity. Streptokinase activates plasminogen to plasmin, a proteolytic enzyme that hydrolyzes fibrin and

promotes the dissolution of thrombi. Plasminogen is activated when streptokinase forms a 1:1 stoichiometric complex with it. Allergic reactions to streptokinase occur commonly because of antibody formation in individuals treated with it. Furthermore, the antibodies inactivate streptokinase and reduce its ability to prolong thrombin time. Streptokinase is indicated for acute myocardial infarction, for local perfusion of an occluded vessel, and before angiography, by intravenous, intra-arterial, and intracoronary administration, respectively.

Urokinase. Urokinase (Abbokinase) is a glycosylated serine protease consisting of 411 amino acid residues, which exists as two polypeptide chains connected by a single disulfide bond. It is isolated from human urine or tissue culture of human kidneys. The only known substrate of urokinase is plasminogen, which is activated to plasmin, a fibrinolytic enzyme. Unlike streptokinase, urokinase is a direct activator of plasminogen. Urokinase is nonantigenic because it is an endogenous enzyme and, therefore, may be used when streptokinase use is impossible because of antibody formation. It is administered intravenously or by the intracoronary route. Its indications are similar to those of streptokinase.

Alteplase. Alteplase (Activase) is a tissue plasminogen activator (t-PA) produced by rDNA technology. It is a single-chain glycoprotein protease consisting of 527 amino acid residues. Native t-PA is isolated from a melanoma cell line. The single-chain molecule is susceptible to enzymatic digestion to a two-chain molecule, in which the two chains remain linked with a disulfide bond. Both forms of the native t-PA are equipotent in fibrinolytic (and plasminogen-activating) properties. It is an extrinsic plasminogen activator associated with vascular endothelial tissue, which preferentially activates plasminogen bound to fibrin. The fibrinolytic action of alteplase (t-PA) is confined to thrombi, with minimal systemic activation of plasminogen. It is produced commercially by rDNA methods by inserting the alteplase gene (acquired from human melanoma cells) into ovarian cells of the Chinese hamster, serving as host cells. The melanoma-derived alteplase is immunologically and chemically identical with the uterine form. Alteplase is indicated for the intravenous management of acute myocardial infarction.

Papain, USP. Papain (Papase), the dried and purified latex of the fruit of *Carica papaya* L. (Caricaceae), can digest protein in either acidic or alkaline media; it is best at a pH between 4 and 7 and at 65 to 90°C. It occurs as light brownish gray to weakly reddish brown granules or as a yellowish gray to weakly yellow powder. It has a characteristic odor and taste and is incompletely soluble in water to form an opalescent solution. The commercial material is prepared by evaporating the juice, but the pure enzyme has also been prepared and crystallized. In medicine, it has been used locally in various conditions similar to those for which pepsin is used. It has the advantage of activity over a wider range of conditions, but it is often much less reliable. Intrapertoneal instillation of a weak solution has been recommended to counteract a tendency to develop adhesions after abdominal surgery, and several enthusiastic reports have been made about its value under these conditions. Papain

has been reported to cause allergies in persons who handle it, especially those who are exposed to inhalation of the powder.

Bromelains. Bromelains (Ananase) is a mixture of proteolytic enzymes obtained from the pineapple plant. It is proposed for use in the treatment of soft tissue inflammation and edema associated with traumatic injury, localized inflammation, and postoperative tissue reactions. The swelling that accompanies inflammation may be caused by occlusion of the tissue spaces with fibrin. If this is true, enough Ananase would have to be absorbed and reach the target area after oral administration to act selectively on the fibrin. This is yet to be established, and its efficacy as an anti-inflammatory agent is inconclusive. An apparent inhibition of inflammation, however, has been demonstrated with irritants such as turpentine and croton oil (granuloma pouch technique). Ananase is available in 50,000-unit tablets for oral use.

Diastase. Diastase (Taka-Diastase) is derived from the action of a fungus, *Aspergillus oryzae* Cohn (Ahlburg), on rice hulls or wheat bran. It is a yellow, hygroscopic, almost tasteless powder that is freely soluble in water and can solubilize 300 times its weight of starch in 10 minutes. It is used in doses of 0.3 to 1.0 g in the same conditions as malt diastase. Taka-Diastase is combined with alkalies as an antacid in Takazyme, with vitamins in Taka-Combex, and in other preparations.

HORMONES

The hormones discussed in this chapter may be classified structurally as polypeptides, proteins, or glycoproteins. These hormones include metabolites elaborated by the hypothalamus, pituitary gland, pancreas, gastrointestinal tract, parathyroid gland, liver, and kidneys. A comprehensive review of the biochemistry of these polypeptides and other related hormones is beyond the scope of this chapter. For a detailed discussion, the reader should refer to the review by Wallis et al.²¹ and other literature cited throughout this chapter.

Hormones From the Hypothalamus

Spatola provides an excellent, although somewhat dated, review on the physiological and clinical aspects of hypothalamic-releasing hormones.²² Through use of these hormones, the central nervous system regulates other essential endocrine systems, including the pituitary, which in turn controls still other systems (e.g., the thyroid).

Thyroliberin (thyrotropin-releasing hormone [TRH]) is the hypothalamic hormone responsible for the release of the pituitary's thyrotropin. Thyrotropin stimulates the production of thyroxine and triiodothyronine by the thyroid. The latter thyroid hormones, by feedback regulation, inhibit the action of TRH on the pituitary. TRH is a relatively simple tripeptide that has been characterized as pyroglutamyl-histidyl-prolineamide. TRH possesses interesting biological properties. In addition to stimulating the release of thyrotropin, it promotes the release of prolactin. It has also some central nervous

system effects that have been evaluated for antidepressant therapeutic potential, but the results of clinical studies are not yet considered conclusive.

Gonadoliberein, as the name implies, is the gonadotropin-releasing hormone (Gn-RH), also known as luteinizing hormone-releasing hormone (LH-RH). This hypothalamic decapeptide stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary. LH-RH is considered to be of potential therapeutic importance in the treatment of hypogonadotropic infertility in both males and females.²³

A hypothalamic growth-releasing factor (GRF), also called somatoliberein, continues to be under intensive investigation. Its identification and biological characterization remain to be completed, but physiological and clinical data support the existence of hypothalamic control of pituitary release of somatotropin.

Somatostatin is another very interesting hypothalamic hormone.²² It is a tetradecapeptide possessing a disulfide bond linking two cysteine residues, 3 and 14, in the form of a 38-member ring. Somatostatin suppresses several endocrine systems. It inhibits the release of somatotropin and thyrotropin by the pituitary. It also inhibits the secretion of insulin and glucagon by the pancreas. Gastrin, pepsin, and secretin are intestinal hormones that are likewise affected by somatostatin. The therapeutic potential of somatostatin is discussed below in relation to the role of glucagon in the pathology of human diabetes.

Other hypothalamic hormones include the luteinizing hormone release-inhibiting factor (LHRIF), prolactin-releasing factor (PRF), corticotropin-releasing factor (CRF), melanocyte-stimulating hormone-releasing factor (MRF), and melanocyte-stimulating hormone release-inhibiting factor (MIF).

As the foregoing discussion illustrates, the hypothalamic endocrine system performs many essential functions affecting other endocrine systems. In turn, the thalamus and cortex exert control on the secretion of these (hypothalamic) factors. A complete review of this field is beyond the scope of this chapter; the interested reader should refer to the literature cited.²¹⁻²³

Pituitary Hormones

The pituitary gland, or the hypophysis, is located at the base of the skull and is attached to the hypothalamus by a stalk. The pituitary gland plays a major role²¹ in regulating activity of the endocrine organs, including the adrenal cortex, the gonads, and the thyroid. The neurohypophysis (posterior pi-

uitary), which originates from the brain, and the adenohypophysis (anterior pituitary), which is derived from epithelial tissue, are the two embryologically and functionally different parts of the pituitary gland. The adenohypophysis is under the control of hypothalamic regulatory hormones, and it secretes adrenocorticotrophic hormone (ACTH), growth hormone (GH), LH, FSH, prolactin, and others. The neurohypophysis is responsible for the storage and secretion of the hormones vasopressin and oxytocin, controlled by nerve impulses traveling from the hypothalamus.

ADRENOCORTICOTROPIC HORMONE

ACTH (adrenocorticotropin, corticotropin) is a medicinal agent that has been the center of much research. In the late 1950s, its structure was elucidated, and the total synthesis was accomplished in the 1960s. Related peptides also have been synthesized, and some of these possess similar physiological action. Human ACTH has 39 amino acid units within the polypeptide chain.

SAR studies of ACTH²⁴ showed that the COOH-terminal sequence is not particularly important for biological activity. Removal of the NH₂-terminal amino acid results in complete loss of steroidogenic activity. Full activity has been reported for synthetic peptides containing the first 20 amino acids. A peptide containing 24 amino acids has full steroidogenic activity, without allergenic reactions. This is of practical importance because natural ACTH preparations sometimes produce clinically dangerous allergic reactions.

Corticotropin exerts its major action on the adrenal cortex, promoting steroid synthesis by stimulating the formation of pregnenolone from cholesterol.²⁵ An interaction between ACTH and specific receptors is implicated in the mechanism leading to stimulation of adenylate cyclase and acceleration of steroid production. The rate-limiting step in the biosynthesis of steroids from cholesterol is the oxidative cleavage of the side chain of cholesterol, which results in the formation of pregnenolone. This rate-limiting step is regulated by cyclic adenosine monophosphate (cAMP). Corticotropin, through cAMP, stimulates the biosynthesis of steroids from cholesterol by increasing the availability of free cholesterol. This involves activation of cholesterol esterase by phosphorylation. Corticotropin also stimulates the uptake of cholesterol from plasma lipoproteins. Other biochemical effects exerted by ACTH include stimulation of phosphorylase and hydroxylase activities. Glycolysis also is increased by this hormone. Enzyme systems that catalyze processes involving the production of reduced nicotinamide adenine dinucleotide phosphate (NADPH) are also stimulated. (NADPH is required by the steroid hydroxylations that take place in the overall transformation of cholesterol to hydrocortisone, the major glucocorticoid hormone.) Pharmaceutically important ACTH products are listed in Table 25-4.

TABLE 25-4 Pharmaceutically Important ACTH Products

Preparation Proprietary Name	Category	Usual Adult Dose ^a	Usual Dose Range ^a	Usual Pediatric Dose ^a
Corticotropin injection, USP Corticotropin for injection, USP <i>Acthar</i>	Adrenocorticotrophic hormone; adrenocortical steroid (anti-inflammatory); diagnostic aid (adrenocortical insufficiency)	Adrenocorticotrophic hormone: parenteral, 20 USP units, q.i.d. Adrenocortical steroid (anti-inflammatory): parenteral, 20 USP units q.i.d. Diagnostic aid (adrenocortical insufficiency): rapid test—IM or IV, 25 USP units, with blood sampling in 1 hour; adrenocortical steroid output—IV infusion, 25 U in 500–1,000 mL of 5% dextrose injection over a period of 8 hours on each of 2 successive days, with 24-hour urine collection each day	Adrenocorticotrophic hormone: 40–80 U/day; adrenocortical steroid (anti-inflammatory): 40–80 U/day	Parenteral, 0.4 U/kg of body weight or 12.5 U/m ² of body surface, q.i.d.
Repository corticotropin injection, USP <i>Acthar Gel</i> , <i>Cortrophin Gel</i>	Adrenocorticotrophic hormone; adrenocortical steroid (anti-inflammatory); diagnostic aid (adrenocortical insufficiency)	Adrenocorticotrophic hormone: IM or SC, 40–80 U every 24–72 hours; IV infusion, 40–80 U in 500 mL of 5% dextrose injection given over an 8-hour period, q.d. Adrenocortical steroid (anti-inflammatory): IM or SC, 40–80 U every 24–72 hours; IV infusion, 40–80 U in 500 mL of 5% dextrose injection given over an 8-hour period, q.d. Diagnostic aid (adrenocortical insufficiency): IM, 40 U b.i.d. on each of 2 successive days, with 24-hour urine collection each day		Adrenocorticotrophic hormone: parenteral, 0.8 U/kg of body weight or 25 U/m ² of body surface per dose
Sterile corticotropin zinc hydroxide suspension, USP <i>Cortrophin-Zinc</i>	Adrenocorticotrophic hormone; adrenocortical steroid (anti-inflammatory); diagnostic aid (adrenocortical insufficiency)	Adrenocorticotrophic hormone: IM, initial, 40–60 U/day, increasing interval to 48, then 72 hours; reduce dose per injection thereafter; maintenance, 20 U/day to twice weekly Adrenocortical steroid (anti-inflammatory): IM, initial, 40–60 U/day, increasing interval to 48, then 72 hours; reduce dose per injection thereafter; maintenance, 20 U/day to twice weekly Diagnostic aid (adrenocortical insufficiency): IM, 40 U on each of 2 successive 24-hour periods		
Cosyntropin <i>Cortrosyn</i>	Diagnostic aid (adrenocortical insufficiency)	IM or IV, 250 µg		Children 2 years of age or less, 0.125 mg

^aSee USP DI for complete dosage information.

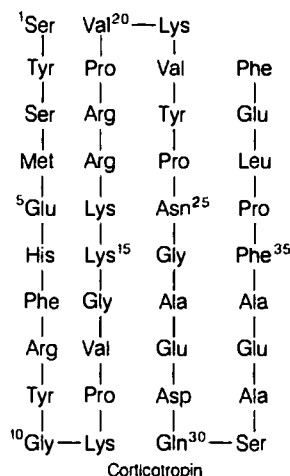

Corticotropin Injection, USP. Adrenocorticotropin injection (ACTH injectinn, Acthar) is a sterile preparation of the principle or principles derived from the anterior lobe of the pituitary of mammals used for food by humans. It occurs as a colorless or light straw-colored liquid or a soluble, amorphous solid by drying such liquid from the frozen state. It exerts a tropic influence on the adrenal cortex. The solution has a pH range of 3.0 to 7.0 and is used for its adrenocorticotrophic activity.

Repository Corticotropin Injection, USP. ACTH purified (ACTH-80, corticotropin gel, purified corticotropin)

is corticotropin in a solution of partially hydrolyzed gelatin to be used intramuscularly for a more uniform and prolonged maintenance of activity.

Sterile Corticotropin Zinc Hydroxide Suspension, USP. Sterile corticotropin zinc hydroxide suspension is a sterile suspension of corticotropin, adsorbed on zinc hydroxide, which contains no less than 45 and no more than 55 µg of zinc for each 20 USP corticotropin units. Because of its prolonged activity due to slow release of corticotropin, an initial dose of 40 USP units can be administered intramus-

cularly, followed by a maintenance dose of 20 units 2 or 3 times a week.

Cosyntropin. Cosyntropin (Cortrosyn) is a synthetic peptide containing the first 24 amino acids of natural corticotropin. Cosyntropin is used as a diagnostic agent to test for adrenal cortical deficiency. Plasma hydrocortisone concentration is determined before and 30 minutes after the administration of 250 μ g of cosyntropin. Most normal responses result in an approximate doubling of the basal hydrocortisone concentration in 30 to 60 minutes. If the response is not normal, adrenal insufficiency is indicated. Such adrenal insufficiency could be due to either adrenal or pituitary malfunction, and further testing is required to distinguish between the two. Cosyntropin (250 μ g infused within 4 to 8 hours) or corticotropin (80 to 120 U/day for 3 to 4 days) is administered. Patients with functional adrenal tissue should respond to this dosage. Patients who respond accordingly are suspected of hypopituitarism, and the diagnosis can be confirmed by other tests for pituitary function. Patients who have Addison's disease, however, show little or no response.

Corticotropin. Corticotropin (ACTH) is a synthetic peptide that may be used as an injectable in the determination of pituitary responsiveness. It possesses the amino acid sequence found in corticotropin-releasing hormone that is responsible for stimulating the release of ACTH.

MELANOTROPINS (MELANOCYTE-STIMULATING HORMONE)

Melanocyte-stimulating hormone (MSH) is elaborated by the intermediate lobe of the pituitary gland and regulates pigmentation of skin in fish, amphibians, and, to a lesser extent, humans. Altered secretion of MSH has been implicated in causing changes in skin pigmentation during the menstrual cycle and pregnancy. The two major types of melanotropin, α -MSH and β -MSH, are derived from ACTH and β -lipotropin, respectively. α -MSH contains the same amino acid sequence as the first 13 amino acids of ACTH; β -MSH has 18 amino acid residues. A third melanotropin, γ -melano-

tropin, is derived from a larger peptide precursor, proopiomelanocortin (POMC). Some important endocrinological correlations include inhibitory actions of hydrocortisone on the secretion of MSH and the inhibitory effects of epinephrine and norepinephrine on MSH action.

LIPOTROPINS (ENKEPHALINS AND ENDORPHINS)

Opiates, such as opium and morphine, have been known for centuries as substances that relieve pain and suffering. Neuropharmacologists have theorized that opiates interact with receptors in the brain that are affected by endogenous substances that function as regulators of pain perception. The important breakthrough came in 1975, with the isolation of two peptides with opiate-like activity²⁶ from pig brains. These related pentapeptides, called methionine-enkephalin (met-enkephalin) and leucine-enkephalin (leu-enkephalin), are abundant in certain nerve terminals and have been found in the pituitary gland.

An examination of the structures of enkephalins revealed that the amino acid sequence of met-enkephalin was identical with the sequence of residues 61 to 65 of β -lipotropin (β -LPH), a larger peptide found in the pituitary gland. This discovery suggested that β -LPH might be a precursor for other larger peptides containing the met-enkephalin sequence. Soon after the structural relationship between β -LPH and met-enkephalin was established, longer peptides, called *endorphins*, were isolated from the intermediate lobe

of the pituitary gland. The endorphins (α , β , and γ) contained the met-enkephalin amino acid sequence and possessed morphine-like activity.²⁷ The longest of these peptides, β -endorphin, a 31-residue peptide (residues 61 to 91 of β -LPH), is about 20 to 50 times more potent than morphine as an analgesic and has a considerably longer duration of action than enkephalins. Numerous enkephalin analogues and derivatives have been prepared, and their biological activity has been evaluated. Like morphine, β -endorphin and the enkephalins can induce tolerance and dependence.

In addition to the enkephalins and endorphins, several other opioid peptides have been extracted from pituitary, adrenal, and nervous tissue, including dynorphins and neo-endorphins. The peptides β -LPH, ACTH, and γ -MSH are derived from the same precursor, POMC.

The endorphins and enkephalins have a wide range of biological effects, and most of their actions are in the central nervous system. Their actions include inhibition of release of dopamine in brain tissue and inhibition of release of acetylcholine from neuromuscular junctions. The role of endorphins and enkephalins as inhibitory neurotransmitters agrees well with the observed biological effects of these peptides in lowering response to pain and other stimuli. The role of endorphins and enkephalins as neurotransmitters and neuromodulators, with emphasis on receptor interactions, has been reviewed.²⁸ Also, see Chapter 22, Analgesic Agents, in this textbook.

GROWTH HORMONE (SOMATOTROPIN)

GH is a 191-residue polypeptide elaborated by the anterior pituitary. The amino acid sequence of GH has been determined, and comparison with growth hormones of different species has revealed considerable structural variation.²⁹ In addition, the structure and properties of human GH have been reviewed.³⁰

The major biological action of GH is to promote overall somatic growth. Deficiency in the secretion of this hormone can cause dwarfism, and an overproduction of this hormone can cause acromegaly and gigantism. Secretion of this hormone is stimulated by growth hormone-releasing hormone (GH-RH), a 44-residue polypeptide secreted by the hypothalamus. Secretion of GH is inhibited by somatostatin.

GH stimulates protein synthesis, both in the skeletal muscles and in the liver. In the liver, GH stimulates uptake of amino acids and promotes the synthesis of all forms of RNA. It stimulates glucagon secretion by the pancreas, increases synthesis of glycogen in muscles, augments the release of fatty acids from adipose tissue, and increases osteogenesis. It also causes acute hypoglycemia followed by elevated blood glucose concentration and, perhaps, glycosuria.

GH has been recognized as an effective replacement therapy for GH-deficient children. The supply of GH, however, was very limited because its source was the pituitary glands of human cadavers, and several reports of deaths in children with Creutzfeldt-Jakob disease (caused by viral contamination of GH) halted the distribution of GH in 1977. Both of these problems were solved with the application of rDNA technology in the commercial production of somatrem and somatropin.

Somatrem (Systemic). Somatrem (Protropin) is a biosynthetic form of human GH that differs from the pituitary-

derived GH and recombinant somatotropin by addition of an extra amino acid, methionine. Because of its structural difference from the natural GH, patients receiving somatrem may develop antibodies, which may result in a decreased response to it. Somatrem is administered intramuscularly or subcutaneously, and the therapy is continued as long as the patient responds, until the patient reaches mature adult height, or until the epiphyses close. The dosage range is 0.05 to 0.1 IU.

Somatropin (rDNA Origin). Somatropin for injection (Humatrope) is a natural-sequence human GH of rDNA origin. Its composition and sequence of amino acids are identical with those of human GH of pituitary origin. It is administered intramuscularly or subcutaneously. The dosage range is 0.05 to 0.1 IU.

PROLACTIN

Prolactin (PRL), a hormone secreted by the anterior pituitary, was discovered in 1928. It is a 198-residue polypeptide with general structural features similar to those of GH. PRL stimulates lactation of parturition.

Gonadotropic Hormones

The two principal gonadotropins elaborated by the adenohypophysis are FSH and LH. LH is also known as *interstitial cell-stimulating hormone*. The gonadotropins along with thyrotropin form the incomplete glycoprotein group of hormones. FSH and LH may be produced by a single cell, the gonadotroph. The secretion of FSH and LH is controlled by the hypothalamus, which produces LH-RH. LH-RH stimulates the secretion of both FSH and LH, although its effects on the secretion of LH are more pronounced.

FOLLICLE-STIMULATING HORMONE

FSH promotes the development of ovarian follicles to maturity as well as spermatogenesis in testicular tissue. It is a glycoprotein, and the carbohydrate component is considered to be associated with its activity.

LUTEINIZING HORMONE

LH is another glycoprotein. It acts after the maturing action of FSH on ovarian follicles, stimulates production of estrogens, and transforms the follicles into corpora lutea. LH also acts in the male to stimulate the Leydig cells that produce testosterone.

MENOTROPINS

Pituitary hormones prepared from the urine of postmenopausal women whose ovarian tissue does not respond to gonadotropin are available for medicinal use as the product menotropins (Pergonal). The latter has FSH and LH gonadotropin activity in a 1:1 ratio. Menotropins are useful in the treatment of anovular women whose ovaries respond to pituitary gonadotropins but who have a gonadotropin deficiency caused by either pituitary or hypothalamus malfunction. Usually, menotropins are administered intramuscularly in an initial

dose of 75 IU of FSH and 75 IU of LH daily for 9 to 12 days, followed by 10,000 IU of chorionic gonadotropin 1 day after the last dose of menotropins.

Thyrotropin

The thyrotropic hormone, also called *thyrotropin* and *thyroid-stimulating hormone* (TSH), is a glycoprotein consisting of two polypeptide chains. This hormone promotes production of thyroid hormones by affecting the kinetics of the mechanism by which the thyroid concentrates iodide ions from the bloodstream, thereby promoting incorporation of the halogen into the thyroid hormones and release of hormones by the thyroid.

TSH (Thyropar) appears to be a glycoprotein (relative molecular mass [M_r] 26,000 to 30,000) containing glucosamine, galactosamine, mannose, and fucose, whose homogeneity is yet to be established. It is produced by the basophil cells of the anterior lobe of the pituitary gland. TSH enters the circulation from the pituitary, presumably traversing cell membranes in the process. After exogenous administration, it is widely distributed and disappears very rapidly from circulation. Some evidence suggests that the thyroid may directly inactivate some of the TSH by an oxidation mechanism that may involve iodine. TSH thus inactivated can be reactivated by certain reducing agents. TSH regulates the production by the thyroid gland of thyroxine, which stimulates the metabolic rate. Thyroxine feedback mechanisms regulate the production of TSH by the pituitary gland.

The decreased secretion of TSH from the pituitary is a part of a generalized hypopituitarism that leads to hypothyroidism. This type of hypothyroidism can be distinguished from primary hypothyroidism by the administration of TSH in doses sufficient to increase the uptake of radioiodine or to elevate the blood or plasma protein-bound iodine (PBI) as a consequence of enhanced secretion of hormonal iodine (thyroxine). Interestingly, massive doses of vitamin A inhibit the secretion of TSH. Thyrotropin is used as a diagnostic agent to differentiate between primary and secondary hypothyroidism. Its use in hypothyroidism caused by pituitary deficiency has limited application; other forms of treatment are preferable.

Somatostatin

Somatostatin was discovered in the hypothalamus. It is elaborated by the δ cells of the pancreas and elsewhere in the body. Somatostatin is an oligopeptide (14 amino acid residues) and is referred to as *somatotropin release-inhibiting factor* (SRIF).

Its primary action is inhibiting the release of GH from the pituitary gland. Somatostatin also suppresses the release of both insulin and glucagon. It causes a decrease in both cAMP levels and adenylate cyclase activity. It also inhibits calcium ion influx into the pituitary cells and suppresses glucose-induced pancreatic insulin secretion by activating and deactivating potassium ion and calcium ion permeability, respectively. The chemistry, SARs, and potential clinical applications have been reviewed.^{22, 31}

A powerful new synthetic peptide that mimics the action of somatostatin, octreotide acetate (Sandostatin), is approved by the Food and Drug Administration (FDA) for the treatment of certain rare forms of intestinal endocrine cancers, such as malignant carcinoid tumors and vasoactive intestinal peptide-secreting tumors (VIPomas). Octreotide acetate is indicated for long-term treatment of severe diarrhea associated with these carcinomas.

Placental Hormones

HUMAN CHORIONIC GONADOTROPIN

Human chorionic gonadotropin (hCG) is a glycoprotein synthesized by the placenta. Estrogens stimulate the anterior pituitary to produce placentalotropin, which in turn stimulates hCG synthesis and secretion. hCG is produced primarily during the first trimester of pregnancy. It exerts effects that are similar to those of pituitary LH.

hCG is used therapeutically in the management of cryptorchidism in prepubertal boys. It also is used in women in conjunction with menotropins to induce ovulation when the endogenous availability of gonadotropin is not normal.

HUMAN PLACENTAL LACTOGEN

Human placental lactogen (hPL) also is called *human choriomammotropin* and *chorionic growth-hormone prolactin*. This hormone exerts numerous actions. In addition to mammotropic and lactotropic effects, it exerts somatotropic and luteotropic actions. It is a protein composed of 191 amino acid units in a single-peptide chain with two disulfide bridges.²³ hPL resembles human somatotropin.

Neurohypophyseal Hormones (Oxytocin, Vasopressin)

The posterior pituitary (neurohypophysis) is the source of vasopressin, oxytocin, α - and β -MSH, and coherin. The synthesis, transport, and release of these hormones have been reviewed by Brownstein.³² Vasopressin and oxytocin are synthesized and released by neurons of the hypothalamic-neurohypophyseal system. These peptide hormones, and their respective neurophysin carrier proteins, are synthesized as structural components of separate precursor proteins, and these proteins appear to be partially degraded into

smaller bioactive peptides in the course of transport along the axon.

The structures of vasopressin and oxytocin have been elucidated, and these peptides have been synthesized. Actually, three closely related nonapeptides have been isolated from mammalian posterior pituitary: oxytocin and arginine vasopressin from most mammals and lysine vasopressin from pigs. The vasopressins differ from one another in the nature of the eighth amino acid residue: arginine and lysine, respectively. Oxytocin has leucine at position 8 and its third amino acid is isoleucine instead of phenylalanine. Several analogues of vasopressin have been synthesized and their antidiuretic activity evaluated. Desmopressin, 1-desamino-8-arginine-vasopressin, is a synthetic derivative of vasopressin. It is a longer-acting and more potent antidiuretic than vasopressin, with much less pressor activity. Desmopressin is much more resistant to the actions of peptidases because of the deamination at position 1, which accounts for its longer duration of action. The substitution of D- for L-arginine in position 8 accounts for its sharply lower vasoconstrictive effects.

Vasopressin also is known as the *pituitary antidiuretic*

hormone (ADH). This hormone can effect graded changes in the permeability of the distal portion of the mammalian nephron to water, resulting in either conservation or excretion of water; thus, it modulates the renal tubular reabsorption of water. ADH has been shown to increase cAMP production in several tissues. Theophylline, which promotes cAMP by inhibiting the enzyme (phosphodiesterase) that catalyzes its hydrolysis, causes permeability changes similar to those caused by ADH. Cyclic AMP also effects similar permeability changes; hence, it is suggested that cAMP is involved in the mechanism of action of ADH.

The nonrenal actions of vasopressin include its vasoconstrictor effects and neurotransmitter actions in the central nervous system, such as regulation of ACTH secretion, circulation, and body temperature.

ADH is therapeutically useful in the treatment of diabetes insipidus of pituitary origin. It also has been used to relieve intestinal paresis and distention.

Oxytocin is appropriately named on the basis of its oxytocic action. Oxytocin exerts stimulant effects on the smooth muscle of the uterus and mammary gland and has a relaxing effect on vascular smooth muscle when administered in high doses. It is considered the drug of choice to induce labor, particularly in cases of intrapartum hypotonic inertia. Oxytocin also is used in inevitable or incomplete abortion after the 20th week of gestation. It also may be used to prevent or control hemorrhage and to correct uterine hypotonicity. In some cases, oxytocin is used to promote milk ejection; it acts by contracting the myoepithelium of the mammary glands. Oxytocin is usually administered parenterally by intravenous infusion, intravenous injection, or intramuscular injection. Oxytocin citrate buccal tablets are also available, but the rate of absorption is unpredictable, and buccal administration is less precise. Topical administration (nasal spray)

TABLE 25-5 Neurohypophyseal Hormones: Pharmaceutical Products

Preparation Proprietary Name	Category	Usual Adult Dose ^a	Usual Pediatric Dose ^a
Oxytocin injection, USP <i>Pitocin, Syntocinon</i>	Oxytocic	IM, 3–10 U after delivery of placenta; IV, initially no more than 1–2 mU/minute, increased every 15–30 minutes in increments of 1–2 mU	
Oxytocin nasal solution, USP <i>Syntocinon</i>	Oxytocic	1 spray or 3 drops in 1 or both nostrils 2–3 minutes before nursing or pumping of breasts	
Vasopressin injection, USP <i>Pitressin</i>	Antidiuretic posterior pituitary hormone	IM or SC, 2.5–10 U t.i.d. or q.i.d. as necessary	IM or SC, 2.5–10 U t.i.d. or q.i.d. as necessary
Sterile vasopressin tannate oil suspension <i>Pitressin</i>	Antidiuretic posterior pituitary hormone	IM, 1.5–5 U every 1–3 days	IM, 1.25–2.5 U every 1–3 days
Desmopressin acetate nasal solution <i>DDAVP</i>	Antidiuretic posterior pituitary hormone	Maintenance: intranasal, 2–4 µg/day, as a single dose or in 2–3 divided doses.	Maintenance: intranasal, 2–4 µg/kg of body weight per day or 5–30 mg/day or in 2–3 divided doses
Desmopressin acetate injection <i>DDAVP, Stimte</i>	Antidiuretic posterior pituitary hormone	IV or SC, 2–4 µg/day usually in 2 divided doses in the morning or evening	IV, 3 µg/kg of body weight diluted in 0.9% sodium chloride injection USP

^aSee USP DI for complete dosage information.

2 or 3 minutes before nursing to promote milk ejection is sometimes recommended.³³ See Table 25-5 for product listing.

Oxytocin Injection, USP. Oxytocin injection is a sterile solution in water for injection of oxytocic principle prepared by synthesis or obtained from the posterior lobe of the pituitary of healthy, domestic animals used for food by humans. The pH is 2.5 to 4.5; expiration date, 3 years.

Oxytocin preparations are widely used with or without amniotomy to induce and stimulate labor. Although injection is the usual route of administration, the sublingual route is extremely effective. Sublingual and intranasal spray (Oxytocin Nasal Solution, USP) routes of administration also will stimulate milk letdown.

Vasopressin Injection, USP. Vasopressin injection (Pitressin) is a sterile solution of the water-soluble pressor principle of the posterior lobe of the pituitary of healthy, domestic animals used for food by humans; it also may be prepared by synthesis. Each milliliter possesses a pressor activity equal to 20 USP posterior pituitary units; expiration date, 3 years.

Vasopressin Tannate. Vasopressin tannate (Pitressin Tannate) is a water-insoluble tannate of vasopressin administered intramuscularly (1.5 to 5 pressor units daily) for its prolonged duration of action by the slow release of vasopressin. It is particularly useful for patients who have diabetes insipidus, but it should never be used intravenously.

Felypressin. Felypressin, 2-L-phenylalanine-8-L-lysine vasopressin, has relatively low antidiuretic activity and little oxytocic activity. It has considerable pressor (i.e., vasoconstrictor) activity, which differs from that of epinephrine (i.e., following capillary constriction in the intestine it lowers the pressure in the vena portae, whereas epinephrine raises the portal pressure). Felypressin also causes increased renal blood flow in the cat, whereas epinephrine brings about a fall in renal blood flow. Felypressin is 5 times more effective as a vasopressor than is lysine vasopressin and is recommended in surgery to minimize blood flow, especially in obstetrics and gynecology.

Lypressin. Lypressin is synthetic 8-L-lysine vasopressin, a polypeptide similar to ADH. The lysine analogue is considered more stable, and it is absorbed rapidly from the nasal mucosa. Lypressin (Diapid) is pharmaceutically available as a topical solution, spray, 50 pressor units (185 µg)/mL in 5-mL containers. Usual dosage, topical (intranasal), one or more sprays applied to one or both nostrils one or more times daily.

Desmopressin Acetate. Desmopressin acetate (DDAVP, Stimate) is synthetic 1-desamino-8-D-arginine vasopressin. Its efficacy, ease of administration (intranasal), long duration of action, and lack of side effects make it the drug of choice for the treatment of central diabetes insipidus. It may also be administered intramuscularly or intravenously. It is preferred to vasopressin injection and oral anti-

diuretics for use in children. It is indicated in the management of temporary polydipsia and polyuria associated with trauma to, or surgery in, the pituitary region.

Pancreatic Hormones

Relationships between lipid and glucose levels in the blood and the general disorders of lipid metabolism found in diabetic subjects have received the attention of many chemists and clinicians. To understand diabetes mellitus, its complications, and its treatment, one has to begin with the basic biochemistry of the pancreas and the ways carbohydrates are correlated with lipid and protein metabolism. The pancreas produces insulin, as well as glucagon; β -cells secrete insulin and α -cells secrete glucagon. Insulin is considered first.

INSULIN

One of the major triumphs of the 20th century occurred in 1922, when Banting and Best extracted insulin from dog pancreas.³⁴ Advances in the biochemistry of insulin have been reviewed with emphasis on proinsulin biosynthesis, conversion of proinsulin to insulin, insulin secretion, insulin receptors, metabolism, effects by sulfonylureas, and so on.³⁵⁻³⁸

Insulin is synthesized by the islet β -cells from a single-chain, 86-amino-acid polypeptide precursor, proinsulin.³⁹ Proinsulin itself is synthesized in the polyribosomes of the rough endoplasmic reticulum of the β -cells from an even larger polypeptide precursor, preproinsulin. The B chain of preproinsulin is extended at the NH₂-terminus by at least 23 amino acids. Proinsulin then traverses the Golgi apparatus and enters the storage granules, where the conversion to insulin occurs.

The subsequent proteolytic conversion of proinsulin to insulin is accomplished by the removal of the Arg-Arg residue at positions 31 and 32 and the Arg-Lys residue at positions 64 and 65 by an endopeptidase that resembles trypsin in its specificity and a thiol-activated carboxypeptidase B-like enzyme.⁴⁰

The actions of these proteolytic enzymes on proinsulin result in the formation of equimolar quantities of insulin and the connecting C-peptide. The resulting insulin molecule consists of chains A and B, with 21 and 31 amino acid residues, respectively. The chains are connected by two disulfide linkages, with an additional disulfide linkage within chain A (Fig. 25-6).

The three-dimensional structure of insulin was determined by x-ray analysis of single crystals. These studies demonstrated that the high bioactivity of insulin depends on the integrity of the overall conformation. The biologically active form of the hormone is thought to be the monomer. The receptor-binding region consists of A-1 Gly, A-4 Glu, A-5 Gln, A-19 Tyr, A-21 Asn, B-12 Val, B-16 Tyr, B-24 Phe, and B-26 Tyr. The three-dimensional crystal structure appears to be conserved in solution and during its receptor interaction.

The amino acid sequence of insulins from various animal species has been examined.³⁵ Details of these are shown in Table 25-6. It is apparent from the analysis that frequent changes in sequence occur within the interchain disulfide ring (positions 8, 9, and 10). The hormonal sequence for porcine insulin is the closest to that of humans, differing

Figure 25-6 ■ Conversion of proinsulin to insulin

TABLE 25-6 Some Sequence Differences in Insulins of Various Species

Species	A Chain				B Chain			
	1	8	9	10	-1	1	29	30
Human	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Thr
Pork	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Ala
Beef	Gly.	Ala.	Ser.	Val.		Phe.	Lys.	Ala
Sheep	Gly.	Ala.	Gly.	Val.		Phe.	Lys.	Ala
Horse	Gly.	Thr.	Gly.	Ile.		Phe.	Lys.	Ala
Rabbit	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Ser
Chicken	Gly.	His.	Asn.	Thr.		Ala.	Lys.	Ala
Cod	Gly.	His.	Arg.	Pro.	Met.	Ala.	Lys.	—

Rat II ^a	Gly.	Thr.	Ser.	Ile.		Phe.	Met.	Ser

See Reference 55 for details.

^aAsp substitution for Glu at position 4 on A chain

only by the substitution of an alanine residue at the COOH-terminus of the B chain. Porcine insulin, therefore, is a good starting material for the synthesis of human insulin.

Insulin composes 1% of pancreatic tissue, and secretory protein granules contain about 10% insulin. These granules fuse with the cell membrane with simultaneous liberation of equimolar amounts of insulin and the C-peptide. Insulin enters the portal vein, and about 50% is removed in its first passage through the liver. The plasma half-life of insulin is approximately 4 minutes, compared with 30 minutes for the C-peptide.

Usually, exogenous insulin is weakly antigenic. Insulin antibodies have been observed to neutralize the hypoglycemic effect of injected insulin. The antibody-binding sites on insulin are quite different from the sites involved in binding of insulin with its receptors.⁴¹

Regulation of insulin secretion is affected by numerous factors, such as food, hormonal and neuronal stimuli, and ionic mechanisms.⁴² In humans, the principal substrate that stimulates the release of insulin from the islet β -cells is glucose. In addition to glucose, other substrates (e.g., amino acids, free fatty acids, and ketone bodies) also can stimulate insulin secretion directly. Secretin and ACTH can directly stimulate insulin secretion. Glucagon and other related peptides can increase the secretion of insulin, whereas somatostatin inhibits its secretion.

Autonomic neuronal mechanisms also play an important role in regulating insulin release. In the sympathetic nervous system, α -adrenergic agonists inhibit insulin release, whereas β -adrenergic agonists stimulate the release of insulin. In the parasympathetic nervous system, cholinomimetic drugs stimulate insulin release.

"Clinical" insulin that has been crystallized 5 times and then subjected to countercurrent distribution (2-butanol:1% dichloroacetic acid in water) yields about 90% insulin A, with varying amounts of insulin B together with other minor components. A and B differ by an amide group and have the same activity. End-member analysis, sedimentation, and diffusion studies indicate an M_r of about 6,000. The value of 12,000 M_r for insulin containing trace amounts of zinc (obtained by physical methods) is probably a bimolecular association product through the aid of zinc. Insulin was the first protein for which a complete amino acid sequence was determined. The extensive studies of Sanger⁴³ and others elucidated the amino acid sequence and structure of insulin. Katsoyannis⁴⁴ and others followed with the synthesis of A and B chains of human, bovine, and sheep insulin. The A and B chains were combined to form insulin in 60 to 80% yields, with a specific activity comparable to that of the natural hormone.

The total synthesis of human insulin was reported by Rittel et al.⁴⁵ These workers selectively synthesized the final molecule appropriately cross-linked by disulfide (-S-S-) groups in yields ranging between 40 and 50%, whereas earlier synthetic methods involved random combination of separately prepared A and B chains of the molecule.

rDNA technology has been applied successfully in the production of human insulin on a commercial scale. Human insulin is produced in genetically engineered *Escherichia coli*.⁴⁶ Eli Lilly and Co., in cooperation with Genentech, began marketing rDNA-derived human insulin (Humulin) in 1982. There are two available methods of applying rDNA technology in the production of human insulin. The earlier

method involved insertion of genes, for production of either the A or the B chain of the insulin molecule, into a special strain of *E. coli* (KI2) and subsequently combining the two chains chemically to produce an insulin that is structurally and chemically identical with pancreatic human insulin. The second, and more recent, method involves the insertion of genes for the entire proinsulin molecule into special *E. coli* cells that are then grown in fermentation process. The connecting C-peptide is then enzymatically cleaved from proinsulin to produce human insulin.⁴⁷ Human insulin produced by rDNA technology is less antigenic than that from animal sources.

Although insulin is readily available from natural sources (e.g., porcine and bovine pancreatic tissue), partial syntheses and molecular modifications have been developed as the basis for SAR studies. Such studies have shown that amino acid units cannot be removed from the insulin peptide chain A without significant loss of hormonal activity. Several amino acids of chain B, however, are not considered essential for activity. Up to the first six and the last three amino acid units can be removed without significant decrease in activity.²³

Two insulin analogues, which differ from the parent hormone in that the NH_2 -terminus of chain A (A^1) glycine has been replaced by L- and D-alanine, respectively, have been synthesized by Cosmatos et al.⁴⁸ for SAR studies. The relative potencies of the L and D analogues reveal interesting SARs. The L- and D-alanine analogues are 9.4 and 95%, respectively, as potent as insulin in glucose oxidation. The relative binding affinity to isolated fat cells is reported to be approximately 10% for the L- and 100% for the D analogue. Apparently, substitution on the α carbon of A^1 glycine of insulin with a methyl in a particular configuration interferes with the binding; hence, the resulting analogue (that of L-alanine) is much less active. Methyl substitution in the opposite configuration affects neither the binding nor the bioactivity.

Molecular modifications of insulin on the amino groups appear to reduce bioactivity, but modifications of the ϵ -amino group of lysine number 29 on chain B (B-29) may yield active analogues. Accordingly, May et al.⁴⁹ synthesized N- ϵ -(+)-biotinyl insulin, which was equipotent with natural insulin. Complexes of this biotinyl-insulin derivative with avidin also were prepared and evaluated biologically; these complexes showed a potency decrease to 5% of that of insulin. Such complexes conjugated with ferritin are expected to be useful in the development of electron microscope stains of insulin receptors.

Alteration in the tertiary structure of insulin appears to drastically reduce biological activity as well as receptor binding. The three-dimensional structure provided by x-ray crystallography of the insulin monomer has revealed an exposed hydrophobic face that is thought to be involved directly in interacting with the receptor.⁵⁰ Thus, loss of biological activity in insulin derivatives, produced by chemical modification, can be interpreted in terms of adversely affecting this hydrophobic region. Also, species variation in this hydrophobic region is very unusual.

Insulin is inactivated *in vivo* by (a) an immunochemical system in the blood of insulin-treated patients, (b) reduction of disulfide bonds (probably by glutathione), and (c) insulinase (a proteolytic enzyme) that occurs in liver. Pepsin and chymotrypsin hydrolyze some peptide bonds that lead to

inactivation. Insulin is inactivated by reducing agents such as sodium bisulfite, sulfurous acid, and hydrogen.

Advances in the area of insulin's molecular mechanisms have been reviewed^{36-38, 51} with emphasis on receptor interactions, effect on membrane structure and functions, effects on enzymes, and the role of second messengers. The insulin receptor is believed to be a glycoprotein complex with a high M_r . The receptor is thought to consist of four subunits: two identical α units with an M_r of about 130,000 Da and two identical β units with an M_r of 95,000 Da, joined together by disulfide bonds. The α subunits are primarily responsible for binding insulin to its receptor, and the β subunits are thought to possess intrinsic protein kinase activity that is stimulated by insulin. The primary effect of insulin may be a kinase stimulation leading to phosphorylation of the receptor as well as other intracellular proteins.^{52, 53} Additionally, insulin binding to its receptors may result in the generation of a soluble intracellular second messenger (possibly a peptide) that may mediate some insulin activity relating to activation of enzymes such as pyruvate dehydrogenase and glycogen synthetase. The insulin-receptor complex becomes internalized and may serve as a vehicle for translocating insulin to the lysosomes, in which it may be broken down and recycled back to the plasma membrane. The half-life of insulin is about 10 hours.

The binding of insulin to its target tissue is determined by several factors. The number of receptors in the target tissue and their affinity for insulin are two important determinants. These factors vary substantially from tissue to tissue. Another important consideration is the concentration of insulin itself. Elevated levels of circulating insulin decrease the number of insulin receptors on target cell surfaces and vice versa. Other factors that affect insulin binding to its receptors include pH, temperature, membrane lipid composition, and ionic strength.⁵³ It is conceivable, therefore, that conditions associated with insulin resistance, such as obesity and type I and type II diabetes mellitus, could be caused by altered receptor kinase activity or impaired generation of second messengers (low- M_r peptides), increased degradation of the messenger, or fewer substrates (enzymes involved in metabolic activity) for the messenger or receptor kinase.⁵⁴

Metabolic Effects of Insulin. Insulin has pronounced effects on the metabolism of carbohydrates, lipids, and proteins.⁵⁵ The major tissues affected by insulin are muscle (cardiac and skeletal), adipose tissue, and liver. The kidney is much less responsive, and others (e.g., brain tissue and red blood cells) do not respond at all. The actions of insulin are highly complex and diverse. Because many of the actions of insulin are mediated by second messengers, it is difficult to distinguish between its primary and secondary actions.

In muscle and adipose tissue, insulin promotes transport of glucose and other monosaccharides across cell membranes; it also facilitates transport of amino acids, potassium ions, nucleosides, and ionic phosphate. Insulin also activates certain enzymes—kinases and glycogen synthetase in muscle and adipose tissue. In adipose tissue, insulin decreases the release of fatty acids induced by epinephrine or glucagon. cAMP promotes fatty acid release from adipose tissue; therefore, it is possible that insulin decreases fatty acid release by reducing tissue levels of cAMP. Insulin also facilitates the incorporation of intracellular amino acids into protein.

Insulin is believed to influence protein synthesis at the ribosomal level in various tissues.⁵⁶ In skeletal muscles, insulin predominantly stimulates translation by increasing the rate of initiation of protein synthesis and the number of ribosomes. In the liver, the predominant effect is on transcription. In cardiac muscles, insulin is believed to decrease the rate of protein degradation.

In the liver, there is no barrier to the transport of glucose into cells; nevertheless, insulin influences liver metabolism, decreasing glucose output, decreasing urea production, lowering cAMP levels, and increasing potassium and phosphate uptake. The lower cAMP levels result in decreased activity of glycogen phosphorylase, leading to diminished glycogen breakdown and increased activity of glycogen synthetase. It appears that insulin induces specific hepatic enzymes involved in glycolysis, while inhibiting gluconeogenic enzymes. Thus, insulin promotes glucose use through glycolysis by increasing the synthesis of glucokinase, phosphofructokinase, and pyruvate kinase. Insulin decreases the availability of glucose from gluconeogenesis by suppressing pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-diphosphatase, and glucose-6-phosphatase.

Insulin's effects on lipid metabolism also are important. In adipose tissue, it has an antilipolytic action (i.e., an effect opposing the breakdown of fatty acid triglycerides). It also decreases the supply of glycerol to the liver. Thus, at these two sites, insulin decreases the availability of precursors for the formation of triglycerides. Insulin is necessary for the activation and synthesis of lipoprotein lipases, enzymes responsible for lowering very low-density lipoprotein (VLDL) and chylomicrons in peripheral tissue. Other effects include stimulation of the synthesis of fatty acids (lipogenesis) in the liver.

Diabetes mellitus is a systemic disease caused by a decrease in the secretion of insulin or reduced sensitivity or responsiveness to insulin by target tissue (insulin receptor activity). The disease is characterized by hyperglycemia, hyperlipidemia, and hyperaminoacidemia. Diabetes mellitus frequently is associated with the development of micro- and macrovascular diseases, neuropathy, and atherosclerosis. Various types of diabetes have been recognized and classified and their pathophysiology discussed.⁵⁷

The two major types of diabetes are type I, insulin-dependent diabetes mellitus (IDDM), and type II, non-insulin-dependent diabetes mellitus (NIDDM). Type I diabetes (also known as juvenile-onset diabetes) is characterized by a destruction of pancreatic β -cells, resulting in a deficiency of insulin secretion. Autoimmune complexes and viruses have been mentioned as two possible causes of β -cell destruction. Generally, in type I diabetes, receptor sensitivity to insulin is not decreased. Type II diabetes, also known as adult-onset diabetes, is characterized primarily by insulin receptor defects or postinsulin receptor defects. There is no destruction of β -cells, and insulin secretion is relatively normal. In reality, however, the two types of diabetes show a considerable overlap of clinical features.⁵⁷

Diabetes mellitus is associated with both microangiopathy (damage to smaller vessels, e.g., the eyes and kidney) and macroangiopathy (damage to larger vessels, e.g., atherosclerosis). Hyperlipidemia (characterized by an increase in the concentration of lipoproteins such as VLDL, intermediate density lipoprotein [IDL], and LDL) has been implicated in

greater stability than acidic solutions; neutral insulin solutions maintain nearly full potency when stored up to 18 months at 5 and 25°C. As noted in Table 25-7, the various preparations differ in onset and duration of action. A major disadvantage of regular insulin is its short duration of action (5 to 7 hours), which necessitates its administration several times daily.

Many attempts have been made to prolong the duration of action of insulin, for example, development of insulin forms less water soluble than the highly soluble (in body fluids) regular insulin. Protamine insulin preparations proved to be less soluble and less readily absorbed from body tissue. Protamine zinc insulin (PZI) suspensions were even longer acting (36 hours) than protamine insulin; these are prepared by mixing insulin, protamine, and zinc chloride with a buffered solution. The regular insulin/PZI ratios in clinically useful preparations range from 2:1 to 4:1.

Isophane insulin suspension incorporates some of the qualities of regular insulin injection and is usually long acting enough (although not as much as PZI) to protect the patient from one day to the next (the term *isophane* is derived from the Greek *iso* and *phane*, meaning equal and appearance, respectively). Isophane insulin is prepared by careful control of the protamine/insulin ratio and the formation of a crystalline entity containing stoichiometric amounts of insulin and protamine. (Isophane insulin also is known as *NPH*; the *N* indicates neutral pH, the *P* stands for protamine, and the *H* for Hegeberg, the developer of the product.) NPH insulin has a quicker onset and a shorter duration of action (28 hours) than PZI. NPH is given in single morning doses and normally exhibits greater activity during the day than

at night. NPH and regular insulin can be combined conveniently and effectively for many patients with diabetes.

The posology of various insulin preparations is summarized in Table 25-7.

A major concern with PZI and NPH insulins is the potential antigenicity of protamine (obtained from fish). This concern led to the development of lente insulins. By varying the amounts of excess zinc, by using an acetate buffer (instead of phosphate), and by adjusting the pH, two types of lente insulin were prepared. At high concentrations of zinc, a microcrystalline form precipitates and is called *ultralente*. Ultralente insulin is relatively insoluble and has a slower onset and a longer duration of action than PZI. At a relatively low zinc concentration, an amorphous form precipitates and is called *semilente insulin*. The latter is more soluble and has a quicker onset and a shorter duration of action than regular insulins. A third type of insulin suspension, lente insulin, is a 70:30 mixture of ultralente and semilente insulins. Lente insulin has a rapid onset and an intermediate duration of action (comparable to that of NPH insulin). Lente insulins are chemically incompatible with the PZI and NPH insulins because of the different buffer system used in the preparation of these insulins (an acetate buffer is used in lente insulins and a phosphate buffer is used in PZI and NPH insulins). Dosage and sources are summarized in Table 25-8.

Additionally, regular insulin will remain fast acting when combined with NPH but not when added to lente. The rapid action of regular insulin is neutralized by the excess zinc present in lente insulin.⁵⁴ Similar products⁶¹ containing rDNA-derived human insulin (instead of the bovine- and porcine-derived insulin) are available.

TABLE 25-8 Dosage and Source of Insulin Preparations

USP Insulin Type	Strengths and Sources	Usual Adult Dose ^a
Insulin injection (regular insulin, crystalline zinc insulin, Cipro)	U-40 mixed. U-100 mixed: purified beef, pork; purified pork; biosynthetic human; semisynthetic human U-500: purified pork	Diabetic hyperglycemia: SC, as directed by physician 15–30 minutes before meals up to t.i.d. or q.i.d.
Isophane insulin suspension (NPH insulin)	U-40 mixed. U-400 mixed: beef; purified beef, pork; purified pork; biosynthetic human; semisynthetic human	SC, as directed by physician, q.d. 30–60 minutes before breakfast; an additional dose before breakfast may be necessary for some patients about 30 minutes before a meal or at bedtime
Isophane insulin suspension (70%) and insulin injection (30%)	U-100: purified pork; semisynthetic human	SC, as directed by physician, q.d. 15–30 minutes before breakfast, or as directed
Insulin zinc suspension (Lente insulin)	U-40 mixed. U-100 mixed: beef; purified beef; purified pork; biosynthetic human; semisynthetic human	SC, as directed by physician, q.d. 30–60 minutes before breakfast; an additional dose may be necessary for some patients about 30 minutes before a meal or at bedtime
Extended insulin zinc suspension (Ultralente Insulin)	U-40 mixed. U-100 mixed: beef; purified beef	SC, as directed by physician, q.d. 30–60 minutes before breakfast
Prompt insulin zinc suspension (Semilente insulin)	U-40 mixed. U-100 mixed: beef; purified pork	SC, as directed by physician, q.d. 30–60 minutes before breakfast; an additional dose may be necessary for some patients about 30 minutes before a meal or at bedtime
Protamine zinc insulin suspension (PZI Insulin)	U-40 mixed. U-100 mixed: purified pork	SC, as directed by physician, q.d. 30–60 minutes before breakfast

SC, subcutaneously.

^aSee USP DI for complete dosage information

Progress in alternative routes of delivery of insulin has been prompted by problems associated with conventional insulin therapy, mentioned above. First, various types of electromechanical devices (infusion pumps) have been developed with the aim of reducing fluctuations in blood glucose levels associated with conventional insulin therapy (subcutaneous injections). These continuous-infusion pumps are either close-loop or open-loop systems. The ultimate goal of research in this area is to develop a reliable implantable (miniature) device for long-term use that would eliminate the need for daily administration and monitoring of blood glucose levels. The second area of research studies alternative routes of administration such as oral, nasal, and rectal. Preliminary results indicate that absorption of insulin at these sites is not uniform and is unpredictable. The third approach to correcting the problems of conventional insulin therapy is to supplement the defective pancreas by transplantation with a normally functioning pancreas from an appropriate donor. The major problem with this approach is rejection of the donor pancreas by the recipient, as well as problems associated with the draining of exocrine enzymes. A modified procedure transplants only viable pancreatic islet cells or fetal or neonatal pancreas. The possibility remains, however, that in type I diabetes, the newly transplanted pancreatic β -cells could be destroyed by the same autoimmune process that caused the disease in the first place.

GLUCAGON

Glucagon, USP. The hyperglycemic–glycogenolytic hormone elaborated by the α cells of the pancreas is known as glucagon. It contains 29 amino acid residues in the sequence shown. Glucagon has been isolated from the amorphous fraction of a commercial insulin sample (4% glucagon).

Attention has been focused on glucagon as a factor in the pathology of human diabetes. According to Unger et al.,⁶² the following observations support this implication of glucagon: elevated glucagon blood levels (hyperglucagonemia) have been observed in association with every type of hyperglycemia; when secretion of both glucagon and insulin is

suppressed, hyperglycemia is not observed unless the glucagon levels are restored to normal by the administration of glucagon; the somatostatin-induced suppression of glucagon release in diabetic animals and humans restores blood sugar levels to normal and alleviates certain other symptoms of diabetes.

Unger et al.⁶² propose that although the major role of insulin is regulation of the transfer of glucose from the blood to storage in insulin-responsive tissues (e.g., liver, fat, and muscle), the role of glucagon is regulation of the liver-mediated mobilization of stored glucose. The principal consequence of high concentrations of glucagon is liver-mediated release into the blood of abnormally high concentrations of glucose, thereby causing persistent hyperglycemia. This indicates that a relative excess of glucagon is an essential factor in the development of diabetes.

Glucagon's solubility is 50 $\mu\text{g/mL}$ in most buffers between pH 3.5 and 8.5. It is soluble, 1 to 10 mg/mL , in the pH ranges 2.5 to 3.0 and 9.0 to 9.5. Solutions of 200 $\mu\text{g/mL}$ at pH 2.5 to 3.0 are stable for at least several months at 4°C if sterile. Loss of activity by fibril formation occurs readily at high concentrations of glucagon at room temperature or above at pH 2.5. The isoelectric point appears to be at pH 7.5 to 8.5. Because it has been isolated from commercial insulin, its stability properties should be comparable to those of insulin.

As with insulin and some of the other polypeptide hormones, glucagon-sensitive receptor sites in target cells bind glucagon. This hormone–receptor interaction leads to activation of membrane adenylate cyclase, which catalyzes cAMP formation. Thus, intracellular cAMP levels are elevated. The mode of action of glucagon in glycogenolysis is basically the same as the mechanism of epinephrine (i.e., stimulation of adenylate cyclase). Subsequently, the increase in cAMP activates the protein kinase that catalyzes phosphorylation of phosphorylase kinase to phosphophosphorylase kinase. The latter is necessary for the activation of phosphorylase to form phosphorylase *a*. Finally, phosphorylase *a* catalyzes glycogenolysis, which is the basis for the hyperglycemic action of glucagon. Although both glucagon and epinephrine exert hyperglycemic action through cAMP, glucagon affects liver cells and epinephrine affects both muscle and liver cells.

Fain⁶³ reviewed the many phenomena associated with hormones, membranes, and cyclic nucleotides, including several factors that activate glycogen phosphorylase in rat liver. These factors involve not only glucagon but also vasopressin and the catecholamines. Glucagon and β -catecholamines mediate their effects on glycogen phosphorylase through cAMP but may involve other factors as well.

Glucagon exerts other biochemical effects. Gluconeogenesis in the liver is stimulated by glucagon, and this is accompanied by enhanced urea formation. Glucagon inhibits the incorporation of amino acids into liver proteins. Fatty acid synthesis is decreased by glucagon. Cholesterol formation is also reduced. Glucagon activates liver lipases, however, and stimulates ketogenesis. Ultimately, the availability of fatty acids from liver triglycerides is elevated, fatty acid oxidation increases acetyl-CoA and other acyl-CoAs, and ketogenesis is promoted. As glucagon effects elevation of cAMP levels, release of glycerol and free fatty acids from adipose tissue also is increased.

Glucagon, whose regulatory effect on carbohydrate and fatty acid metabolism is well understood, is therapeutically important. It is recommended for the treatment of severe hypoglycemic reactions caused by the administration of insulin to diabetic or psychiatric patients. Of course, this treatment is effective only when hepatic glycogen is available. Nausea and vomiting are the most frequently encountered reactions to glucagon.

Usual dose: parenteral, adults, 500 μg to 1 mg (0.5 to 1 unit), repeated in 20 minutes if necessary; pediatric, 25 μg /kg of body weight, repeated in 20 minutes if necessary.

Gastrointestinal Hormones

There is a formidable array of polypeptide hormones of the gastrointestinal tract that includes secretin, pancreatico-zymin-cholecystokinin, gastrin, motilin, neurotensin, vaso-active intestinal peptide, somatostatin, and others. The biosynthesis, chemistry, secretion, and actions of these hormones have been reviewed.⁶⁴

GASTRIN

Gastrin is a 17-residue polypeptide isolated from the antral mucosa. It was isolated originally in two different forms. In one of the forms, the tyrosine residue in position 12 is sulfated. Both forms are biologically active. Cholinergic response to the presence of food in the gastrointestinal tract provides the stimulus for gastrin secretion. The lowering of pH in the stomach inhibits the secretion of gastrin. The effects of structural modification of gastrin on gastric acid secretion have been reviewed.⁶⁵ These studies revealed that the four residues at the COOH terminus retain significant biological activity and that the aspartate residue is the most critical for activity. The most important action of gastrin is to stimulate the secretion of gastric acid and pepsin. Other actions of gastrin include increased secretion of pancreatic enzymes; contraction of smooth muscles; water and electrolyte secretion by the stomach and pancreas; water and electrolyte absorption by the small intestine; and secretion of insulin, glucagon, and somatostatin. A synthetic pentapeptide derivative, pentagastrin, is currently used as a gastric acid secretagogue.

Pentagastrin. Pentagastrin (Pceptavlon), a physiological gastric acid secretagogue, is the synthetic pentapeptide derivative *N*-*t*-butyloxycarbonyl- β -alanine-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanyl amide. It contains the COOH-terminal tetrapeptide amide (H · Try · Met · Asp · Phe · NH₂), which is considered to be the active center of the natural gastrins. Accordingly, pentagastrin appears to

have the physiological and pharmacological properties of the gastrins, including stimulation of gastric secretion, pepsin secretion, gastric motility, pancreatic secretion of water and bicarbonate, pancreatic enzyme secretion, biliary flow and bicarbonate output, intrinsic factor secretion, and contraction of the gallbladder.

Pentagastrin is indicated as a diagnostic agent to evaluate gastric acid secretory function, and it is useful in testing for anacidity in patients with suspected pernicious anemia, atrophic gastritis or gastric carcinoma, hypersecretion in suspected duodenal ulcer or postoperative stomal ulcers, and Zollinger-Ellison tumor.

Pentagastrin is usually administered subcutaneously; the optimal dose is 6 μg /kg. Gastric acid secretion begins approximately 10 minutes after administration, and peak responses usually occur within 20 to 30 minutes. The usual duration of action is from 60 to 80 minutes. Pentagastrin has a relatively short plasma half-life, perhaps less than 10 minutes. The available data from metabolic studies indicate that pentagastrin is inactivated by the liver, kidney, and tissues of the upper intestine.

Contraindications include hypersensitivity or idiosyncrasy to pentagastrin. It should be used with caution in patients with pancreatic, hepatic, or biliary disease.

SECRETIN

Secretin is a 27-amino-acid polypeptide that is structurally similar to glucagon. The presence of acid in the small intestine is the most important physiological stimulus for the secretion of secretin. The primary action of secretin is on pancreatic acinar cells that regulate the secretion of water and bicarbonate. Secretin also promotes the secretion of pancreatic enzymes, to a lesser extent. Secretin inhibits the release of gastrin and, therefore, gastric acid. It also increases stomach-emptying time by reducing the contraction of the pyloric sphincter.⁶⁴

CHOLECYSTOKININ-PANCREOZYMIN

It was thought originally that cholecystokinin and pancreatico-zymin were two different hormones. Cholecystokinin was

thought to be responsible for contraction of the gallbladder, whereas pancreozymin was believed to induce secretion of pancreatic enzymes. It is now clear that both actions are caused by a single 33-residue polypeptide, referred to as *cholecystokinin-pancreozymin* (CCK-PZ). CCK-PZ is secreted in the blood in response to the presence of food in the duodenum, especially long-chain fatty acids. The five COOH-terminal amino acid residues are identical with those in gastrin. The COOH-terminal octapeptide retains full activity of the parent hormone.

The octapeptide is found in the gut as well as the central nervous system. SARs of cholecystokinin have been reviewed.⁶⁴ The COOH-terminal octapeptide is present in significant concentrations in the central nervous system. Its possible actions here, the therapeutic implications in the treatment of Parkinson's disease and schizophrenia, and its SAR have been reviewed.⁶⁵

VASOACTIVE INTESTINAL PEPTIDE

Vasoactive intestinal peptide (VIP) is widely distributed in the body and is believed to occur throughout the gastrointestinal tract. It is a 28-residue polypeptide with structural similarities to secretin and glucagon. It causes vasodilatation and increases cardiac contractility. VIP stimulates bicarbonate secretion, relaxes gastrointestinal and other smooth muscles, stimulates glycogenesis, inhibits gastric acid secretion, and stimulates insulin secretion. Its hormonal and neurotransmitter role has been investigated.⁶⁶

GASTRIC INHIBITORY PEPTIDE

Gastric inhibitory peptide (GIP) is a 43-amino-acid polypeptide isolated from the duodenum. Secretion of GIP into the blood is stimulated by food. The primary action of GIP is inhibition of gastric acid secretion. Other actions include stimulation of insulin and glucagon secretion and stimulation of intestinal secretion.⁶⁴

MOTILIN

Motilin is a 22-residue polypeptide isolated from the duodenum. Its secretion is stimulated by the presence of acid in

Vasoactive Intestinal Peptide

the duodenum. Motilin inhibits gastric motor activity and delays gastric emptying.

NEUROTENSIN

Neurotensin is a 13-amino-acid peptide, first isolated from bovine hypothalamus. It has now been identified in the intestinal tract. The ileal mucosa contains 90% of the total neurotensin of the body. It is implicated as a releasing factor for several adenohipophyseal hormones. It causes vasodilatation, increases vascular permeability, and increases gastrin secretion. It decreases secretion of gastric acid and secretin.

Parathyroid Hormone

This hormone is a linear polypeptide containing 84 amino acid residues. SAR studies⁶⁷ of bovine parathyroid hormone revealed that the biological activity is retained by an NH₂-terminal fragment consisting of 8 amino acid residues. It regulates the concentration of calcium ion in the plasma within the normal range, in spite of variations in calcium intake, excretion, and anabolism into bone. Also, for this hormone, cAMP is implicated as a second messenger. Parathyroid hormone activates adenylate cyclase in renal and skeletal cells, and this effect promotes formation of cAMP from ATP. The cAMP increases the synthesis and release of the lysosomal enzymes necessary for the mobilization of calcium from bone.

Parathyroid Injection, USP. Parathyroid injection has been used therapeutically as an antihypocalcemic agent for the temporary control of tetany in acute hypoparathyroidism.

CALCITONIN

Calcitonin (thyrocalcitonin) is a 32-amino-acid polypeptide hormone secreted by parafollicular cells of the thyroid glands in response to hypocalcemia. The entire 32-residue peptide appears to be required for activity, because smaller fragments are totally inactive. Common structural features of calcitonin isolated from different species are a COOH-terminal prolinamide, a disulfide bond between residues 1

and 7 at the NH₂ terminus, and a chain length of 32 residues. Calcitonin inhibits calcium resorption from bone, causing hypocalcemia, with parallel changes in plasma phosphate concentration. In general, calcitonin negates the osteolytic effects of parathyroid hormone.

The potential therapeutic uses of calcitonin are in the treatment of hyperparathyroidism, osteoporosis and other bone disorders, hypercalcemia of malignancy, and idiopathic hypercalcemia.

Angiotensins

The synthesis of angiotensins in the plasma is initiated by the catalytic action of renin (a peptidase elaborated by the kidneys) on angiotensinogen, an α -globulin produced by the liver and found in the plasma. The hydrolytic action of renin on angiotensinogen yields angiotensin I, a decapeptide consisting of the first 10 residues of the NH_2 -terminal segment of angiotensinogen. Angiotensin I has weak pharmacological activity. It is converted to angiotensin II, an octapeptide, by the catalytic actions of angiotensin-converting enzyme (ACE). Angiotensin II is a highly active peptide and is hydrolyzed to angiotensin III, a heptapeptide, by an aminopeptidase. Angiotensin III retains most of the pharmacological activity of its precursor. Further degradation of angiotensin III leads to pharmacologically inactive peptide fragments.

Angiotensin II is the most active form; hence, it is the most investigated angiotensin for pharmacological action and SARs. The two primary actions of angiotensin II are vasoconstriction and stimulation of synthesis and secretion of aldosterone by the adrenal cortex. Both of these actions lead to hypertension.

Mechanisms and sites of action of angiotensin agonists and antagonists in terms of biological activity and receptor interactions have been reviewed.⁶⁸ Additionally, compounds that inhibit ACE have found therapeutic use as antihypertensive agents (e.g., captopril). The synthesis and the biological activity of several ACE inhibitors have been reviewed.⁶⁹ Further, the agents used to target this enzyme are discussed in the cardiovascular section of this textbook.

Angiotensin Amide. Angiotensin amide (Hypertensin) is a synthetic polypeptide (1-1-aspariginyl-5-1-valine angio-

Angiotensin (angiotensin octapeptide) and has twice the pressor activity of angiotensin II. It is pharmaceutically available as a lyophilized powder for injection (0.5 to 2.5 mg diluted in 500 mL of sodium chloride injection or 5% dextrose for injection) to be administered by continuous infusion. The pressor effect of angiotensin is due to an increase in peripheral resistance; it constricts resistance vessels but has little or no stimulating action on the heart and little effect on the capacitance vessels. Angiotensin has been used as an adjunct in various hypotensive states. It is mainly useful in controlling acute hypotension during administration of general anesthetics that sensitize the heart to the effects of catecholamines.

Plasmakinolaz

Bradykinin and kallidin are potent vasodilators and hypotensive agents that have different peptide structures: bradykinin is a nonapeptide, whereas kallidin is a decapeptide. Kallidin is lysyl-bradykinin; that is, it has an additional lysine at the NH_2 terminus of the chain. These two compounds are made available from kininogen, a blood globulin, on hydrolysis. Trypsin, plasmin, or the proteases of certain snake venoms can catalyze the hydrolysis of kininogen.

Bradykinin is one of the most powerful vasodilators known: 0.05 to 0.5 $\mu\text{g/kg}$ intravenously can decrease blood pressure in all mammals investigated so far.

Although the kinins per se are not used as medicinals, kallikrein enzyme preparations that release bradykinin from the inactive precursor have been used in the treatment of Raynaud's disease, claudication, and circulatory diseases of the eyegrounds. (*Kallikreins* is the term used to designate the group of proteolytic enzymes that catalyze the hydrolysis of kininogen, forming bradykinin.)

SUBSTANCE P

Substance P is a polypeptide consisting of 11 amino acid residues. It has been implicated in the transmission of "painful" sensory information through the spinal cord to higher centers in the central nervous system.⁷⁰⁻⁷² Substance P is localized in the primary afferent sensory fibers. Other pharmacological effects are vasodilatation, stimulation of smooth muscles, stimulation of salivary secretion, and diuresis. In addition, this neuropeptide contributes to some inflammatory responses. Approximately 50% of the known neuropeptides are synthesized as biologically inactive glycine-extended precursors that require a carboxy-terminal posttranslational amidation for biological activity. Amidation enzymes are responsible for the conversion of the carboxyl group of the neuropeptide to the corresponding amide group and include the two amidating enzymes peptidylglycine α -monooxygenase (PAM) and peptidylamidoglycolate lyase (PGL), which work sequentially to produce the inflammatory neuropeptide Substance P from an inactive precursor peptide. Much research is being performed to exploit this mechanism of inflammation.

Thyroglobulin

Thyroglobulin, a glycoprotein, is composed of several peptide chains; it also contains 0.5 to 1% iodine and 8 to 10% carbohydrate in the form of two types of polysaccharide. The formation of thyroglobulin is regulated by TSH. Thyroglobulin has no hormonal properties. It must be hydrolyzed to release the hormonal iodothyronines thyroxine and liothyronine (see "Thyroid Hormones" in Chapter 19).

BLOOD PROTEINS

The blood is the transport system of the organism and thus performs important distributive functions. Considering the multitude of materials transported by the blood (e.g., nu-

trients, oxygen, carbon dioxide, waste products of metabolism, buffer systems, antibodies, enzymes, and hormones), its chemistry is very complex. Grossly, approximately 45% consists of the formed elements that can be separated by centrifugation, and of these, only 0.2% are other than erythrocytes. The 55% of removed plasma contains approximately 8% solids, of which a small portion (less than 1%) can be removed by clotting to produce defibrinated plasma, called *serum*. Serum contains inorganic and organic compounds, but the total solids are chiefly protein, mostly albumin, and the rest nearly all globulin. The plasma contains the protein fibrinogen, which is converted by coagulation to insoluble fibrin. The separated serum has an excess of the clotting agent thrombin.

Serum globulins can be separated by electrophoresis into α -, β -, and γ -globulins, which contain most of the antibodies. The immunological importance of globulins is well known. Many classes and groups of immunoglobulins are produced in response to antigens or even to a single antigen. The specificity of antibodies has been studied from various points of view, and Richards et al.⁷³ have suggested that even though immune sera appear to be highly specific for antigen binding, individual immunoglobulins may not only interact with several structurally diverse determinants, but may bind such diverse determinants to different sites within the combining region.

The importance of the blood coagulation process has been obvious for a long time. Coagulation mechanisms are covered in several biochemistry texts (see recommended readings), so a brief summary suffices here. The required time for blood clotting is normally 5 minutes, and any prolongation beyond 10 minutes is considered abnormal. Thrombin, the enzyme responsible for the catalysis of fibrin formation, originates from the inactive zymogen prothrombin; the prothrombin-thrombin transformation depends on calcium ions and thromboplastin. The fibrinogen-fibrin reaction catalyzed by thrombin involves proteolytic cleavage (partial hydrolysis), polymerization of the fibrin monomers from the preceding step, and actual clotting (hard clot formation). The final process forming the hard clot occurs in the presence of calcium ions and the enzyme fibrinase.

Thrombin, USP. Thrombin is a sterile protein substance prepared from prothrombin of bovine origin. It is used as a topical hemostatic because it can clot blood, plasma, or a solution of fibrinogen without addition of other substances. Thrombin also may initiate clotting when combined with gelatin sponge or fibrin foam.

For external use it is applied topically to the wound, as a solution containing 100 to 2,000 NIH units/mL in sodium chloride irrigation or sterile water for injection or as a dry powder.

Hemoglobin

Erythrocytes contain 32 to 55% hemoglobin, about 60% water, and the rest as stroma. Stroma can be obtained, after hemolysis of the corpuscles by dilution, through the process of centrifuging and consists of lecithin, cholesterol, inorganic salts, and a protein, stromatin. Hemolysis of the corpuscles, or "laking" as it is sometimes called, may be brought about by hypotonic solution, by fat solvents, by bile

salts that dissolve the lecithin, by soaps or alkalies, by saponins, by immune hemolysins, and by hemolytic sera, such as those from snake venom and numerous bacterial products.

Hemoglobin (Hb) is a conjugated protein; the prosthetic group heme (hematin) and the protein (globin), which is composed of four polypeptide chains, are usually in identical pairs. The total M_r is about 66,000, including four heme molecules. The molecule has an axis of symmetry and, therefore, is composed of identical halves with an overall ellipsoid shape of the dimensions $55 \times 55 \times 70 \text{ \AA}$.

Iron in the heme of hemoglobin (ferrohemoglobin), is in the ferrous state and can combine reversibly with oxygen to function as a transporter of oxygen.

In this process, the formation of a stable oxygen complex, the iron remains in the ferrous form because the heme moiety lies within a cover of hydrophobic groups of the globin. Both Hb and O_2 are magnetic, whereas HbO_2 is diamagnetic because the unpaired electrons in both molecules have become paired. When oxidized to the ferric state (methemoglobin or ferrihemoglobin), this function is lost. Carbon monoxide combines with hemoglobin to form carboxyhemoglobin (carbonmonoxyhemoglobin) to inactivate it.

The stereochemistry of the oxygenation of hemoglobin is very complex, and it has been investigated to some extent. Some evidence from x-ray crystallographic studies reveals that the conformations of the α and β chains are altered when their heme moieties complex with oxygen, thus promoting complexation with oxygen. It is assumed that hemoglobin can exist in two forms, the relative position of the subunits in each form being different. In the deoxy form, α and β subunits are bound to each other by ionic bonds in a compact structure that is less reactive toward oxygen than is the oxy form. Some ionic bonds are cleaved in the oxy form, relaxing the conformation. The latter conformation is more reactive to oxygen.

IMPACT OF BIOTECHNOLOGY ON THE DEVELOPMENT AND COMMERCIAL PRODUCTION OF PROTEINS AND PEPTIDES AS PHARMACEUTICAL PRODUCTS

Over the past decade and a half, far-reaching and revolutionary breakthroughs in molecular biology, especially research involving gene manipulations (i.e., genetic engineering), have led the way in the development of new biotechnology-derived products for the treatment of diseases. The term *bi-therapy* has been coined to describe the clinical and diagnostic use of biotechnology-derived products. Generally, these products are proteins, peptides, or nucleic acids that are structurally and/or functionally similar to naturally occurring biomolecules. The large-scale production of these complex biomolecules was beyond the capabilities of traditional pharmaceutical technologies. According to the 1995 survey⁷⁴ conducted by the Pharmaceutical Research and Manufacturers of America, there are currently more than 230 biotechnology-derived products in various stages of development and 24 approved biotechnology-derived products available in the market. The currently approved biotechnology products are

listed in Table 25-9. There are 14 approval applications pending at the FDA and 49 in the third and final stage of clinical testing. A detailed discussion of the various processes and methodologies involved in biotechnology and the wide array of biotechnology-derived pharmaceutical products is beyond the scope of this chapter and is covered in Chapter 6. There are a number of reference sources^{72, 75-77} available.

Since the emphasis in this chapter is on proteins, peptides, and enzymes, the discussion of biotechnology processes and products is limited to these topics. The various biotechnology-derived products⁷⁴ include enzymes, receptors, hormones and growth factors, cytokines, vaccines, monoclonal antibodies, and nucleic acids (genes and antisense RNA).

Biotechnology techniques are constantly changing and expanding; however, the two primary techniques responsible for the development of most of the products are rDNA technology and monoclonal antibody technology. The emphasis in this chapter is on rDNA technology and products derived from this technology. The monoclonal antibody technology and resulting products are discussed elsewhere in this book. Excellent references^{78, 79} are available for review. The following discussion of rDNA technology assumes that the reader has thorough comprehension of the normal process of genetic expression in human cells (i.e., replication, transcription, and translation). A number of biochemistry textbooks are available for review.

rDNA Technology

rDNA technology frequently has been referred to as *genetic engineering* or *gene cloning*. A comprehensive discussion of the process and application of rDNA technology is available in several good reviews.^{72, 75-77} The concept of genetic engineering is based on the fact that the genetic material (DNA) in all living organisms is made of the same four building blocks, that is, four different deoxynucleotides. Therefore, genetic material from one organism or cell may be combined with the genetic material of another organism or cell. Since every single protein, regardless of its source, is produced as a result of expression of a specific gene coding for it, the application of this technology in the mass production of desired human proteins is obvious. A number of human diseases are caused by deficiencies of desired proteins or peptides. For example, insulin deficiency is a major cause of diabetes, and human growth hormone deficiency causes dwarfism. If a human gene coding for a deficient protein is identified and isolated, then it may be combined with fast-replicating, nonchromosomal bacterial DNA (i.e., plasmids). The recombinant DNA is placed back into the bacteria, which then are grown in ideal media. The plasmids replicate and the genes within the plasmid are expressed, including the human gene, resulting in large quantities of the desired human protein.

The major steps in a typical rDNA process used in commercial-scale synthesis of human proteins are discussed below and summarized in Fig. 25-7.

1. Identification and isolation of the desired gene: The possible nucleotide sequence of a desired gene can be ascertained by (a) isolating and determining the amino acid sequence of the protein expressed by the gene and then determining the possible nucleotide sequences for the corresponding mRNA and the DNA

TABLE 25-9 Approved Biotechnology of Drugs and Vaccines

Product Name	Company	Indication (Date of U. S. Approval)
Actimmune Interferon gamma-1b	Genentech ^a (San Francisco, CA)	Management of chronic granulomatous disease (December 1990)
Activase Alteplase, recombinant	Genentech ^a (San Francisco, CA)	Acute myocardial infarction (November 1987); acute massive pulmonary embolism (June 1990)
Alferon N Interferon alfa-n3 (injection)	Interferon Sciences (New Brunswick, NJ)	Genital warts (October 1989)
Betaseron Interferon beta-1b, recombinant	Berlex Laboratories ^a (Wayne, NJ) Chiron ^a (Emeryville, CA)	Relapsing, remitting multiple sclerosis (July 1993)
Cerezyme Imglucerase for injection (recombinant glucocerebrosidase)	Genzyme (Cambridge, MA)	Treatment of Gaucher's disease (May 1994)
Engerix-B Hepatitis B vaccine (recombinant)	SmithKline Beecham ^a (Philadelphia, PA)	Hepatitis B (September 1989)
Epogen Epoetin alfa (rEPO)	Amgen ^a (Thousand Oaks, CA)	Treatment of anemia associated with chronic renal failure, including patients on dialysis and not on dialysis, and anemia in Retrovir-treated, HIV-infected patients (June 1989); treatment of anemia caused by chemotherapy in patients with nonmyeloid malignancies (April 1993)
Procrit [†] Epoetin alfa (rEPO)	Ortho Biotech ^a (Raritan, NJ)	Treatment of anemia associated with chronic renal failure, including patients on dialysis and not on dialysis, and anemia in Retrovir-treated, HIV-infected patients (December 1990); treatment of anemia caused by chemotherapy in patients with nonmyeloid malignancies (April 1993)
Humatrope Somatropin (rDNA origin) for injection	Eli Lilly ^a (Indianapolis, IN)	Human growth hormone deficiency in children (March 1987)
Humulin Human insulin (rDNA origin)	Eli Lilly ^a (Indianapolis, IN)	Diabetes (October 1982)
Intron A Interferon alfa-2b (recombinant)	Schering-Plough ^a (Madison, NJ)	Hairy cell leukemia (June 1986); genital warts (June 1988); AIDS-related Kaposi's sarcoma (November 1988); hepatitis C (February 1991); hepatitis B (July 1992)
KoGENate Antihemophilic factor (recombinant)	Miles ^a (West Haven, CT)	Treatment of hemophilia A (February 1993)
Leukine Sargramostim (yeast-derived GM-CSF)	Immunex ^a (Seattle, WA)	Autologous bone marrow transplantation (March 1991)
Neupogen Filgrastim (rG-CSF)	Amgen ^a (Thousand Oaks, CA)	Chemotherapy-induced neutropenia (February 1991); autologous or allogeneic bone marrow transplantation (June 1994); chronic severe neutropenia (December 1994)
Nutropin Somatropin for injection	Genentech ^a (San Francisco, CA)	Growth failure in children due to chronic renal insufficiency, growth hormone inadequacy in children (March 1994)
OncoScint CR/OV Satumomab pentetide	CYTOGEN ^a (Princeton, NJ)	Detection, staging, and follow-up of colorectal and ovarian cancers (December 1992)
ORTHOCLONE OKT 3 Muromonab-CD3	Ortho Biotech ^a (Raritan, NJ)	Reversal of acute kidney transplant rejection (June 1986); reversal of heart and liver transplant rejection (June 1993)
Proleukin Aldesleukin (interleukin-2)	Chiron ^a (Emeryville, CA)	Renal cell carcinoma (May 1992)
Protropin Somatrem for injection	Genentech ^a (San Francisco, CA)	Human growth hormone deficiency in children (October 1985)
Pulmozyme DNAse (dornase alpha)	Genentech ^a (San Francisco, CA)	Cystic fibrosis (December 1993)
RECOMBINATE Antihemophilic factor recombinant (rAHF)	Baxter Healthcare/Hyland Division (Glendale, CA) Genetics Institute ^b (Cambridge, MA)	Hemophilia A (December 1992)

(Continued)

TABLE 25-9 Approved Biotechnology of Drugs and Vaccines—Continued

Product Name	Company	Indication (Date of U. S. Approval)
RECOMBIVAX HB Hepatitis B vaccine (recombinant), MSD	Merck ^a (Whitehouse Station, NJ)	Hepatitis B prevention (July 1986)
ReoPro Abciximab	Centocor (Malvern, PA) Eli Lilly ^a (Indianapolis, IN)	Antiplatelet prevention of blood clots (December 1994)
Roferon-A Interferon alfa-2a, recombinant	Hoffmann-La Roche ^a (Nutley, NJ)	Hairy cell leukemia (June 1986); AIDS-related Kaposi's sarcoma (November 1988)

^aPhRMA member company.

^bPhRMA research affiliate.

^cProcrit was approved for marketing under Amgen's epoetin alfa PLA. Amgen manufactures the product for Ortho Biotech. Under an agreement between the two companies, Amgen licensed to Ortho Pharmaceuticals the U.S. rights to epoetin for indications in human use excluding dialysis and diagnostics.

- (gene), (b) isolating the mRNA and determining its nucleotide sequence, and (c) using DNA probes to "fish out" the desired gene from the genomic library (cellular DNA chopped up into segments 10,000 to 20,000 nucleotides long).
2. Constructing rDNA: Once the desired human gene is identified and isolated, it is recombined with genes of microbial cells that are known to have rapid rates of cell division. To accomplish

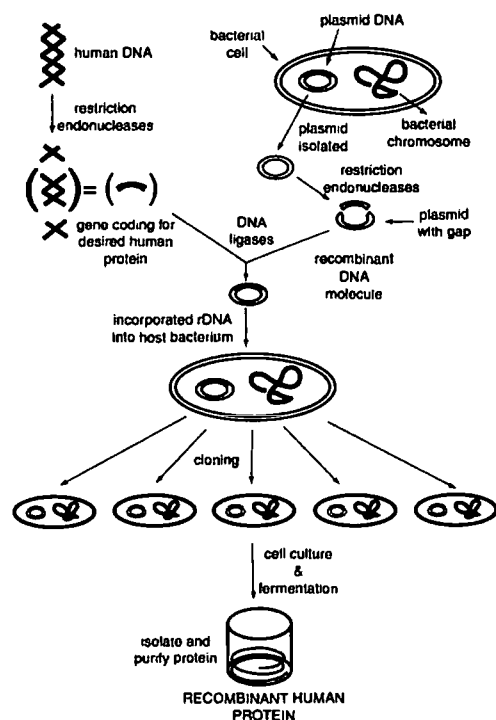

Figure 25-7 ■ Summary of a typical rDNA process used in the commercial-scale production of human proteins.

this task, bacterial enzymes known as *restriction endonucleases* are used. Over 100 different variations of these hydrolytic enzymes, which act like scissors in hydrolyzing the phosphodiester bonds of DNA at specific sites (i.e., nucleotide sequences), are available. The use of a specific restriction endonuclease both to obtain the human gene and to open a site on the microbial gene allows easy formation of the hybrid (recombined) DNA molecule because of the "sticky" ends on both genes. The ends of the human gene and the microbial DNA vector are "glued" together by enzymes known as *DNA ligases*. The human genes are placed in specific locations on the microbial DNA vector to ensure expression of the human gene when the microbial cells divide. Plasmids are the most commonly used microbial DNA. These extrachromosomal circular DNAs replicate independently of the chromosomes and are much smaller than chromosomal DNA. Plasmids are easy to manipulate and are considered excellent vectors to carry human genes. Other microbial cells used as hosts are yeast cells. Mammalian cells, such as Chinese hamster ovary cells, are used when glycosylation of the rDNA-derived protein is essential for biological activity (e.g., erythropoietin). Nonmammalian cells cannot glycosylate proteins.

3. Cloning: The cells carrying the recombined human gene are then allowed to grow in appropriate media. As the cells divide, the rDNA replicates and expresses its products, including the desired human protein as well as the normal bacterial proteins.
4. Isolation and purification of rDNA-derived protein: From this complex mixture containing bacterial proteins, cell components, chemicals used in preparing the media, etc., isolating and purifying the desired human protein is a daunting task indeed. This task requires sophisticated isolation techniques, such as complex filtrations, precipitations, and HPLC. The primary goal of the purification process is to ensure that the protein isolated will retain the biological activity of the native protein in the body. The rDNA-derived protein is then formulated into a pharmaceutical product that is stable during transportation, storage, and administration to a patient.

BIOTECHNOLOGY-DERIVED PHARMACEUTICAL PRODUCTS

The two dozen FDA-approved biotechnology-derived pharmaceutical products are listed in Table 25-9. There are more

than 200 other products in various stages of development.⁷⁴ The FDA-approved products fall loosely into five major categories: enzymes, hormones, lymphokines, hematopoietic factors, and biologicals. A detailed discussion of all of these products is beyond the scope of this chapter. Since most of these products are proteins or peptides, a cursory evaluation of them and their uses⁸⁰ follows.

rDNA-DERIVED ENZYMES

Alteplase, Recombinant. Alteplase (Activase) was discussed above in this chapter.

Dornase Alpha. Dornase alpha, rhDNase (Pulmozyme), is a mucolytic enzyme identical with the natural human DNase and is used in the treatment of cystic fibrosis. Patients with cystic fibrosis suffer from decreased pulmonary function and infections caused by the secretion of thick mucus. Proteins contained in the mucus are bound to extracellular DNA, produced as a result of disintegration of bacteria in the lungs. This enzyme is involved in cleaving extracellular DNA and separates DNA from proteins, allowing proteolytic enzymes to break down proteins and thus decrease the viscosity of mucus in the lungs.⁸¹ Proteins bound to extracellular DNA are not susceptible to proteolytic enzymes.⁸² Dornase alpha is a glycoprotein containing 260 amino acids that is commercially produced in genetically engineered Chinese hamster ovary cells.

Dornase alpha is indicated for the treatment of cystic fibrosis in conjunction with other available therapies, such as antibiotics, bronchodilators, and corticosteroids. Adult dosage is 2.5 mg inhaled once daily, administered via a recommended nebulizer. Dornase alpha should not be mixed or diluted with other agents in the nebulizer because of the possibility of adverse physicochemical changes that may affect activity. Common adverse effects include sore throat, hoarseness, and facial edema.

Imiglucerase. Imiglucerase (Cerezyme)⁸⁰ is a glycoprotein containing 497 amino acid residues and is N-glycosylated at four different positions. It is an analogue of the natural human enzyme β -glucocerebrosidase and contains arginine at position 495 instead of the histidine in the natural enzyme. It is commercially produced in genetically engineered Chinese hamster ovary cells.

Like the natural enzyme, imiglucerase catalyzes the hydrolysis of glucocerebroside, a glycolipid, to glucose and ceramide within the lysosomes of phagocytic cells. Gaucher's disease is caused by a deficiency of this enzyme, which results in the accumulation of glucocerebroside within tissue macrophages. The glycolipid-engorged macrophages are known as *Gaucher cells* and are responsible for the numerous clinical manifestations of Gaucher's disease. The common clinical manifestations of Gaucher's disease are severe anemia, thrombocytopenia, and skeletal complications that include osteonecrosis and osteopenia.

Imiglucerase is indicated for the long-term replacement therapy of Gaucher's disease. It is administered intravenously at an initial dose of 2.5 to 60 U/kg, infused over 1 to 2 hours. This dose is usually repeated every 2 weeks. Both the dose and the frequency of administration may be varied, however, depending on the response.⁸³ Common ad-

verse effects include dizziness, headache, abdominal discomfort, nausea, and rash.

rDNA-DERIVED HORMONES

The rDNA-derived hormones include insulin human injection USP (Humulin R, Novolin R, Velosulin Human), growth hormone (somatotropin; Humatrope), and somatrem (Protropin). All of these products, as well as other products containing human insulin, are discussed above in this chapter.

rDNA-DERIVED CYTOKINES

Interferons.⁸⁰ Interferons are natural glycoproteins produced by virtually all eukaryotic cells; they possess immunomodulating, antiviral, and cytotoxic activities. This family of glycoproteins is produced by cells in response to a wide range of stimuli.⁸⁴ In humans, interferons bind to cellular receptors, which leads to the synthesis of over a dozen proteins that contribute to viral resistance. The antiviral effects of interferons may be caused by inhibition of the synthesis of viral mRNA or proteins or prevention of viral penetration or uncoating.^{85, 86} Based on their antigenic subtypes, the interferons are classified into three major groups: α , β , and γ . α -Interferon and β -interferon are produced by virtually all cells in response to a viral infection and various other stimuli. γ -Interferon is produced specifically by the T lymphocytes and the natural killer cells. γ -Interferons have greater immunoregulatory, but lower antiviral, effects than α - or β -interferons.⁸⁶ More than 12 subspecies of α -interferons, 1 β -interferon, and 2 γ -interferons are known to exist. In general, the interferons are glycoproteins consisting of 165 to 166 amino acid residues. There are four rDNA-derived α -interferons available for clinical use around the world and three available in the United States (described below). All α -interferons exhibit antiviral and antiproliferative activity, enhance phagocytic activity, and augment specific cytotoxicity of lymphocytes for certain target cells.⁸⁷ The most common adverse effects of α - and β -interferons include flu-like symptoms, bone marrow suppression, neurotoxic effects, hypocalcemia, anorexia and other gastrointestinal symptoms, and weight loss.

Interferon Alfa-2a, Recombinant. Interferon alfa-2a, recombinant (Roferon), is produced from genetically engineered *E. coli* and contains 165 amino acid residues. At position 23, interferon alfa-2a has a lysine residue. The pharmaceutical product contains a single α -interferon subtype. A murine monoclonal antibody is used during purification by affinity chromatography. Interferon alfa-2a is used in the treatment of hairy cell leukemia and acquired immunodeficiency syndrome (AIDS)-related Kaposi's sarcoma. It is absorbed well after intramuscular or intravenous administration and has a half-life of 5 to 7 hours when administered by the intramuscular route. The solution should be stored in the refrigerator at 36 to 46°F and should not be frozen or shaken.

Interferon Alfa-2b, Recombinant. Interferon alfa-2b, recombinant (Intron A), also contains a single subtype of α -interferon. It is a glycoprotein containing 165 amino acid

residues and is commercially produced from genetically engineered *E. coli*. It differs from interferon α -2b in possessing an arginine residue at position 23. It is used in the treatment of hairy cell leukemia, condyloma acuminata (genital warts), AIDS-related Kaposi's sarcoma, hepatitis C, and hepatitis B. It is administered intramuscularly or subcutaneously with a half-life of 2 to 3 hours and via intravenous infusion with a half-life of 8 hours. The reconstituted solution is stable for 1 month when stored at a temperature of 36 to 46°F.

Interferon Alfa-n3 (injection). Interferon α -n3 (Alferon N) is a polyclonal mixture of up to 14 natural α -interferon subtypes and contains 166 amino acid residues. Its commercial production involves induction of pooled units of human leukocytes with an avian virus (Sendai virus). The purification process involves immunoaffinity and filtration chromatography. It is indicated primarily by intralesional injection for the treatment of genital warts. The solution should be stored at a temperature of 36 to 46°F and should not be shaken.

Interferon Beta-1b, recombinant. Interferon β -1b, recombinant (Betaseron), has biological effects similar to those of natural β -interferon and α -interferons. The natural β -interferon is a glycoprotein containing 166 amino acid residues. The rDNA product differs from the natural form, in that it is not glycosylated, it lacks the amino-terminal methionine, and it has serine in the place of methionine at position 17.⁸⁸ It is used for a wide variety of indications via intravenous, intramuscular, subcutaneous, intrathecal, and intralesional routes. Its primary indication is for the prevention of exacerbations in patients suffering from relapsing/remitting multiple sclerosis. Recommended dosage is 8 million units, administered subcutaneously, every other day. It also is indicated in the treatment of malignant glioma and malignant melanoma. Recommended temperature for storage is 36 to 46 °F, and unused reconstituted solution should be discarded.

Aldesleukin. Aldesleukin, interleukin-2 (Proleukin),⁸⁰ is an rDNA-derived lymphokine that differs structurally from native interleukin-2 (IL-2) but has biological activity similar to that of the natural lymphokine.⁸⁹ Natural IL-2 is produced primarily by the peripheral blood lymphocytes and contains 133 amino acid residues. The immunoregulatory effects of aldesleukin include enhancing mitogenesis of lymphocytes, stimulating the growth of IL-2-dependent cell lines, enhancing cytotoxicity of lymphocytes, inducing lymphokine-activated killer (LAK) cells and natural killer (NK) cells, and inducing interferon- γ production. The exact mechanism of the antitumor activity of aldesleukin in humans is unknown.

The rDNA process involves genetically engineered *E. coli* (pBR 322 plasmids). The gene for IL-2 was synthesized after first isolating and identifying the mRNA from the human Jurkat cell line and then preparing the complementary DNA (cDNA). The IL-2 gene was genetically engineered before it was hybridized into pBR 322 plasmid. Further manipulation of the hybridized plasmid resulted in the production of a modified IL-2, aldesleukin.⁹⁰ Aldesleukin differs structur-

ally from the native IL-2 in that the former is not glycosylated, it lacks the N-terminal alanine residue, and it has serine in the place of cysteine at position 125. Noncovalent, molecular aggregation of aldesleukin is different from IL-2, and the former exists as a microaggregate of 27 molecules.

The primary indication for aldesleukin is in the treatment of adult metastatic renal carcinoma. It is administered via intravenous infusion in doses of 10,000 to 50,000 U/kg every 8 hours for 12 days. It is primarily metabolized by the kidneys, with no active form found in the urine. Aldesleukin causes serious adverse effects in patients, including fever, hypotension, pulmonary congestion and dyspnea, coma, gastrointestinal bleeding, respiratory failure, renal failure, arrhythmias, seizures, and death.

rDNA-DERIVED HEMATOPOIETIC FACTORS

Hematopoietic growth factors are glycoproteins produced by a number of peripheral and marrow cells. More than 200 billion blood cells are produced each day; and the hematopoietic factors, along with other lymphopoietic factors such as the stem cell factor and the interleukins, are involved in the proliferation, differentiation, and maturation of various types of blood cells derived from the pluripotent stem cells.

Erythropoietin.⁸⁰ Erythropoietin is a heavily glycosylated protein containing 166 amino acid residues. It is produced primarily by the peritubular cells in the cortex of the kidney, and up to 15% is produced in the liver. It is the principal hormone responsible for stimulating the production of red blood cells from erythroid progenitor cells, erythrocyte burst-forming units, and erythrocyte colony-forming units.⁹¹ Small amounts of erythropoietin are detectable in the plasma; however, most of the hormone is secreted by the kidneys in response to hypoxia or anemia, when levels of the hormone can rise more than 100-fold.

Decreased erythropoietin production is one of several potential causes of anemia of chronic renal disease. Other causes of anemia of chronic renal disease include infection or inflammatory condition in the kidneys, iron deficiency, marrow damage, and vitamin or mineral deficiency. Regardless of the underlying disease causing renal failure, erythropoietin levels decrease in patients with renal failure. Until rDNA technology was used to produce commercial quantities of erythropoietin, it was obtained from the urine of patients suffering from severe aplastic anemia. This process of obtaining natural hormone was costly and time-consuming and produced only small quantities of the hormone.

Epoetin Alfa. Epoetin alfa, rEPO (Epogen, Procrit), is the recombinant human erythropoietin produced in Chinese hamster ovary cells into which the human erythropoietin gene has been inserted. These mammalian cells glycosylate the protein in a manner similar to that observed in human cells.⁹²

Epoetin alfa is indicated in anemic patients with chronic renal failure, including both those who require regular dialysis and those who do not. Epoetin alfa is also indicated in anemia associated with AIDS, treatment of AIDS with zidovudine, frequent blood donations, and neoplastic diseases. It is indicated to prevent anemia in patients who donate blood prior to surgery for future autologous transfusions

and to reduce the need for repeated maintenance transfusions.⁹³ The hormone is available as an isotonic buffered solution, which is administered by the intravenous route. The solution should not be frozen or shaken and is stored at 36 to 46°F.

Colony-Stimulating Factors.⁸⁰ Colony-stimulating factors are natural glycoproteins produced in lymphocytes and monocytes. These factors bind to cell-surface receptors of hematopoietic progenitor cells and stimulate proliferation, differentiation, and maturation of these cells into recognizable mature blood cells.⁹³ Colony-stimulating factors produced by rDNA technology have the same biological activity as the natural hormones. Currently, there are two colony-stimulating factors commercially produced by rDNA technology. These products are discussed below.

Filgrastim. Filgrastim, rG-CSF (Neupogen), is a 175-amino-acid polypeptide produced in genetically engineered *E. coli* cells containing the human granulocyte colony-stimulating factor (G-CSF) gene. Filgrastim differs from the natural hormone in that the former is not glycosylated and contains an additional methionine group at the N terminus, which is deemed necessary for expression of the gene in *E. coli*.

Filgrastim specifically stimulates the proliferation and maturation of neutrophil granulocytes and, hence, is considered lineage specific. Accepted indications for filgrastim include the following: (a) to decrease the incidence of febrile neutropenia in patients with nonmyeloid malignancies who receive myelosuppressive chemotherapeutic agents, thus lowering the incidence of infections in these patients; (b) to accelerate myeloid recovery in patients undergoing autologous bone marrow transplantation; and (c) in AIDS patients, to decrease the incidence of neutropenia caused by the disease itself or by drugs used to treat the disease. The usual starting dose for filgrastim is 5 µg/kg per day in patients with nonmyeloid cancer who receive myelosuppressive chemotherapy.

Filgrastim solution should be stored at 36 to 46°F and used within 24 hours of preparation. The solution should not be shaken or allowed to freeze. Any solution left at room temperature for more than 6 hours should be discarded. The most frequent adverse effects of filgrastim are medullary bone pain, arthralgia, and myalgia.

Sargramostim. Sargramostim, rGM-CSF (Leukine), is a glycoprotein commercially produced in genetically engineered yeast cells. Its polypeptide chain contains 127 amino acids. It differs from the natural hormone by substitution of leucine at position 23 and variations in the glycosylation.⁹⁴ Sargramostim is a lineage-nonspecific hematopoietic factor because it promotes the proliferation and maturation of granulocytes (neutrophils and eosinophils) and monocytes (macrophages and megakaryocytes).

The primary indication for sargramostim is in myeloid engraftment following autologous bone marrow transplantation and hematopoietic stem cell transplantation. Handling, storage precautions, and adverse effects are similar to those for filgrastim.

rDNA-DERIVED MISCELLANEOUS PRODUCTS

Antihemophilic Factor. Antihemophilic factor (factor VIII) (Humate-P, Hemophil M, Koate HP, Monoclate-P) is a glycoprotein found in human plasma and a necessary cofactor in the blood-clotting mechanism. This high-molecular-weight glycoprotein has a complex structure with several components (subfactors).⁹⁵ The commercially available concentrates derived from blood collected from volunteer donors by the American Red Cross Blood Services are used primarily for the treatment of patients with hemophilia A. Since the commercially available products are purified concentrates derived from blood pooled from millions of donors, the major precautions in using the products relate to transmission of viruses, such as hepatitis virus, herpesvirus, and HIV. This major problem has been alleviated, mostly because of the development and marketing of rDNA-derived antihemophilic factors.

Antihemophilic Factor (Recombinant). Antihemophilic factor (recombinant), rAHF (KoGENate, Helixate), is an rDNA-derived factor VIII expressed in genetically engineered baby hamster kidney cells.⁹⁶ KoGENate has the same biological activity as the human plasma-derived antihemophilic factor (pdAHF). The purification process for rAHF includes monoclonal antibody immunoaffinity chromatography to remove any protein contaminants.

rAHF is indicated for the treatment of hemophilia A and is administered by the intravenous route. Patients suffering from hemophilia A exhibit a decrease in the activity of plasma clotting factor VIII. This product temporarily prevents bleeding episodes in hemophiliacs and may be used to prevent excessive bleeding during surgical procedures in these patients. A major advantage of the rAHF over the natural factor VIII is the lack of virus in the product. rAHF does not contain von Willebrand's factor; therefore, it is not indicated in the treatment of von Willebrand's disease. Patients receiving rAHF should be monitored carefully for the development of antibodies.

Bioclate is an rDNA-derived factor VIII expressed in genetically engineered Chinese hamster ovary cells. It has the same biological activity as pdAHF and is structurally similar. Its indications and adverse effects are similar to those for KoGENate.

Vitamins and Related Compounds

GUSTAVO R. ORTEGA, MICHAEL J. DEIMLING, JAIME N. DELGADO*

Vitamins traditionally have been considered to be "accessory food factors." Generally, vitamins are among those nutrients that the human organism cannot synthesize from other dietary components. Together with certain amino acids (i.e., essential amino acids), the vitamins constitute a total of 24 organic compounds that have been characterized as dietarily essential.¹ Many vitamins function biochemically as precursors in the synthesis of coenzymes necessary in human metabolism; thus, vitamins perform essential functions. When they are not available in appropriate amounts, the consequences may lead to serious disease states.

Although there are relatively few therapeutic indications for vitamin pharmaceutical preparations, diseases caused by certain vitamin deficiencies do respond favorably to vitamin therapy. Additionally, there are products indicated for prophylactic use as dietary supplements. An optimal diet provides all of the necessary nutrients; in some cases of increased demands, however, vitamin and mineral supplementation is recommended.²

Two organizations provide guidelines for daily vitamin intake in the United States. The first, the Food and Drug Administration (FDA), regulates the labeling of foods with respect to their nutritional content, including vitamins. The current labeling requirements for vitamins, established following the Dietary Supplement Health and Education Act (DSHEA) of 1994 and published in the Code of Federal Regulations (CFR),³ requires that the vitamin content of food be listed as a percentage of the daily value (DV). The daily value for nutrients is determined by using the daily reference value (DRV) if the nutrient is a source of energy, such as protein, carbohydrates, and fats, or by using the reference daily intake (RDI) for vitamins and minerals. The RDI replaces the previously used term, U. S. RDA (recommended daily allowance), to prevent confusion with the RDAs published by the National Academy of Sciences. The RDIs for each of the vitamins as published in the CFR are the same as the values used under the older term, RDAs. The DV for each of the vitamins (Table 26-1) is based on a 2,000-calorie diet, and the %DV that is placed on the food label is determined by dividing the content of one serving of the food by the DV and expressing the result as a percentage.

The second organization that provides nutritional guidelines is the Nutrition Board of the National Academy of Sciences, Institute of Medicine. Their guidelines are published in the form of dietary reference intakes (DRIs), which include several ways of evaluating the proper intake of vitamins and minerals, such as the estimated average requirement (EAR), recommended dietary allowance (RDA), ade-

quate intake (AI), and tolerable upper intake level (UL). Generally, the RDA is the most specific recommendation of the recommended daily intake, with the AI used if not enough data exist to support determination of a RDA. Table 26-2 contains the current dietary DRIs, in terms of the RDA (when available) or the AI (when the RDA is not available) for the vitamins covered in this chapter.

The medicinal chemistry of vitamins is fundamental not only to the therapeutics of nutritional problems but also to the understanding of the biochemical actions of other medicinal agents that directly or indirectly affect the metabolic functions of vitamins and coenzymes. Accordingly, this chapter includes a brief summary of the basic biochemistry of vitamins, structure-activity relationships, physicochemical properties and some stability considerations, nutritional and therapeutic applications, and brief characterizations of representative pharmaceutical products.

In 1912, Funk⁴ described a substance, present in rice polishings and in foods, that cured polyneuritis in birds and beriberi in humans. This substance was referred to as *vitamine* because it was characterized as an amine and as a vital nutritional component. After other food factors were noted to be vital nutritional components that were not amines and did not even contain nitrogen,⁵ Drummond suggested the modification that led to the term *vitamin*. McCollum and

TABLE 26-1 Daily Values of the Vitamins Used in Food Labeling

Vitamin	Daily Value ^a
Vitamin A	5,000 IU ^b
Vitamin C	60 mg
Vitamin D	400 IU
Vitamin E	30 IU
Vitamin K	80 µg
Thiamin	1.5 mg
Riboflavin	1.7 mg
Niacin	20 mg
Vitamin B ₆	2 mg
Folate	400 µg
Vitamin B ₁₂	6 µg
Biotin	300 µg
Pantothenic acid	10 mg

From Code of Federal Regulations, Section 101.9, 1977.

^aBased on a 2,000-calorie diet.

^bInternational units.

*Deceased.

TABLE 26-2 Dietary Reference Intakes of the Vitamins for Individuals^a

Life Stage Group	Biotin (mg/d)	Choline (mg/d)	Folate (mg/d)	Niacin (mg/d)	Pantothenic Acid (mg/d)	Riboflavin (mg/d)	Thiamin (mg/d)	Vitamin A (mg/d)	Vitamin B ₆ (mg/d)	Vitamin B ₁₂ (mg/d)	Vitamin C (mg/d)	Vitamin D (mg/d)	Vitamin E (mg/d)	Vitamin K (mg/d)
Infants

Dietary Reference Intakes: Applications in Dietary Assessment. 2001 Food and Nutrition Board, National Academy of Sciences, Institute of Medicine. Washington, DC: National Academy Press, 2001. and Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc. 2001 Food and Nutrition Board, National Academy of Sciences, Institute of Medicine. Washington, DC: National Academy Press, 2001.

Abbreviations: d, day; y, year.

Numbers in this table represent the current Recommended Daily Allowance (RDA) as determined by the Food and Nutrition Board of the Institute of the National Academy of Sciences, Institute of Medicine unless marked with an asterisk (*), in which case they represent the Adequate Intake (AI).

Davis^{6, 7} described a lipid-soluble essential food factor in butterfat and egg yolk, and 2 years later, reference was made to a water-soluble factor in wheat germ. Thus, the terms *fat-soluble A* and *water-soluble B*, respectively, were applied to these food factors. Since then, many other dietary components have been discovered to be essential nutritional components (i.e., vitamins). It is traditional to classify these compounds as either lipid-soluble or water-soluble vitamins. This classification is convenient because members of each category possess important properties in common.

LIPID-SOLUBLE VITAMINS

The lipid-soluble vitamins include vitamins A, D, E, and K. These compounds possess other characteristics in common besides solubility. They are usually associated with the lipids in foods and are absorbed from the intestine with these dietary lipids. The lipid-soluble vitamins are stored in the liver and, thus, conserved by the organism, whereas storage of the water-soluble vitamins is usually not significant.

Vitamin A

Vitamin A was first recognized as a vitamin by McCollum and Davis^{6, 7} in 1913 to 1915, but studies of the molecular mechanism of action of retinol in the visual process were not significantly productive until 1968 to 1972. The mechanism of action of vitamin A in physiological processes other than vision has been very difficult to study. Advances in molecular biology have, however, started to identify the role of retinoids in bone growth, reproduction, embryonic development, protein synthesis, sperm production, and control and differentiation of epithelial tissues. This has led to the suggestion that vitamin A has hormone-like properties. There is convincing evidence that vitamin A performs an important function in the biosynthesis of glycoproteins and in sugar-transfer reactions in mammalian membranes.⁸ Investigations on the mechanism of this action were stymied by difficulties in clearly defining the biochemically active form of the vitamins, whether it is all-*trans*-retinol or retinoic acid. This question was reviewed comprehensively by Chytil and Ong.⁹ Most, if not all, vitamin A actions in development, differentiation, and metabolism are mediated through nuclear receptors that bind to retinoic acid.¹⁰

TABLE 26-3 Weight Equal to 1 IU

Retinoid	μg
All- <i>trans</i> -retinol	0.3
All- <i>trans</i> -retinol acetate	0.334
All- <i>trans</i> -retinol propionate	0.359
All- <i>trans</i> -retinol palmitate	0.55
β -Carotene	0.6

The term *vitamin A* currently is applied to compounds possessing biological activity like that of retinol. The term *vitamin A₁* refers to all-*trans*-retinol. The term *retinoid* is applied to retinol and its naturally occurring derivatives plus synthetic analogues, which need not have vitamin A activity.

Vitamin A activity is expressed as USP units, international units (IU), retinol equivalents (RE), and β -carotene equivalents. The USP units and IU are equivalent. Each unit expresses the activity of 0.3 μg of all-*trans*-retinol. Thus, 1 mg of all-*trans*-retinol has the activity of 3,333 units. Other equivalents are listed in Table 26-3. One RE represents the biological activity of 1 μg of all-*trans*-retinol, 6 μg of β -carotene, and 12 μg of mixed dietary carotenoids. The RE is used to convert all dietary sources of vitamin A into a single unit for easy comparison.¹¹

The stereochemistry of vitamin A and related compounds is complex, and a complete stereochemical analysis is beyond the scope of this chapter. A brief summary of some stereochemical features is presented here as the basis for the characterization of the biochemical actions exerted by this vitamin. The study of the structural relationships among vitamin A and its stereoisomers has been complicated by the common use of several numbering systems, as shown below. The first numbering system (A) is the one currently recommended by the International Union of Pure and Applied Chemistry (IUPAC). The second system (B) places emphasis on the conjugated π system, while the third (C) is used by the *USP Dictionary of USAN and International Drug Names*.

For steric reasons, the number of isomers of vitamin A most likely to occur is limited. These are all-*trans*, 9-*cis*, 13-*cis*, and the 9,13-di-*cis*. A *cis* linkage at double bond 7 or 11 encounters steric hindrance. The 11-*cis* isomer is twisted as well as bent at this linkage; nevertheless, this is the only isomer that is active in vision. The biological activ-

TABLE 26-4 USP Units per Gram of Selected Retinoids

All- <i>trans</i> -retinal	3,050,000
11- <i>cis</i> -Retinal	3,120,000
9- <i>cis</i> -Retinal	637,000
9,13-Di- <i>cis</i> -retinal	581,000
9,11-Di- <i>cis</i> -retinal	11,610,000

ity¹² of the isomers of vitamin A acetate, in terms of USP units per gram, are listed in Table 26-4. Disregarding stereochemical variations, several compounds with structures corresponding to vitamin A, its ethers, and its esters have been prepared.¹³⁻¹⁶ These compounds as well as synthetic vitamin A acid possess biological activity.

Dietary vitamin A is obtained exclusively from foods of animal origin as retinyl esters. The provitamin carotenoids are obtained from plant and dairy sources. The highest sources of natural vitamin A are fish liver oils, which vary greatly in the content of this vitamin (Table 26-5). Most liver oils contain vitamin A and neovitamin A in the ratio of 2:1. Vitamin A occurs free and combined as the biologically active esters, chiefly of palmitic and some myristic and dodecanoic acids. It is also found in the livers of animals, especially those that are herbivorous. Milk and eggs are fair sources of this vitamin.

The livers of freshwater fish contain vitamin A₂ (3,4-dehydroretinol).

TABLE 26-5 Vitamin A Content of Some Fish Liver Oils

Source	Animal Species	Potency (IU/g)
Hallbut, liver	<i>Hippoglossus hippoglossus</i>	60,000
Percomorph. liver	Percomorph fishes (mixed oils)	60,000
Shark, liver	<i>Galeus cygopterus</i>	25,500
Shark, liver	<i>Hypoprius brevirostris</i> and other varieties	16,500
Burbot, liver	<i>Lota maculosa</i>	4,880
Cod, liver	<i>Gadus morrhua</i>	850

Dietary retinyl esters are hydrolyzed in the intestinal lumen by various hydrolases. The retinol is absorbed into the enterocytes by facilitated diffusion in normal concentrations. At pharmacological doses, however, retinol can be absorbed by passive diffusion.¹⁷ Within the enterocytes, the retinol is esterified by two enzymes, acylcoenzyme A (CoA): retinol acyltransferase (ARAT) and lecithin:retinal acyltransferase (LRAT). LRAT esterifies retinol bound to an intracellular protein, cellular retinol-binding protein type II (CRBP [II]), while ARAT can esterify unbound retinol. It has been proposed that LRAT esterifies retinol at normal doses, while ARAT esterifies excess retinol.¹⁸

The retinyl esters are incorporated into chylomicrons, which in turn enter the lymph. Once in the general circulation, chylomicrons are converted into chylomicron remnants, which are cleared primarily by the liver. As the esters enter the hepatocytes, they are hydrolyzed. In the endoplasmic reticulum, the retinol is bound to retinol-binding protein (RBP). This complex is released into the blood or transferred to liver stellate cells for storage. Within the stellate cells, the retinol is bound to CRBP(I) and esterified for storage by ARAT and LRAT. Stellate cells contain up to 95% of the liver vitamin A stores. The RBP-retinol complex released into the general circulation from hepatocytes or stellate cells, in turn, is bound to transthyretin (TTR), which protects retinol from metabolism and renal excretion.¹⁹

The cellular uptake of plasma retinol remains to be fully understood. This is further complicated because chylomicron remnants also contribute retinol to the target cells. The fate of retinol after absorption is just beginning to be understood. RBP and TTR do not enter the cell. On entering the cell, the retinol is bound to CRBP(I) in the cytoplasm. Most tissues contain CRBP(I) and CRBP(II). These intracellular proteins function in the transport and metabolism of retinol and retinoic acid by solubilizing them in aqueous media and presenting them to the appropriate enzymes while protecting them from catabolizing enzymes.²⁰ These proteins also limit the concentration of free retinoids within the cell. CRBP(I) regulates the esterification of retinol and its oxidation to retinoic acid from retinal, while CRBP(II) controls the reduction of retinal to retinol and its subsequent esterification.²¹

Retinol is susceptible to glucuronide conjugation, followed by enterohepatic recycling. It may be oxidized to retinoic acid by two enzymes, retinol dehydrogenase and retinal dehydrogenase, with the former being rate-limiting.²² Unlike retinol, retinoic acid has no specific carrier in the blood. Retinoic acid undergoes decarboxylation, followed by glucuronide conjugation. Normally, no unchanged retinol is excreted. Retinal, retinoic acid, and other metabolites are, however, found in the urine and feces.

Although fish liver oils are used for their vitamin A content, purified or concentrated forms of vitamin A are of great commercial significance. These are prepared in three ways: (a) saponification of the oil and concentration of the vitamin A in the nonsaponifiable matter by solvent extraction, with

the product marketed as such; (b) molecular distillation of the nonsaponifiable matter, from which the sterols have been removed by freezing, giving a distillate of vitamin A containing 1 to 2 million IU/g; and (c) subjecting the fish oil to direct molecular distillation to recover the free vitamin A, vitamin A palmitate, and myristate.

Pure crystalline vitamin A occurs as pale yellow plates or crystals. It melts at 63 to 64°C and is insoluble in water but soluble in alcohol, the usual organic solvents, and the fixed oils. It is unstable in the presence of light and oxygen and in oxidized or readily oxidized fats and oils. It can be protected by the exclusion of air and light and by the presence of antioxidants.

Like all substances that have a polyene structure, vitamin A gives color reactions with many reagents, most of which are either strong acids or chlorides of polyvalent metals. An intense blue is obtained with vitamin A in dry chloroform solution on the addition of a chloroform solution of antimony trichloride. This color reaction (Carr-Price reaction) has been studied extensively and is the basis of a colorimetric assay for vitamin A.²³

Vitamin A (all-*trans*-retinol) is biosynthesized in animals from plant pigments called *carotenoids*, which are terpenes composed of isoprenoid units. These pigments protect plant cells from photochemical damage and transfer radiant energy to the pigments responsible for photosynthesis. Although hundreds of carotenoids have been identified, only a few function as provitamins.²⁴

The provitamin As (e.g., α -, β -, and γ -carotenes and cryptoxanthin) are found in deep green, yellow, and orange fruits and vegetables, such as carrots, spinach, broccoli, kale, collard and turnip greens, mangoes, apricots, nectarines, pumpkins, and sweet potatoes. The carotenoid pigments are used poorly by humans, whereas animals differ in their ability to use these compounds. These carotenoid pigments are provitamins A because they are converted to the active vitamin A. For example, β -carotene is absorbed intact by the intestinal mucosa, then cleaved to retinal by β -carotene-15,15'-dioxygenase, which requires molecular oxygen.²⁵ β -Carotene can

give rise to two molecules of retinal, whereas with the other three carotenoids, only one molecule is possible by this transformation. These carotenoids have only one ring (see formula for β -carotene) at the end of the polyene chain, which is identical with that found in β -carotene and is necessary for vitamin A activity. This accounts for the low activity of β -carotene.

The conjugated double-bond systems found in vitamin A and β -carotene are necessary for activity; when these compounds are partially or completely reduced, activity is lost. The β -ionone ring of retinol or the dehydro- β -ionone ring found in dehydroretinol (vitamin A₂) is essential for activity. Saturation results in loss of activity. The ester and methyl ethers of vitamin A have a biological activity on a molar basis equal to that of vitamin A. Retinoic acid (vitamin A acid) is biologically active but is not stored in the liver.

Carotenoid absorption is by passive diffusion and depends on absorbable fats and bile. It is assumed that one sixth of normal dietary β -carotene but only one twelfth of the other provitamin A carotenoids is absorbed. The enterocytes convert the carotenoids into retinol, but up to 20 to 30% are absorbed unchanged.

The intestinal mucosa is the main site of β -carotene transformation²⁵ to retinal, but the enzymes that catalyze the transformation also occur in hepatic tissue. Two mechanisms for the conversion to retinal have been proposed. Originally, it was proposed that cleavage occurred centrally by β -carotene-15,15'-dioxygenase.²⁶ Evidence exists, however, for peripheral cleavage to yield apo-carotenals, which can be converted further to retinal.²⁷ The retinal thus formed is reduced to retinol and esterified before entering the chylomicrons for transport from the liver.

Retinoic acid, the corresponding carboxylic acid, promotes development of bone and soft tissues and sperm production, but it does not participate in the visual process. Retinoic acid is found in the bile in the glucuronide form.

Vitamin A is often called the *growth vitamin* because a deficiency of it in the diet causes cessation of growth in young rats. A deficiency of vitamin A is manifested chiefly

by degeneration of the mucous membranes throughout the body. This degeneration is more pronounced in the eye than in any other part of the body and gives rise to a condition known as xerophthalmia. In the earlier stages of vitamin A deficiency, night blindness (*nyctalopia*) may develop, which can be cured by vitamin A. *Night blindness* can be defined as the inability to see in dim light.

Dark adaptation or *visual threshold* is a more suitable description than *night blindness* in many subclinical cases of vitamin A deficiency. The *visual threshold* at any moment is just that light intensity required to elicit a visual sensation. *Dark adaptation* is the change that the visual threshold undergoes during a stay in the dark after an exposure to light. This change may be very great. After exposure of the eye to daylight, a stay of 30 minutes in the dark decreases the threshold by a factor of 1 million. This phenomenon is used as the basis for detecting subclinical cases of vitamin A deficiency. These tests vary in their technique, but essentially they measure visual dark adaptation after exposure to bright light and compare it with the normal.^{28, 29}

Advanced deficiency of vitamin A gives rise to dryness and scaliness of the skin, accompanied by a tendency to infection. Characteristic lesions of the human skin caused by vitamin A deficiency usually occur in sexually mature persons between the ages of 16 and 30 and not in infants. These lesions appear first on the anterolateral surface of the thigh and the posterolateral portion of the upper forearms and later spread to adjacent areas of the skin. The lesions consist of pigmented papules, up to 5 mm in diameter, at the site of the hair follicles.

Vitamin A regulates the activities of osteoblasts and osteoclasts, influencing the shape of the bones in the growing animal. The teeth also are affected. In vitamin A deficiency states, a long overgrowth occurs. Overdoses of vitamin A in infants for prolonged periods lead to irreversible changes in the bones, including retardation of growth, premature closure of the epiphyses, and differences in the lengths of the lower extremities. Thus, a close relationship exists between the functions of vitamins A and D relative to cartilage, bones, and teeth.³⁰ The tocopherols exert a sparing and what appears to be a synergistic action³¹ with vitamin A.

Blood levels of vitamin A decrease very slowly, and decreased dark adaptation was observed in only 2 of 27 volunteers (maintained on a vitamin A-free diet) after 14 months, at which time blood levels had decreased from 88 to 60 IU/100 ml. of blood.

Vitamin A performs numerous biochemical functions. It promotes the production of mucus by the basal cells of the epithelium, whereas in its absence keratin can be formed. Vitamin A performs a function in the biosynthesis of glycogen and some steroids, and increased quantities of coenzyme Q are found in the livers of vitamin-deficient rats. Significantly, the best-known action of vitamin A is its function in the chemistry of vision.

Hypervitaminosis A can lead to both short- and long-term effects.³² Short-term doses of 0.5 to 4 million IU can lead, within hours to several days, to central nervous system effects including increased intracranial pressure, headache, irritability, and seizures; gastrointestinal effects including nausea, vomiting, and pain; dermatological effects such as desquamation; ophthalmic effects such as papilledema, scotoma, and photophobia; and liver damage. Most of these

reactions have been reported in infants following treatment with large doses of vitamin A, but some have resulted from ingestion of food rich in vitamin A, such as liver, especially from polar bears.

Long-term intake of doses of vitamin A lower than the intake required for short-term toxicity but still above that required by the body can lead to long-term effects, including effects on the skin, liver, central nervous system, and bone. Although the amount required varies, doses as low as 15,000 IU/day have led to some adverse effects, although higher doses, generally above 100,000 IU/day, are required to see all the reported adverse effects. In patients with low body weight, malnutrition, or liver or renal disease, the doses required for long-term adverse effects may be lower still.

Dermatological adverse effects include drying of the skin and mucosa, dermatitis, pruritus, swelling and fissuring of the lips, and (sometimes) loss of body hair. Hepatic effects include hypertrophy and hyperplasia of the Ito cells (which store vitamin A), hepatomegaly, fibrosis, and cirrhosis, which can lead to portal hypertension, ascites, and jaundice. Splenomegaly is also seen. Central nervous system effects include increased intracranial pressure (pseudotumor cerebri) leading to headache, visual disturbances (e.g., diplopia), drowsiness, vomiting, seizures, and a bulging fontanel in infants. Finally, pain in the bone and joints, with accompanying tenderness, and reduced bone mineralization³³ have also been reported.

The teratogenic effects of vitamin A are also well known.^{32,34} Intake of as little as 10,000 IU/day during pregnancy may increase the risk of birth defects, and the risk increases with increasing intake of vitamin A.³⁵ Birth defects include craniofacial, neural tube, and urogenital and musculoskeletal abnormalities.

β -Carotene, in contrast, is relatively nontoxic. After long-term exposure to high levels of β -carotene (30 to 180 mg/day for 15 years), which is equivalent to 50,000 to 300,000 IU of vitamin A, patients have not developed any problems other than skin discoloration and asymptomatic hypercarotemia. Furthermore, β -carotene is not teratogenic. The most likely mechanism is the slow rate of conversion of β -carotene to retinol.

The molecular mechanism of action of vitamin A in the visual process has been under investigation for many years. Wald in 1968³⁶ and Morton in 1972³⁷ characterized this mechanism of action. The chemistry of vision was reviewed comprehensively in *Accounts of Chemical Research* (1975) by numerous investigators. These reviews include theoretical studies of the visual chromophore, characterization of rhodopsin in synthetic systems, dynamic processes in vertebrate rod visual pigments and their membranes, and the dynamics of the visual protein opsin.³⁸⁻⁴³

Vitamin A (all-*trans*-retinol) undergoes isomerization to the 11-*cis* form in the liver. This transformation is catalyzed by a retinol isomerase. Subsequently, 11-*cis*-retinol interacts with RBP to form a complex that is transported to the retinal photoreceptor cells, which contain specific receptors for the RBP-retinol complex.

The retina has been considered^{41,43} to be a double-sense organ in which the rods are concerned with colorless vision at low light intensities and the cones are concerned with color vision at high light intensities. A dark-adapted, excised retina is rose red; when it is exposed to light, its color

changes to chamois, to orange, to pale yellow; finally, on prolonged irradiation, it becomes colorless. The rods contain photosensitive visual purple (rhodopsin), which, when acted on by light of a definite wavelength, is converted to visual yellow and initiates a series of chemical steps necessary to vision. Visual purple is a conjugated carotenoid protein with a relative molecular mass (M_r) of about 40,000 and one prosthetic group per molecule. It contains seven hydrophobic α -helices, which are embedded in the membrane. Short hydrophilic loops interconnect the helices and are exposed to the aqueous environment on either side of the membrane. It has an absorption maximum of about 510 nm. The prosthetic group is retinene (neoretinene b or retinal), which is joined to the protein through a protonated Schiff base linkage.

The function of retinene in visual purple is to increase the absorption coefficient in visible light and, thereby, sensitize the protein, which is denatured. This process initiates a series of physical and chemical steps necessary to vision. The protein itself differs from other proteins in having a lower energy of activation, which permits it to be denatured by a quantum of visible light. Other proteins require a quantum of ultraviolet (UV) light to be denatured. The bond between the pigment and the protein is much weaker when the protein is denatured than when it is native. The denaturation of the protein is reversible and takes place more readily in the dark to give rise, when combined with retinene, to visual purple. The effectiveness of the spectrum in bleaching visual purple runs fairly parallel with its absorption spectrum (510 nm) and with the sensibility distribution of the eye in the spectrum at low illuminations. It has been calculated that for a human to see a barely perceptible flash of light, only one molecule of visual purple in each 5 to 14 rod cells needs to be photochemically transformed in a dark-adapted eye. The system possesses such sensitivity because of biological amplification. In vivo, visual purple is re-formed constantly as it is bleached by light, and under continuous illumination, an equilibrium is maintained between visual purple, visual yellow, and visual white. If an animal is placed in the dark, the regeneration of visual purple continues until a maximum concentration is obtained. Visual purple in the eyes of an intact animal may be bleached by light and regenerated in the dark an enormous number of times.

In the resting state (dark), rod and cone membranes exhibit a steady electrical current. The membrane allows sodium ions to enter freely through specific channels. A Na^+/K^+ -ATPase pump maintains the ion gradient. The closing of the pores hyperpolarizes the membrane and initiates the neuronal response.

The pores are kept open by binding to cyclic guanosine monophosphate (cGMP). The light-induced isomerization of retinal causes a conformational change in the protein part of rhodopsin, activating the molecule. One active rhodopsin activates several hundred G-protein molecules, called *transducin*. (G proteins can bind with guanosine nucleotides.) Activation of transducin consists of an exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP). Activated transducin, in turn, activates a phosphodiesterase, which hydrolyzes thousands of cGMP molecules. The decreased concentration of cGMP results in closing of the sodium channels.

Hydrolysis of transducin-bound GTP to GDP inactivates the phosphodiesterases. The activated rhodopsin must also

be deactivated, however. This is accomplished by phosphorylation of opsin by opsin kinase. Guanylate cyclase replenishes the cGMP concentration, which reopens the channels.

Visual purple occurs in all vertebrates. It is not distributed evenly over the retina. It is missing in the fovea, and in the regions outside the fovea, its concentration undoubtedly increases to a maximum in the region about 20° off center, corresponding to the high density of rods in this region. Therefore, to see an object best in the dark, one should not look directly at it.

The diagrams represent some of the changes that take place in the visual cycle involving the rhodopsin system in which the 11-*mono-cis* isomer of vitamin A is functional in the aldehyde form.⁴⁴

After the light-catalyzed reaction, all-*trans*-retinal is released, which in turn is reduced to all-*trans*-retinol. To be used again by opsin, the all-*trans*-retinol must be converted to 11-*cis*-retinol. Isomerization occurs in the pigment epithelium of the retina.⁴⁵ Oxidation of 11-*cis*-retinol to 11-*cis*-retinaldehyde occurs while retinol is bound to the protein cellular retinaldehyde-binding protein (CRALBP) by a microsomal enzyme in the pigment epithelium.⁴⁶

The isomerization of *trans*-retinal may take place in the

presence of blue light. Vision continues very well, however, in yellow, orange, and red light, in which no isomerization takes place. The 11-*mono-cis*-retinal under these circumstances is replaced by an active form of vitamin A from the bloodstream, which came from stores in the liver. The isomerization of *trans*-vitamin A in the body to *cis-trans*-vitamin A seems to keep pace with long-term processes such as growth, since vitamin A, neovitamin A, and 11-*mono-cis*-retinal are equally active in growth tests in rats. The sulfhydryl groups (two for each 11-*mono-cis*-retinal molecule isomerized) exposed on the opsin initiate the transmission of impulses in the phenomenon of vision.

Research since the mid-1980s has taken vast strides in determining the molecular mechanism of action of vitamin A. It appears that the vitamin exerts its biological function with respect to development, differentiation, and metabolism like a steroid hormone.⁴⁷⁻⁴⁹ The biologically active species is believed to be retinoic acid. Two intracellular retinoic acid-binding proteins have been isolated, CRABP(I) and CRABP(II). These appear to have functions similar to those of the CRBPs.

More importantly, several retinoic acid receptors (RARs) have been identified: RAR α , RAR β , and RAR γ .⁴⁸ These differ in their tissue distribution and the level of expression during cell development and differentiation. After binding with retinoic acid, the complex binds to specific recognition sequences on DNA (RAREs), thus influencing the transcription of specific genes. The ultimate biological effects of retinoic acid are mediated through various proteins that remain to be identified. Retinoids influence embryonic development by inhibiting cell proliferation and inducing cell differentiation and apoptosis.⁵⁰ A new family of retinoic acid receptors has been identified.⁵¹ These are called *retinoid X receptors*, RXR α , RXR β , and RXR γ . They have a different tissue distribution from the RARs. The ligand for RXR has been identified as 9-*cis*-retinoic acid.⁵²

These retinoid receptors must form dimers before they interact with RAREs. RARs must form heterodimers with RXRs, whereas RXRs may also form homodimers. It appears that the RAREs for the homodimers differ from those for the heterodimers. This implies that they may activate different sets of genes.^{53, 54} RXRs also form heterodimers with thyroid hormone receptors and vitamin D receptors, increasing their affinity for DNA.⁵⁵ Several enzymes whose expression depends on RXR have been found.⁵² The available experimental data provide convincing evidence that these proteins are, in fact, nuclear receptors belonging to the steroid/thyroid hormone superfamily. They mediate important aspects of vitamin A function. The existence of proteins that specifically bind retinoic acid substantiates the implication of retinoic acid as a physiological form of vitamin A.

Studies have shown a correlation between a diet high in β -carotene and a reduced risk of certain cancers. Several reviews of these studies are available.^{56, 57}

PRODUCTS

Vitamin A, USP. Vitamin A (AquaSol A) contains retinol (vitamin A alcohol) or its esters from edible fatty acids (chiefly acetic and palmitic acids), whose activity is not less than 95% of the labeled amount; a dosage of 0.3 μg of vitamin A alcohol (retinol) equals 1 USP unit.

Vitamin A is indicated only for treatment of vitamin A deficiencies. Because the vitamin is prevalent in the diet, especially with supplementation of milk, this disorder is not common. It is associated with conditions that result in the malabsorption of fats (e.g., biliary or pancreatic diseases, sprue, hepatic cirrhosis).

Pure vitamin A has an activity of 3.5 million IU/g. Moderate-to-massive doses of vitamin A have been used in pregnancy, lactation, acne, termination of colds, removal of persistent follicular hyperkeratosis of the arms, persistent and abnormal warts, corns, and calluses, and similar conditions. Phosphatides or the tocopherols enhance the absorption of vitamin A. Vitamin A applied topically appears to reverse the impairment of wound healing by corticoids.

Vitamin A occurs as a yellow to red, oily liquid. It is nearly odorless or has a fishy odor and is unstable to air and light. It is insoluble in water or glycerin and is soluble in absolute alcohol, vegetable oils, ether, and chloroform.

Tretinoin, USP. Tretinoin, retinoic acid (Retin-A), is a yellow to light-orange, crystalline powder. It is insoluble in water and slightly soluble in alcohol.

Tretinoin, indicated for topical treatment of acne vulgaris, was initially used systemically. Therapeutic doses frequently resulted in hypervitaminosis A, however. It appears to exert its action by decreasing the adhesion of corneocytes and by increasing the proliferation of the follicular epithelium.⁵⁸

Tretinoin is usually applied as a 0.05% polyethylene glycol (PEG)-400/ethanol liquid or a 0.05% hydrophilic cream. Daily application results in inflammation, erythema, and peeling of the skin. After 3 to 4 weeks, pustular eruptions may be seen, causing the expulsion of microcomedones. Treatment may then be changed to applications every 2 or 3 days. Because the horny layer is thinned, the skin is more susceptible to irritation by chemical or physical abuse. Thus, it is recommended that other kerolytic agents (salicylic, sulfur, resorcinol, benzoyl peroxide) be discontinued before beginning treatment with tretinoin.

Sunscreens labeled SPF-15 or higher are recommended. Unlabeled uses of tretinoin include the treatment of some forms of skin cancer, lamellar ichthyosis, Darier's disease, and photoaging. Photoaging of the skin is mainly the result of excessive exposure to sunlight and is manifested by lax, yellow, mottled, wrinkled, leathery, rough skin. Once-daily application has been reported to aid in the early stages of photoaging.⁵⁹ Tretinoin is believed to exert this action by its function in regulating epithelial differentiation, cell division, and protein synthesis.⁶⁰ Termination of treatment, however, results in reversal within 1 year. Tretinoin is believed to exert its antineoplastic effect by promoting cellular differentiation toward normal cells.⁶¹

Isotretinoin, USP. Isotretinoin, 13-*cis*-retinoic acid (Accutane), is a yellow-orange to orange, crystalline powder. It is insoluble in water and sparingly soluble in alcohol.

Isotretinoin is indicated for the treatment of severe recalcitrant cystic acne. Because of the risks of adverse effects, its use should be reserved for patients who are unresponsive to conventional acne therapies. Treatment should be individualized and modified depending on the course of the disease. The mechanism is believed to involve inhibition of sebaceous gland function and follicular keratinization. Isotretinoin reduces sebum production, the size of the glands, and gland differentiation.

The initial dose is 0.5 to 1 mg/kg daily in two divided doses. Absorption is rapid, but bioavailability is low (~25%) because of degradation in the lumen and metabolism by the gastrointestinal mucosa and the liver on the first pass. The chief metabolite is 4-oxoisotretinoin. Both isotretinoin and its metabolite are conjugated to the glucuronide and excreted in the urine and feces. The usual course of therapy is 15 to 20 weeks.

The adverse effects of isotretinoin are typical of chronic hypervitaminosis A. Because of the high potential to cause teratogenic effects, isotretinoin should be used with extreme caution in females of childbearing age. The manufacturer of the drug strongly recommends that patients have pregnancy tests performed before starting therapy and use a form of birth control during therapy.

Etretinate. Etretinate (Tegison) is indicated for the treatment of severe recalcitrant psoriasis. Because of its potential adverse effects, therapy should be limited to diseases that do not respond to standard therapies. The exact mechanism of etretinate's action is unknown but is believed to result from some of the actions common to the retinoids.

Oral bioavailability of etretinate is approximately 40%. Milk and lipids increase the absorption. Etretinate is converted significantly to the free acid on the first pass through the liver. The free acid (acitretin) is also active. After a single dose, the half-life of etretinate is 6 to 13 hours, but after long-term therapy, the half-life is 120 days. Etretinate's high lipid character results in storage in adipose tissue, from which it is released slowly. After discontinuation of therapy, etretinate can be detected for up to 1 year.

Acitretin has the advantage of a shorter half-life, 2 hours after a single dose and 50 hours after multiple doses. It is, however, more susceptible to conversion to 13-*cis*-etretin. Thus, it appears that the ester provides metabolic stability.

The initial dosage of etretinate is 0.75 to 1 mg/kg in di-

vided doses. After 8 to 16 weeks, a maintenance dosage of 0.5 to 0.75 mg/kg may be started. As with isotretinoin, extreme caution is needed in the administration of etretinate. The manufacturer discontinued this product in 1998.

Acitretin. Acitretin (Soriatane) is a yellow to greenish-yellow powder. It is the active species of etretinate. After absorption, acitretin is extensively metabolized and also undergoes isomerization to its 13-*cis* isomer. Acitretin is less lipid soluble than etretinate and thus is eliminated faster by the body. The elimination half-life is 50 hours.

Acitretin is indicated for the treatment of severe psoriasis. The initial dose is 25 to 50 mg in a single dose with food. Because of significant variation in pharmacokinetics and efficacy, however, the maintenance dose should be individualized. Initial response may occur in 2 weeks, but maximal response requires 2 to 3 months. Because of significant adverse effects associated with its use, acitretin should be reserved for patients who do not respond to other therapies or whose clinical condition contraindicates the use of other treatments.

Concurrent administration with ethanol is contraindicated because etretinate is formed. Because the half-life of etretinate is much longer, the teratogenic risk to women is significantly increased.⁶¹

Alitretinoin. Alitretinoin, 9-*cis*-retinoic acid (Panretin), is a yellow powder that is slightly soluble in ethanol and insoluble in water. Alitretinoin is a naturally occurring endogenous retinoid.

Alitretinoin is indicated for the treatment of cutaneous lesions in patients with AIDS-related Kaposi's sarcoma. It is not indicated when systemic anti-Kaposi's sarcoma therapy is required. It is not indicated as a systemic drug.

Alitretinoin is applied as a 0.1% gel. Initial application is twice daily but may be increased gradually to 4 times daily. Application, however, must be limited to the lesion. Application to normal skin and mucosal tissue should be avoided. The gel should be allowed to dry before dressing. Occlusive dressings should not be used.

Unlike its geometric isomer all *trans*-retinoid acid, which binds only RAR receptors, alitretinoin is a ligand for both RAR and RXR. It has been called a "pan-agonist," since it binds all retinoid receptors. Because of this ability it has been proposed that alitretinoin may be more potent and thus more effective than other retinoids.⁶²

Adapalene. Adapalene (Differin) is a white to off-white powder that is soluble in tetrahydrofuran, sparingly soluble in ethanol, and practically insoluble in water. Adapalene is applied as a 0.1% solution or gel for the treatment of acne vulgaris. The eyes, lips, and mucous membranes should be avoided.

Adapalene is a naphthoic acid derivative, thus differing markedly from the endogenous retinoids. This results in different ability to bind the many retinoic acid-binding proteins. It binds with RARs but not RXRs or CRABPs.⁶³

Bexarotene. Bexarotene (Targretin) is a white to off-white powder that is insoluble in water and slightly soluble in ethanol and vegetable oil. It is available in 75-mg soft capsules. Bexarotene has FDA approval for use in the treatment of cutaneous T-cell lymphoma (CTCL) refractory to at least one prior systemic therapy. The recommended initial dose is 300 mg/m² daily with a meal. Depending on toxicity, the dose may be adjusted up to 400 mg/m² or down by 100 mg/m² or be temporarily suspended.

Bexarotene binds selectively with retinoid X receptors.⁶⁴ Activation of the RXR pathway leads to apoptosis and other cellular activities mediated by proteins resulting from gene expression. The exact mechanism in the treatment of cutaneous T-cell lymphoma is not known.

Absorption of bexarotene is enhanced by fatty meals, thus the recommendation that it be taken with a meal. It is oxidized by P-450 isozyme 3A4 (CYP 3A4), but its interactions with CYP 3A4 inhibitors or inducers have not been studied. Because this drug is administered orally, it must not be given to pregnant women or those expecting to get pregnant.

Tazarotene. Tazarotene (Tazorac) is indicated for the treatment of stable plaque psoriasis. It is applied topically as a 0.05% or 0.1% emollient cream. It has been used on up to 20% of the skin. As with other topical retinoids, care must be taken to protect eye, mouth, and mucous membranes, and occlusive dressings should be avoided.

Tazarotene is an acetylenic prodrug. On application, it is rapidly converted to the active form, tazarotenic acid.⁶⁵ Although tazarotenic acid can bind all three RARs, it shows selectivity for RAR β and RAR γ . The latter is the primary receptor found in the epidermis.⁶⁶ Gene expression then normalizes keratinocyte differentiation, producing less inflammation and decreasing hyperproliferation.⁶⁷ Tazarotenic acid is retained in the skin for up to 3 months, and its therapeutic effect continues after cessation of therapy.⁶⁵

β -Carotene, USP. β -Carotene (Soleten) is a red or reddish-brown to violet-brown powder. It is insoluble in water and alcohol and sparingly soluble in vegetable oils. It is a naturally occurring carotenoid pigment found in green and yellow vegetables.

β -Carotene is indicated for the treatment of erythropoietic protoporphyria. It does not provide total protection against the sun, but patients who respond to its treatment can remain in the sun the same as normal individuals. Discontinuance of the drug results in a return of hypersensitivity. β -Carotene does not function as a sunscreen in normal patients and should not be used as such.

The dosage range is 30 to 300 mg/day in a single or divided dose, usually administered with food because its absorption depends on the presence of bile and absorbable fat.

Most β -carotene is converted to retinol during absorption, but the fraction that is absorbed is distributed widely and accumulates in the skin. The metabolic pathway of β -carotene is similar to that of retinol. Several weeks of therapy are required before enough accumulates in the skin to exert protective effects. Carotenoderma, a result of accumulation in the skin, is the major side effect. A "tanning" capsule containing β -carotene and canthaxanthin, however, uses this effect.

VITAMIN A₂

Vitamin A₂ is found in vertebrates that live or, at least, begin their lives in freshwater. Vitamin A₂ exhibits chemical, physical, and biological properties very similar to those of vitamin A. It has the structural formula depicted above (see page 869). Vitamin A₂ has a biological potency of 1.3 million USP U/g, which is approximately 40% of the activity of crystalline vitamin A acetate.

Vitamin Ds

The recognition in 1919 that rickets was the result of a nutritional deficiency led to the isolation of antirachitic compounds from food products.⁶⁸ The role of sunlight in the prevention of rickets was noted at the same time.⁶⁹ The term

vitamin D was applied to all agents with antirachitic activity. Several compounds were isolated, designated D₁, D₂, or D₃. D₁ was the material obtained by irradiation of yeast ergosterol. This material later was found to be a 1:1 mixture of ergocalciferol and lumisterol. On purification and further characterization, ergocalciferol (calciferol) proved to possess the antirachitic properties and became known as vitamin D₂. Cholecalciferol was designated vitamin D₃.

In a classical sense, vitamin D₃, the form produced in animals, is not a true "vitamin" because it is produced in the skin from 7-dehydrocholesterol by UV radiation in the range of 290 to 300 nm.⁷⁰ 7-Dehydrocholesterol is produced from cholesterol metabolism. Only when exposure to sunlight is inadequate does vitamin D₃ become a vitamin in the historical sense. Further, vitamin D₃ is now termed a *provitamin* because it requires hydroxylation by the liver and the kidney to be fully active.

On UV irradiation, 7-dehydrocholesterol is converted rapidly to previtamin D₃. Previtamin D₃ undergoes slow thermal conversion to vitamin D₃ and the biologically inactive lumisterol₃ and tachysterol₃. Excess exposure increases production of the inactive compounds. The slow conversion of previtamin D₃ to vitamin D₃ ensures adequate supplies when the exposure is brief. Further, lumisterol and tachysterol can be converted back to previtamin D₃ and thus serve as a reservoir.⁷⁰ It has been estimated that a 10-minute exposure of just the uncovered hands and face will produce sufficient vitamin D₃.⁷¹

The mechanism responsible for the movement of vitamin D₃ from the skin to the blood is not known. In the blood, vitamin D₃ is bound primarily to an α protein known as vitamin D-binding protein (VDBP). This protein selectively removes vitamin D₃ from the skin because it has low affinity for 7-dehydrocholesterol, previtamin D₃, lumisterol, and tachysterol.

Cholecalciferol (vitamin D₃) does not perform its function directly. It must be transformed by the liver and the kidney. The first step occurs in the liver by the enzyme vitamin D₃ 25-hydroxylase. This enzyme converts the provitamin to 25-hydroxyvitamin D₃ (25-OHD₃). This enzyme, which requires both molecular oxygen and reduced nicotinamide adenine dinucleotide phosphate (NADPH), appears to be a cytochrome P-450 monooxygenase and is found in the endoplasmic reticulum and the mitochondria.⁷² The rate of this hydroxylation correlates with substrate concentration.⁷⁰ The 25-OHD₃ thus formed is the major circulating form of the vitamin bound to VDBP. The circulating levels of 25-OHD₃ are proportional to vitamin D intake. Thus plasma levels of 25-OHD₃ are used to indicate vitamin D status.⁷³

The epithelial cells of the proximal convoluted tubules convert 25-OHD₃ to 1 α ,25-OHD₃ by the enzyme 25-OHD 1 α -hydroxylase. The activity of this mitochondrial cytochrome P-450 enzyme is controlled by 1 α ,25-OHD₃ and parathyroid hormone as well as high concentrations of calcium and phosphate.⁷⁰

Catabolism of vitamin D is initiated by the enzyme vitamin D 24-hydroxylase, whose expression is stimulated by 1 α ,25-OHD₃ itself. 24-Hydroxylation is followed by oxidation to the ketone. Subsequent hydroxylation at C-23 leads to cleavage of the side chain, resulting in the biologically inactive product calcitronic acid.^{73, 74}

The need for calcium stimulates parathyroid hormone secretion. Parathyroid hormone, in turn, suppresses the 24-hydroxylase and stimulates the 1α -hydroxylase system. When phosphate availability is below normal, the 1α -hydroxylase is stimulated and the 24-hydroxylase is suppressed.

As with vitamin A, most of the effects of vitamin D involve a nuclear receptor. The vitamin D receptor is a member of the steroid/thyroid hormone superfamily of receptors. When $1\alpha,25\text{-OHD}_3$ binds to its receptor, the complex forms a heterodimer with an unoccupied RXR. This heterodimer subsequently binds to the regulatory regions on specific genes in target tissue. These regions are called *vitamin D response elements* (VDREs). The binding to VDREs can increase or decrease expression of genes.⁷⁰ The proteins thus made carry out the functions of vitamin D.

The physiological role of vitamin D is to maintain calcium homeostasis. Phosphate metabolism is also affected. Vitamin D accomplishes its role by enhancing the absorption of calcium and phosphate from the small intestines, promoting their mobilization from bone, and decreasing their excretion by the kidney. Also involved are parathyroid hormone and calcitonin.

$1\alpha,25\text{-OHD}_3$ promotes Ca^{2+} intestinal absorption and increases Ca^{2+} renal reabsorption in the distal tubules and mobilization of Ca^{2+} from bone. The mechanism of action promoting Ca^{2+} transport in the intestine involves formation

of a calcium-binding protein. $1\alpha,25\text{-OHD}_3$ promotes availability of this protein. A calcium-dependent ATPase, Na^+ , and the calcium-binding protein are necessary for intestinal Ca^{2+} transport. $1\alpha,25\text{-OHD}_3$ also promotes intestinal phosphate absorption, mobilization of Ca^{2+} and phosphate from bone, and renal reabsorption of Ca^{2+} and phosphate. $1\alpha,25\text{-OHD}_3$ induces the synthesis of a Na-Pi cotransport.⁷⁵

Vitamin D deficiency results in rickets in infants and children as a result of inadequate calcification of bones. In adults, osteomalacia most often occurs during pregnancy and lactation. Rickets is rare in the United States because of fortification of foods. Deficiencies in the elderly, however, result from underexposure to sunlight.

Hypervitaminosis D apparently cannot arise from excessive exposure to sunlight⁷⁶ but only occurs following ingestion of large quantities of synthetic vitamin D for months. The amount necessary has been estimated at 50,000 units or more in a person with normal parathyroid function.⁷⁷ The mechanism may involve formation of excessive amounts of the vitamin D metabolite 25-OHD. Toxicity involves derangements of calcium metabolism, resulting in hypercalcemia and metastatic calcification of soft tissue. Most problems result from the hypercalcemia, which typically causes muscular weakness, anorexia, nausea, vomiting, and depression of the central nervous system (which can result in coma and death). In addition, deposition of calcium salts in the kidneys (nephrocalcinosis) and the tubules (nephrolithiasis)

Ergocalciferol has a half-life of 24 hours (19 to 48 hours) and a duration of action of up to 6 months. After oral or intramuscular administration, the onset of action (hypercalcemia) is 10 to 24 hours, with maximal effects seen 4 weeks after daily administration.

After irradiation, the steroid undergoes fission of ring B; therefore, it is known as a secosteroid. This is indicated in the name by the "9,10-seco" portion. The "ergosta" portion indicates the presence of 28 atoms in the carbon skeleton.

The history and preparation of this vitamin are described above. Vitamin D₂ is a white, odorless crystalline compound that is soluble in fats and in the usual organic solvents, including alcohol. It is insoluble in water. Vitamin D₂ is oxidized slowly in oils by oxygen from the air, probably through the fat peroxides that are formed. Vitamin A is much less stable under the same conditions.

Cholecalciferol, USP. Cholecalciferol, (3 β ,5Z,7E)-9,10-secocholesta-5,7,10(19)-trien-3-ol, vitamin D₃, activated 7-dehydrocholesterol, occurs as white odorless crystals that are soluble in fatty oils, alcohol, and many organic solvents. It is insoluble in water. Vitamin D₃ also occurs in tuna and halibut liver oils. It has the same activity as vitamin D₂ in rats but is more effective in the chick; both vitamins, however, have equal activity in humans. Vitamin D₃ exhibits stability comparable to that of vitamin D₂.

Epimerization of the hydroxyl at C-3 in vitamin D₂ or D₃ or conversion of the hydroxyl at C-3 to a ketone group greatly diminishes the activity but does not completely destroy it. Ethers and esters that cannot be cleaved in the body have no vitamin D activity. Inversion of the hydrogen at C-9 in ergosterol and other 7-dehydrosterols prevents the normal course of irradiation.

Dihydrotachysterol, USP. Tachysterol (represented below) is a by-product of ergosterol irradiation. Reduction of tachysterol led to dihydrotachysterol, (3 β ,5E,7E,10 α ,22E)-9,10-ergosta-5,7,22-trien-3-ol, dihydrotachysterol₂, dichysterol, DHT.

Dihydrotachysterol occurs as colorless or white crystals or a white, crystalline odorless powder. It is soluble in alcohol, freely soluble in chloroform, sparingly soluble in vegetable oils, and practically insoluble in water.

Dihydrotachysterol has slight antirachitic activity. It increases the calcium concentration in the blood, an effect for which tachysterol is only one tenth as active. In high doses, dihydrotachysterol is more effective than the other analogues

in mobilizing calcium. Thus, it is used in hypoparathyroidism.

After oral administration, the onset of action is seen within hours. This fast onset of action is an advantage of this drug. Maximal activity is seen in 2 weeks after daily administration. Its duration of action is 2 weeks.

Dihydrotachysterol is activated by hepatic enzymes to its 25-hydroxylated metabolite. It does not require renal activation, for the hydroxy on ring A occupies the same position as that of the 1-hydroxyl in the activated forms of the vitamin Ds. 25-Hydroxydihydrotachysterol₁ has weak antirachitic activity, but it is a more important bone-mobilizing agent and is more effective than dihydrotachysterol₂. Also, it is more effective in increasing intestinal calcium transport and bone mobilization in thyroparathyroidectomized rats. Its activity suggests that it may be the drug of choice in the treatment of hypoparathyroidism and similar bone diseases.⁷⁹

Calcifediol, USP. Calcifediol, (3 β ,5Z,7E)-9,10-secocholesta-5,7,10(19)-trien-3,25-diol, 25-hydroxycholecalciferol, 25-hydroxyvitamin D₃, occurs as a white powder. It is practically insoluble in water and sensitive to light and heat. The half-life of calcifediol is 16 days (10 to 22 days). Its onset of action occurs within 2 to 6 hours, and its duration of action is 15 to 20 days.

Calcifediol is indicated for patients receiving long-term renal dialysis.

Calcitriol. Calcitriol, (1 α ,3 β ,5Z,7E)-9,10-secocholesta-5,7,10(19)-trien-1,3,25-triol, 1,25-dihydroxycholecalciferol, 1,25-dihydroxyvitamin D₃, occurs as colorless crystals that are insoluble in water. Because calcitriol does not require activation, increased calcium absorption is seen within 2 hours of administration. Its half-life is 3 to 8 hours, and its duration of action is 1 to 2 days.

Calcitriol is the most active form of vitamin D₃. It is indicated in patients who are receiving long-term renal dialysis or who cannot properly metabolize ergocalciferol.

Calcipotriene. Calcipotriene, (1 α ,3 β ,5Z,7E,22E,24S)-24-cyclopropyl-9,10-secocholesta-5,7,10(19),22-tetraene-1,3,24-triol, calcipotriol (Dovonex), is a synthetic vitamin D₁ analogue indicated for topical application in the treatment of moderate plaque psoriasis. It has the same affinity for the vitamin D receptor as calcitriol, but its effect on calcium metabolism is 100 to 200 times less. Calcipotriene inhibits epidermal cell proliferation and enhances cell differentia-

tion. It reduces cell numbers and total DNA content.⁸⁰ Antiproliferative effects are caused by a reduction in the mRNA levels of a cellular oncogene associated with proliferation, *c-myc*. The mechanism resulting in differentiation changes is not completely known but involves the secondary messengers inositol triphosphate (IP₃) and diacylglycerol (DAG).⁷⁰

Doxercalciferol. Doxercalciferol, (1 α ,3 β ,5Z,7E,22E)-9,10-secoergosta-5,7,10(19),22-tetraene-1,3-diol, 1 α -hydroxy-ergocalciferol, 1 α -hydroxyvitamin D₃ (Hectorol), is a colorless crystalline compound soluble in oils and organic solvents but relatively insoluble in water. Doxercalciferol is indicated for the reduction of elevated intact parathyroid hormone (iPTH) in the management of secondary hyperparathyroidism in patients undergoing chronic renal dialysis.

Following gastrointestinal absorption after oral administration, doxercalciferol is activated in the liver to 1 α ,25(OH)₂D₃. The activation does not require involvement of the kidney. Being a prodrug, doxercalciferol does not stimulate the absorption of dietary calcium and phosphorus.⁸¹ The mean half-life in healthy volunteers is approximately 32 to 37 hours, which is similar to the half-life in patients with end-stage renal disease.⁸²

The dose must be individualized for each patient. The goal is to lower blood iPTH into the 150 to 300 pg/mL range. The recommended initial dose is 10 μ g 3 times weekly, administered at dialysis. If the iPTH levels are not lowered by 50% and fail to reach the indicated range, the dose may be increased by 2.5 μ g every 8 weeks. The maximal recommended dose is 60 μ g/week.

Paricalcitol. Paricalcitol, (1 α ,3 β ,5Z,7E,22E)-19-nor-9,10-secoergosta-5,7,22-triene-1,3,25-triol (Zemlar), is a white powder. Paricalcitol is indicated for the prevention and treatment of secondary hyperparathyroidism in patients

undergoing chronic renal dialysis. It has a lower incidence of hypercalcemia and hyperphosphatemia than calcitriol.⁸¹

Paricalcitol is a calcitriol analogue intended for intravenous use. The recommended initial dose is 0.04 to 0.1 μ g/kg as a bolus dose during dialysis. The dose may be given no more often than every other day. The goal of therapy is to lower iPTH levels to no more than 1.5 to 3 times the nonuremic upper normal limit. The dose may be increased by 2 to 4 μ g at 2- to 4-week intervals.

Vitamin E

Since the early 1920s, it has been known that rats fed only cow's milk cannot produce offspring. The principle from wheat germ that can rectify this deficiency in both male and female rats was named *vitamin E*. When the compound known as vitamin E was isolated in 1936, it was named *tocopherol*. Since then, several other closely related compounds have been discovered from natural sources, and this family of natural products took the generic name *tocopherols*.

The tocopherols are especially abundant in wheat germ, rice germ, corn germ, other seed germs, lettuce, soya, and cottonseed oil. All green plants contain some tocopherols, and there is evidence that some green leafy vegetables and rose hips contain more than wheat germ. It is probably synthesized by leaves and translocated to the seeds. All four tocopherols have been found in wheat germ oil; α -, β -, and γ -tocopherols have been found in cottonseed oil. Corn oil contains predominantly γ -tocopherol and thus furnishes a convenient source for the isolation of this difficult member of the tocopherols to prepare. δ -Tocopherol is 30% of the mixed tocopherols of soya bean oil.

Several tocopherols have been isolated. Some have the 4',8',12'-trimethyltridecyl-saturated side chain; others have unsaturation in the side chain. It has been suggested that these polyunsaturated tocopherols be named "tocotrienols." The best known is α -tocopherol (vitamin E), which has the greatest biological activity. The base structure, represented below, shows that the tocopherols are methyl-substituted tocol derivatives: α -tocopherol is 5,7,8-trimethyltolcol; β -tocopherol is 5,8-dimethyltolcol; the γ -compound is 7,8-dimethyltolcol; and δ -tocopherol is 8-methyltolcol. The tocotrienols have similar substituents. Natural α -(+)-tocopherol has the configuration 2R,4'R,8'R. The natural tocotrienols have a 2R,3'E,7'E configuration. The tocopherols are diterpenoid natural products biosynthesized from a combination of four isoprenoid units; geranylgeranyl pyrophosphate is the key intermediate that leads to these compounds.⁸⁴

The tocopherols and their acetates are light yellow, viscous, odorless oils that have an insipid taste. They are insoluble in water and soluble in alcohol, organic solvents, and fixed oils. The acid succinate esters are white powders insoluble in water and soluble in ethanol and vegetable oils. Tocopherols are stable in air for reasonable periods but are oxidized slowly by air. They are oxidized readily by ferric salts, mild oxidizing agents, and air in the presence of alkali. They are inactivated rapidly by exposure to UV light; not all samples behave alike in this respect, however, because traces of impurities apparently greatly affect the rate of oxidation. Tocopherols have antioxidant properties for fixed oils in the following decreasing order of effectiveness: δ , γ , β , and α .⁸⁵ In the process of acting as antioxidants, tocopherols are destroyed by the accumulating fat peroxides that they decompose. They are added to Light Mineral Oil NF and Mineral Oil USP because of their antioxidant property. Tocopherols can be converted to acetates and benzoates, which are oils as active as the parent compounds but more stable toward oxidation.

(+)- α -Tocopherol is about 1.36 times as effective as (\pm)- α -tocopherol in rat antisterility bioassays. β -Tocopherol is about half as active as α -tocopherol, and the γ - and δ -tocopherols are only 1/100 times as active as α -tocopherol. The esters of tocopherol (e.g., acetate, propionate, and butyrate) are more active than the parent compound.⁸⁶ This is also true of the phosphoric acid ester of (\pm)- δ -tocopherol when it is administered parenterally.⁸⁷ The ethers of the tocopherols are inactive. Oxidation of the tocopherols to their corresponding quinones also leads to inactive compounds. Replacement of the methyl groups by ethyl groups decreases activity. The introduction of a double bond in the 3,4 position of α -tocopherol reduces its activity by about two thirds. Reduction of the size of the long alkyl side chain or the introduction of double bonds in this side chain markedly reduces activity. Vitamin E activity currently is expressed in terms

of the α -(+)-tocopherol equivalents based on the former USP units and mass listed in Table 26-6. One former USP unit is equal to one former IU. Vitamin E, USP, may consist of (+)- or (\pm)- α -tocopherols or their acetates or succinates, 96.0 to 102.0% pure.

(-)- α -Tocopherol is absorbed from the gut more rapidly than the (+)-form; absorption of the mixture of (+)- and (-)- α -tocopherol, however, was considerably higher (about 55%) than that expected from the data obtained after administration of the single compounds. As doses increase, the fraction absorbed decreases. No marked differences were noted in the distribution in various tissues and the metabolic degradation of (+)- and (-)- α -tocopherols.⁸⁸ The liver is

TABLE 26-6 Relative Potencies of Various Commercial Forms of Vitamin E

Form of Vitamin E	Potency
Potency (in former USP units) of 1 mg	
(\pm)- α -Tocopherol	1.1
(\pm)- α -Tocopherol acetate	1.0
(\pm)- α -Tocopherol acid succinate	0.89
(+)- α -Tocopherol	1.49
(+)- α -Tocopherol acetate	1.36
(+)- α -Tocopherol acid succinate	1.21
Potency (in terms of (+)-tocopherol equivalents) of 1 mg	
(+)- α -Tocopherol acetate	0.91
(+)- α -Tocopherol acid succinate	0.81
(\pm)- α -Tocopherol	0.74
(\pm)- α -Tocopherol acetate	0.67
(\pm)- α -Tocopherol acid succinate	0.60

an important storage site. Most of the gastrointestinal absorption of vitamin E occurs through the mucosa and the lymphatic system. Bile performs an important function in promoting tocopherol absorption. The ester derivatives are hydrolyzed by pancreatic enzymes before absorption. Although hydrolysis of the ester is not required, it does improve absorption. Vitamin E preparations are absorbed better from aqueous solutions than from oily solutions. α -Tocopherol and γ -tocopherol are absorbed from the intestines and distributed to the liver equally well. γ -Tocopherol is secreted primarily into the bile, however, while α -tocopherol enters the circulation, where it is found in much higher levels than γ -tocopherol, even though the latter predominates in the diet. This difference is attributed to a liver cytosolic binding protein that is selective for α -tocopherol.

The tocopherols in lymph are associated with chylomicrons and very-low-density lipoproteins (VLDLs). Circulating tocopherols are also associated mainly with the blood low-density lipoproteins (LDLs). The tocopherols are readily and reversibly bound to most tissues, including adipose tissue, and the vitamin is thus stored. The vitamin is concentrated in membrane structures, such as mitochondria, endoplasmic reticulum, and nuclear and plasma membranes.

Vitamin E is metabolized primarily to tocopheronic acid and its γ -lactone, followed by glucuronide conjugation. The terminal methyl group is oxidized to a carboxylic acid and shortened by β -oxidation to produce tocopheronic acid. The chroman ring is hydrolyzed to a quinone, which subsequently is reduced to a hydroquinone. Nucleophilic attack by a hydroxyl on the carbonyl side chain produces tocopheronolactone. These metabolites are excreted in the bile. Vitamin E may undergo some enterohepatic circulation.

Tocopheronic acid

Tocopheronolactone

For decades, there has been significant interest in investigating the biochemical functions of vitamin E, but it is still difficult to explain many of the biochemical derangements caused by vitamin E deficiency in animals. There seems to be general agreement that one of the primary metabolic functions of the vitamin is preventing the oxidation of lipids, particularly unsaturated fatty acids. This antioxidant function does not, however, explain all of the biochemical abnormalities caused by vitamin E deficiency. Moreover, vitamin E is not the only *in vivo* antioxidant. Two enzyme systems, glutathione reductase and *o*-phenylenediamine peroxidase, also function in this capacity.⁸⁹

It has been postulated that vitamin E has a role in the regulation of protein synthesis. Other actions of this vitamin have also been investigated, for example, effects on muscle

creatine kinase and liver xanthine oxidase. Vitamin E deficiency leads to an increase in the turnover of creatine kinase. Vitamin E-deficient animals also exhibit increased liver xanthine oxidase activity, which is due to increased *de novo* synthesis.⁸⁹

Although it has been difficult to establish clinical correlates of vitamin E deficiency in humans, Bieri and Farrell⁸⁹ have summarized some useful generalizations and conclusions. These workers noted that the infant, especially the premature infant, is susceptible to tocopherol deficiency because of ineffective transfer of the vitamin from placenta to fetus and that growth in infants requires greater availability of the vitamin. In adults, the tocopherol storage depots provide adequate availability that is not readily depleted, but intestinal malabsorption syndromes, when persistent, can lead to depletion of the storage depots. Children with cystic fibrosis suffer from severe vitamin E deficiency caused by malabsorption. Tropical sprue, celiac disease, gastrointestinal resections, hepatic cirrhosis, biliary obstruction, and excessive ingestion of mineral oil may also cause long-term malabsorption.

Vitamin E therapeutic indications include the clinical conditions characterized by low serum tocopherol levels and increased fragility of red blood cells to hydrogen peroxide or conditions that require additional amounts. The latter can be exemplified by individuals who consume excessive amounts of polyunsaturated fatty acids (more than 20 g/day over normal diet).⁹⁰

It has been claimed that vitamin E could be of therapeutic benefit in ischemic heart disease, but evidence against this claim continues to accumulate. It has also been suggested that megadoses of tocopherol be used in the treatment of peripheral vascular disease with intermittent claudication. Although some studies support this proposal, experts in the field state that further clinical studies are necessary to make a definitive recommendation. Nevertheless, it continues to be popular and controversial to consider the beneficial effects of vitamin E and other vitamins in large (mega) dietary supplements, and investigations of megavitamin E therapy for cardiovascular disease continue to appear in the literature.⁸⁹

The eminent vitamin biochemist R. J. Williams has emphasized that

[l]ipid peroxidation, the formation of harmful peroxides, from the interaction between oxygen and highly unsaturated fats (polyunsaturates) needs to be controlled in the body. Both oxygen and the polyunsaturated lipids are essential to our existence, but if the protection against peroxidation is inadequate, serious damage to various body proteins may result. Vitamin E is thought to be the leading agent for the prevention of peroxidation and the free radical production that is associated both with it and with radiation.⁹¹⁻⁹³

Williams also noted that although exact mechanisms of action of these antioxidants are not yet known,

[p]roviding plenty of vitamin E and ascorbic acid (both harmless antioxidants) is indicated as a possible means of preventing premature aging, especially if one's diet is rich in polyunsaturated acids.

Considering the foregoing implication of unnecessary peroxidation of unsaturated lipids, it is interesting that atherosclerosis appears to be due to a deficiency of prostacyclin,

which is caused by inhibition of prostacyclin synthetase by lipid peroxides or by free radicals that are likely to be generated during hyperlipidemia. Although no direct evidence indicates that in experimental or human atherosclerosis, lipid peroxidation is the earliest sign of the disease state, lipid peroxides have been found in arteries from atherosclerotic patients and in ceroid atheromatic plaques, and at the same time, hardly any prostacyclin is generated in human atheromatic plaques.⁹⁴

Vitamin E used in high doses, as high as 3,200 mg/day, has a proven record of safety.³² A variety of reports, many single case reports or uncontrolled studies, have suggested adverse effects such as interference with clotting, weakness, decreased thyroid hormone levels, and gastrointestinal upset. The importance of these is unknown. The only notable adverse effects have occurred in premature infants given large doses of this vitamin. Hepatotoxicities have been seen in premature infants of less than 1,500 g birth weight given vitamin E intravenously, and the incidence of necrotizing enterocolitis and sepsis increased under similar conditions following oral or intravenous dosing.

Vitamin Ks

Lipid-free diet research by Henrik Dam starting in 1929 resulted in the discovery of an antihemorrhagic factor that was named *vitamin K* (from the German word *Koagulation*). Along with the work of Edward A. Doisy, the structure of vitamin K was determined in 1931 as shown below. For their work, Dam and Doisy shared the 1943 Nobel Prize in medicine. The term *vitamin K* was applied to the vitamin isolated from alfalfa, and a similar principle from fish meal was named *vitamin K₂*. *Vitamin K₂* refers to a series of compounds called the *menaquinones*. These have a longer side chain with more unsaturation. This side chain may be composed of 1 to 13 isoprenyl units. The most common are depicted below.

Vitamin K₁
Phytonadione
(2-Methyl-3-phytyl-1,4-naphthoquinone)

$n = 4$ = Vitamin K₂₍₃₀₎ Menaquinone-6
 $n = 5$ = Vitamin K₂₍₃₅₎ Menaquinone-7

Many other closely related compounds possess vitamin K activity (e.g., menadione [2-methyl-1,4-naphthoquinone] is as active as vitamin K on a molar basis). The synthetic compounds menadione and menadiol are referred to as *vitamin K₃* and *K₄*, respectively. Vitamin K is a naphthoquinone derivative containing diterpenoid units biosynthesized by the intermediate geranylpyrophosphate.⁹⁵

TABLE 26-7 Vitamin K Content of Selected Foods

Food	µg/100 g
Broccoli	200
Brussels sprouts	220
Cabbage, Chinese	175
Cabbage, red	50
Cabbage, white	80
Green onions	60
Kale	750
Lettuce	120
Parsley	700
Spinach	350
Turnip greens	300
Watercress	200

Animals depend on two sources for their intake of this vitamin, dietary and bacterial synthesis. Table 26-7 lists excellent sources of vitamin K₁.

Natural K₁ occurs as a *trans* isomer and has an *R,R,E* configuration. The synthetic, commercially available form is a mixture of *cis* and *trans* isomers, with no more than 20% *cis*. Vitamin K₂ is synthesized by the intestinal flora, especially by Gram-positive bacteria. It is not available commercially.

Numerous compounds have been tested for their antihemorrhagic activity, and significant biological activity is manifested in compounds with the following structure

when

1. Ring A is aromatic or hydroaromatic.
2. Ring A is not substituted.
3. Ring B is aromatic or hydroaromatic.
4. R is OH, CO, OR, OAc (the R in OR is methyl or ethyl).
5. R' is methyl.
6. R'' is H, sulfonic acid, dimethylamino, or an alkyl group containing 10 or more carbon atoms. A double bond in the β,γ position of this alkyl group enhances potency; if the double bond is further removed, it exerts no effect. Isoprenoid groups are more effective than straight chains. In the vitamin K_{2(30)}}-type compounds, the 6',7'-mono-*cis*- isomer is significantly less active than the all-*trans*- or the 18',19'-mono-*cis*- isomer. This was also true of the vitamin K_{2(30)}}-isoprenologue. A vitamin K₂₋₂₅ isoprenologue was 20% more active than vitamin K_{1(37)}}.
7. R''' is H, OH, NH₂, CO, OR, Ac (the R in OR is methyl or ethyl).

Decreased antihemorrhagic activity is obtained when

1. Ring A is substituted.
2. R' is an alkyl group larger than a methyl.
3. R'' is a hydroxyl group.
4. R''' contains a hydroxyl group in a side chain.

If ring A is benzenoid, the introduction of sulfur in place of a $-\text{CH}=\text{CH}-$ in this ring in 2-methylnaphthoquinone permits the retention of some antihemorrhagic activity. This might indicate that in the process of exerting vitamin K activity, the benzenoid end of the molecule must fit into a pocket carefully tailored to it. That the other end is not so closely surrounded is shown by the retention of activity on changing the alkyl group in the 2 position.

Although marked antihemorrhagic activity is found in many naphthoquinone compounds, these compounds may be converted in the body to a vitamin K₁-type compound. The esters of the hydroquinones may be hydrolyzed, and the resulting hydroquinone may be oxidized to the quinone. The methyl tetralones, which are very active, could be dehydrogenated to the methylnaphthols, which are hydroxylated, and the latter product converted to the biologically equivalent quinone. Compounds with a dihydrobenzenoid ring (e.g., 5,8-dihydrovitamin K₁) appear to be moderately easily dehydrogenated, whereas the corresponding tetrahydrides are resistant to such change.

Vitamins K₁ and K₂ are absorbed by an active process in the proximal small intestines. Bile of normal composition is necessary to facilitate the absorption. The bile component principally concerned in the absorption and transport of fat-soluble vitamin K from the digestive tract is thought to be deoxycholic acid. The molecular compound of vitamin K with deoxycholic acid was effective on oral administration to rats with biliary fistula. Vitamin K is absorbed through the lymph in chylomicrons. It is transported to the liver, where it is concentrated, but no significant storage occurs.

The entire metabolic pathway of vitamin K has not been elucidated. The major urinary metabolites, however, are glucuronide conjugates of carboxylic acids derived from shortening of the side chain. High fecal concentrations are probably due to bacterial synthesis.

The accepted mechanism for vitamin K is to function as a cofactor in the posttranslational synthesis of γ -carboxyl-glutamic acid (Gla) from glutamic acid residues.⁹⁶ The discovery of Gla in 1974^{97,98} clarified the mechanism of vitamin K and led to the identification of additional vitamin K-dependent proteins. The only known function of vitamin K in mammals is to maintain adequate levels of vitamin K-dependent proteins involved in coagulation. These include prothrombin (factor II), factor VII (proconvertin), factor IX (autoprothrombin II), factor X (Stuart-Prower factor), and proteins C, S, and Z. Prothrombin and factors VII, IX, and X promote coagulation, while proteins C and S have anticoagulant activity. The function of protein Z is not known.

It follows that any condition that does not permit full use of the antihemorrhagic agents or the production of prothrombin would lead to increased clotting time or hemorrhagic disorders. Some of these conditions are (a) faulty absorption caused by several disorders (e.g., obstructive jaundice, biliary fistulas, intestinal polyposis, chronic ulcerative colitis, intestinal fistula, intestinal obstruction, and sprue); (b) damaged livers or primary hepatic diseases (e.g., atrophy, cirrhosis, or chronic hepatitis); (c) insufficient amounts of bile or abnormal bile in the intestinal tract; and (d) insufficient amounts of vitamin K.

Prothrombin and factors VII, IX, and X participate in the cascade of reactions leading to fibrin clot formation. Protein

C exerts its anticoagulant effect by inactivating activated factors V_a and VIII_a.⁹⁹ Protein C is first activated by prothrombin. This activation requires a cell surface receptor, thrombomodulin, calcium, and protein S. Protein C also increases fibrinolysis by inactivating the major inhibitor of tissue plasminogen activator.¹⁰⁰ Protein S functions as a cofactor in the protein C inactivation of activated factor V_a and VIII_a. Protein S is found in the plasma and is bound to C4b-binding protein, an inhibitor in the complement system.¹⁰¹ Protein S is also a cofactor in protein C fibrinolysis.

All of these proteins are synthesized in the liver, and they have considerable structural homology. All contain 10 to 12 Gla residues.^{102,103} The coagulation activity is proportional to the number of Gla residues present. For example, prothrombin has 10 Gla residues. Loss of just two residues decreases activity by 80%.¹⁰³

This system requires reduced vitamin K (a hydroquinone, KH₂), carbon dioxide, and molecular oxygen. Although the reaction does not require ATP, it uses the energy from the oxidation of KH₂ to execute the carboxylation of glutamic acid.¹⁰⁴ The carboxylase must create a carbanion by extracting a proton from the glutamate γ -carbon. This requires a base with a pK_a of 26 to 28. The anion of the hydroquinone, however, has a pK_a of only about 9.

A proposed mechanism for the above carboxylation creates such a base from vitamin K.^{105,106} Vitamin K is reduced to its hydroquinone form (vitamin KH₂). Molecular oxygen is incorporated into the conjugate acid form of vitamin KH₂ to form a peroxy anion, which subsequently forms a dioxetane intermediate. The peroxy bond is cleaved by the adjacent enolate anion to produce an intermediate sufficiently basic to deprotonate the α -carbon.

Extraction of the proton allows the carboxylase to carboxylate the glutamate residue. The vitamin K intermediate is converted to vitamin K oxide, which must be reduced back to vitamin K. Vitamin K oxide is recycled back to vitamin K by vitamin K epoxide reductase and vitamin K quinone reductase. Both of these enzymes are dithiol dependent and are inhibited by the 4-hydroxycoumarin anticoagulants.

All vitamin K-dependent proteins contain Gla residues. Vitamin K thus participates in the formation of specific γ -carboxylglutamic acid Ca²⁺-binding sites on the vitamin K-dependent proteins. Further, the Gla residues are found in essentially the same region, near the amino terminus, and this region is called the *Gla domain*.¹⁰⁷ These Gla residues function as ion bridges linking the blood-clotting protein to phospholipids on endothelial cells and platelets.¹⁰⁸ The vitamin K-dependent carboxylase system is located on the endoplasmic reticulum.¹⁰⁹ Binding to membrane surfaces is critical in the activation of these proteins.¹⁰⁸

The discovery of Gla not only clarified the biochemical mechanism of vitamin K but also resulted in the isolation of several nonhepatic vitamin K-dependent proteins: osteocalcin, matrix Gla protein, Gas6, PRGP 1 and PRGP 2. Osteocalcin is synthesized in the osteoplast and odontoblasts. Its expression is regulated by 1 α ,25-dihydroxyvitamin D¹⁰⁹ and retinoic acid.¹¹⁰ Studies on osteocalcin-deficient mice indicate that osteocalcin is a negative regulator of bone formation via an unknown mechanism but does not alter bone resorption or mineralization.¹¹¹ Matrix Gla protein is found in bone, cartilage, and soft tissue. Its synthesis is regulated by 1 α ,25-dihydroxyvitamin D₃ and retinoic acid, and it

inhibits soft tissue calcification.¹¹² Gas6 is encoded by growth arrest-specific gene 6, and it contains 10 to 11 Gla residues.¹¹³ It is involved in cell proliferation regulation through an unknown mechanism. The physiological roles of three other Gla-containing proteins remain unknown. Nephrocalcin has been isolated from renal tissue,¹¹⁴ while plaque Gla protein has been isolated from atherosclerotic plaque.¹¹⁵ The latest Gla-containing proteins have wide tissue distribution and are rich in proline residues; thus they have been named proline-rich Gla proteins (PRGP 1 and PRGP 2).¹¹⁶

Phytonadione is considered relatively nontoxic even at high doses. Rare cases of hemolytic anemia have been reported, and the manufacturer has reported anaphylactic reactions following use of the injectable product. Menadione, in contrast, can produce hemolytic anemia, hyperbilirubinemia, and kernicterus in newborns, especially premature infants. In addition, menadione can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency.¹¹⁷⁻¹¹⁹

PRODUCTS

Phytonadione, USP. Phytonadione, 2-methyl-3-phytyl-1,4-naphthoquinone, vitamin K₁ (Mephyton, Aqua-MEPHYTON), is a clear, yellow, very viscous, odorless or nearly odorless liquid. Pure vitamin K₁ is a yellow crystalline solid that melts at 69°C. It is insoluble in water, slightly

soluble in alcohol, and soluble in vegetable oils and in the usual fat solvents. It is unstable toward light, oxidation, strong acids, and halogens. It can be reduced easily to the corresponding hydroquinone, which in turn can be esterified.

The therapeutic use of vitamin K as a systemic hemostatic agent is based on the critical function that the vitamin performs in blood coagulation. Vitamin K₁ (phytonadione) is effective both in the treatment of hypoprothrombinemia caused by dietary deficiency of the vitamin or malabsorption and in the bleeding caused by oral anticoagulants (e.g., coumadin derivatives). Phytonadione exerts prompt and prolonged action. It can be administered orally, subcutaneously, or intramuscularly; in emergencies it can be given by slow intravenous injection.

Vitamin K is administered in conjunction with bile salts or their derivatives in preoperative and postoperative jaundiced patients to bring about and maintain a normal prothrombin level in the blood. In the average infant, the birth values of prothrombin content are adequate, but during the first few days of life, they appear to fall rapidly, even dangerously low, and then slowly recover spontaneously. This transition period was and is critical because of the numerous sites of hemorrhagic manifestations, traumatic or spontaneous, that may prove serious if not fatal. This condition is now considered a type of alimentary vitamin K deficiency. The spontaneous recovery is perhaps due to establishment of an intestinal flora.

tinal flora that can synthesize vitamin K after ingestion of food. Oral administration of vitamin K, however, effects a prompt recovery.

Vitamin K₁ acts more rapidly (effect on prothrombin time) than menadione, within 2 hours after intravenous administration. No difference, however, could be detected after 2 hours.¹²⁰ The menadiones are much less active than vitamin K₁ in normalizing the prolonged blood-clotting times caused by dicumarol and related drugs.¹²⁰ Vitamin K₁ is the drug of choice for humans because of its low toxicity. Its duration of action is longer than that of menadione and its derivatives. Vitamin K should not be administered to patients receiving warfarin or coumarin anticoagulants.

Vitamin K can be used to diagnose liver function accurately. Intramuscular injection of 2 mg of 2-methyl-1,4-naphthoquinone elicits a response in prothrombin index in patients with jaundice of extrahepatic origin but not in those with jaundice of intrahepatic origin (e.g., cirrhosis).

Menadione, USP. Menadione, 2-methyl-1,4-naphthoquinone, menaphthone, vitamin K₃, can be prepared readily by the oxidation of 2-methylnaphthalene with chromic acid. It is a bright yellow, crystalline powder and is nearly odorless. It is affected by sunlight. Menadione is practically insoluble in water; it is soluble in vegetable oils, and 1 g of it is soluble in about 60 mL of alcohol. The USP/NF cautions that menadione powder is irritating to the respiratory tract and the skin and that an alcoholic solution has vesicant properties.

On a mole-for-mole basis, menadione is equal to vitamin K₁ in activity and can be used as a complete substitute for this vitamin. It is effective orally, intravenously, and intramuscularly. Oral absorption occurs in the distal small intestines and the colon. If given orally to patients with biliary obstruction, bile salts or their equivalent should be administered simultaneously to facilitate absorption. It can be administered intramuscularly in oil when the patient cannot tolerate an oral product or has a biliary obstruction or when a prolonged effect is desired.

Carbon-14-labeled menadiol diacetate in small physiological doses is converted in vivo to vitamin K₂₍₂₀₎, and the side chain probably originates from mevalonic acid. This suggests that menadione may be an intermediate or a provitamin K.¹²⁰

Menadione in oil is 3 times more effective than a menadiol suspension in water. More of menadione than of vitamin K₁ is absorbed orally, but 38% of menadione is excreted by the kidney in 24 hours, whereas only very small amounts of vitamin K₁ are excreted by this route in 24 hours. In rats, menadione in part is reduced to the hydroquinone and excreted as the glucuronide (19%) and the sulfate (9.3%).

Menadione Sodium Bisulfate. Menadione sodium bisulfate, 2-methyl-1,4-naphthoquinone sodium bisulfite, is prepared by adding a solution of sodium bisulfite to menadione.

Menadione sodium bisulfate occurs as a white, crystalline, odorless powder. One gram of it dissolves in about 2 mL of water, and it is slightly soluble in alcohol. It decomposes in the presence of alkali to liberate the free quinone.

Menadiol Sodium Diphosphate, USP. Menadiol sodium diphosphate, tetrasodium 2-methyl-1,4-naphthalenediol bis(dihydrogen phosphate), tetrasodium 2-methylnaphthohydroquinone diphosphate, vitamin K₄, is a white hygroscopic powder, very soluble in water, giving solutions with a pH of 7 to 9. It is available in ampuls for use subcutaneously, intramuscularly, or intravenously and in tablets for oral administration. Unlike the other vitamin K analogues, menadiol⁹⁹ oral absorption does not depend on the presence of bile. Once absorbed, it is converted to menadione.

Menadiol Sodium Diphosphate

Menadione hisulfite and menadiol diphosphate produce hemolytic symptoms (reticulocytosis, increase in Heinz bodies) in newborn, premature infants when given in excessive doses (more than 5 to 10 mg/kg). In severe cases, overt hemolytic anemia with hemoglobinuria may occur. The increased red cell breakdown may lead to hyperbilirubinemia and kernicterus.

These compounds may also interfere with bile pigment secretion. Newborns with a congenital defect of glucose-6-phosphate dehydrogenase can react with severe hemolysis, even to small doses of menadione derivatives. Small nonhemolyzing doses, however, can be used in the newborn, and a combination with vitamin E is not considered essential.¹²¹

WATER-SOLUBLE VITAMINS

Although the water-soluble vitamins are structurally diverse, they are put in a general class to distinguish them from the lipid-soluble vitamins. This class includes the B-complex vitamins and ascorbic acid (vitamin C). The term *B-complex vitamins* usually refers to thiamine, riboflavin, pyridoxine, nicotinic acid, pantothenic acid, biotin, cyanocobalamin, and folic acid. Dietary deficiencies of any of the B vitamins commonly are complicated by deficiencies of another member(s) of the group, so treatment with B-complex preparations is usually indicated.

Thiamine (Vitamin B₁)

Thiamine was the first water-soluble vitamin to be discovered (1926), but the complete determination of its structure and synthesis was not accomplished until 1936.

Many natural foods provide adequate amounts of this vitamin. The germ of cereals, brans, egg yolks, yeast extracts, peas, beans, and nuts usually provide enough thiamine to satisfy adult requirements. The requirement for thiamine is related directly to caloric intake, 0.2 to 0.3 mg/1,000 calories. It is not economically practical to isolate the crystalline vitamin from natural sources on a commercial scale, so commercially available thiamine is prepared synthetically.

Thiamine is synthesized biologically from the pyrimidine derivative 4-amino-5-hydroxymethyl-2-methyl pyrimidine methylpyrimidine and 5-(β -hydroxyethyl)-4-methylthiazole. These two precursors are converted to phosphate derivatives under kinase catalysis, which requires ATP. The respective phosphate derivatives then interact to form thiamine phosphate in a reaction catalyzed by thiamine phosphate pyrophosphorylase.

In higher mammalian organisms, thiamine is transformed to the coenzyme thiamine pyrophosphate by direct pyrophosphate transfer from ATP. This coenzyme performs important metabolic functions, for example, as cocarboxylase in the decarboxylation of α -keto acids (such as pyruvate to form acetyl-CoA) and in transketolases (such as use of pentoses in the hexose monophosphate shunt).

In the decarboxylation of pyruvate, the coenzyme interacts with pyruvic acid to form so-called active aldehyde, as shown below.

The active aldehyde intermediate then interacts with thioctic acid to form acetyl-thioctate, which is responsible for acetylating CoA-SH to form acetyl-CoA. In deficiency states, the oxidation of α -keto acids is decreased, resulting in increased pyruvate levels in the blood.

Thiamine hydrochloride is stable in acid but unstable in aqueous solutions with a pH above 5. Under these conditions, it undergoes decomposition and inactivation. Exposure of thiamine to the atmosphere or to oxidizing reagents such as hydrogen peroxide, permanganate, or alkaline potassium ferricyanide oxidizes it readily to thiochrome, shown below. Thiochrome exhibits a vivid blue fluorescence; hence, this reaction is the basis for the quantitative fluorometric assay of thiamine in the USP.

Oxythiamine and neopyrithiamine are antivitamin used in the study of the deficiency state. Oxythiamine is a competitive inhibitor of thiamine pyrophosphate. Neopyrithiamine inhibits the pyrophosphorylation of thiamine.

PRODUCTS

Thiamine Hydrochloride, USP. Thiamine hydrochloride, thiamine monohydrochloride, thiamine chloride, vitamin B₁ hydrochloride, vitamin B₁, aneurine hydrochloride, occurs as small white crystals or as a crystalline powder. It has a slight, characteristic yeast-like odor. The anhydrous product, when exposed to air, rapidly absorbs about 4% of water. One gram is soluble in 1 mL of water and in about 100 mL of alcohol. It is soluble in glycerin. An aqueous solution, 1:20, has a pH of 3. Aqueous solutions 1:100 have a pH of 2.7 to 3.4. Thiamine has pK_a values of 4.8 and 9.0. Thiamine hydrochloride is sensitive to alkali. The addition of 3 moles of sodium hydroxide per mole of thiamine hydrochloride gives the reaction shown on page 887.

Thiamine hydrochloride absorption is sodium dependent; thus, saturation limits absorption to 8 to 15 mg daily. Absorption is decreased in alcoholism and cirrhosis. Food affects the rate, but not the amount, absorbed. After absorption, thiamine hydrochloride is distributed to all tissues. There is limited storage of the vitamin in the body (about 30 mg). Normally, little or no thiamine is excreted in the urine. If doses exceed physiological needs after body stores are saturated, however, thiamine can be found in the urine as pyrimidine or as the unchanged compound.

Severe thiamine deficiency is called *beriberi*. The major organs affected are the nervous system (in dry beriberi), the cardiovascular system (in wet beriberi), and the gastrointestinal tract. Thiamine administration reverses the gastrointestinal and cardiovascular symptoms. The neurological damage may be permanent, however, if the deficiency has been severe or of long duration. Thiamine hydrochloride is indicated

PRODUCTS

Pantothenic Acid. Pantothenic acid, vitamin B₅, occurs as a viscous hygroscopic oil, freely soluble in water but unstable to heat, acid, and alkali. Because of this instability, the calcium salt is used commercially.

Pantothenic acid and its derivatives have essentially no pharmacological actions per se. Because of the ubiquitous nature of the vitamin, deficiency states usually do not develop. They have been produced by use of synthetic diets devoid of the vitamin or by use of a vitamin antagonist. ω -Methylpantothenic acid has produced fatigue, headache, paresthesia of the hands and feet, cardiovascular instability, and gastrointestinal problems.

Pantothenic acid and its derivatives are readily absorbed and widely distributed. The highest concentrations are found in the liver, adrenal glands, heart, and kidneys. Pantothenic acid apparently undergoes little if any metabolism; the amount eliminated approximates the amount consumed. About 70% of a dose is eliminated unchanged in the urine, and the remainder is eliminated in the feces.

The only official indication for pantothenic acid is in the prevention or treatment of vitamin B deficiencies. Because a deficiency of a single B vitamin is rare, it is commonly formulated in multivitamin preparations or B-complex preparations.

Calcium Pantothenate, USP. Calcium pantothenate, calcium D-pantothenate, is a slightly hygroscopic, white, odorless, bitter powder that is stable in air. It is insoluble in alcohol and soluble 1:3 in water; aqueous solutions have a pH of about 9 and $[\alpha]_D^{25} = +25$ to $+27.5^\circ$. Autoclaving calcium pantothenate at 120°C for 20 minutes may cause 10 to 30% decomposition. Some of the phosphates of pantothenic acid that occur naturally in coenzymes are quite stable to both acid and alkali, even on heating.^{1,2,3}

Racemic Calcium Pantothenate, USP. Racemic calcium pantothenate provides a more economical source of this vitamin. Other than containing not less than 45% of the dextrorotatory biologically active form, its properties are very similar to those of calcium pantothenate, USP.

Panthenol, USP. Panthenol, the racemic alcohol analogue of pantothenic acid, exhibits both qualitatively and quantitatively the vitamin activity of pantothenic acid. It is considerably more stable than pantothenic acid in solutions with pH values of 3 to 5 but of about equal stability at pH 6 to 8. It appears to be absorbed more readily from the gut, particularly in the presence of food.

Dexpanthenol, USP. Dexpanthenol occurs as a slightly hygroscopic, viscous oil freely soluble in water and alcohol. It is the dextrorotatory alcohol derivative of pantothenic acid and is converted readily in vivo to the acid form.

Dexpanthenol and the racemic mixture are used in the treatment of paralytic ileus and postoperative distention. Dexpanthenol in combination with choline is used to relieve gas retention.

Nicotinic Acid

Nicotinic acid (niacin) was prepared first by oxidation of the alkaloid nicotine, but not until 1913 was it isolated from yeast and recognized as an essential food factor (see the structures). In 1934–1935, nicotinamide was obtained from the hydrolysis of a coenzyme isolated from horse red blood cells. This coenzyme was later named *coenzyme II* and is now more commonly called *nicotinamide adenine dinucleotide phosphate* (NADP).

Generous sources of this vitamin include pork, lamb, and beef livers; hog kidneys; yeasts; pork; beef tongue; hearts; lean meats; wheat germ; peanut meal; and green peas. Nicotinic acid can be synthesized by almost all plants and animals. Tryptophan can be metabolized to a nicotinic acid nucleotide in animals, but the efficiency of this multistep process varies from species to species. Plants and many microorganisms synthesize this vitamin through alternative routes by use of aspartic acid.

In the human, nicotinic acid reacts with 5-phosphoribosyl-1-pyrophosphate to form nicotinic acid mononucleotide, which then reacts with ATP to produce desamido-NAD (the intermediate dinucleotide with the nicotinic acid moiety). Finally, the latter intermediate is converted to NAD (originally called *coenzyme I*) by transformation of the carboxyl of the nicotinic acid moiety to the amide by glutamine. This final step is catalyzed by NAD synthetase; NADP is produced from NAD by ATP under kinase catalysis.¹

$\text{R} = \text{H} =$ Nicotinamide adenine dinucleotide

$\text{R} = \text{PO}_3^{2-} =$ Nicotinamide adenine dinucleotide phosphate

NAD and NADP are oxidizing coenzymes for many (more than 200) dehydrogenases. Some dehydrogenases require

Ethanol oxidation is schematically illustrated below

Figure 26-1 ■ Generalized representation of the hydride transfer reaction.

NAD, others require NADP, and some function with either. The generalized representation in Figure 26-1 illustrates the function of these coenzymes in metabolic oxidations and reductions. The abbreviation $[\text{NAD}^+]$ emphasizes the electrophilicity of the pyridine C_4 moiety (which is the center of reactivity) and the substrate designated

could be a primary or secondary alcohol. *Arrow a* in Figure 26-1 symbolizes the function of NAD as oxidant in the hydride transfer from the substrate to the coenzyme, forming NADH, reduced coenzyme. The hydroxyl of the substrate is visualized as undergoing deprotonation concertedly by either water or the pyridine nitrogen of NADH. *Arrow b* shows concerted formation of the carbonyl π -bond of the oxidation product. *Arrow c* symbolizes the reverse hydride transfer from reduced coenzyme, NADH, to the carbonyl carbon; and concertedly, as the carbonyl oxygen undergoes protonation, the reduction of the carbonyl group forms the corresponding alcohol. Thus, NAD and NADP are hydride

acceptors, and NADH and NADPH are hydride donors. Although this is a simplistic representation, it shows the dynamism of the oxidation-reduction reactions effected by these coenzymes under appropriate dehydrogenase catalysis. Alternatively, the reduced coenzymes may be used in ATP production through the electron-transport system.

Ethanol Oxidation Is Schematically Illustrated Below

As noted above, nicotinic acid (also known as *niacin* to avoid confusion with nicotine) can be made available in nucleotide form from the amino acid tryptophan. It has been estimated that a dosage of 60 mg of tryptophan equals that of 1 mg of nicotinic acid. Consequently, humans and other mammals can synthesize the vitamin, provided there is appropriate dietary availability of tryptophan. (Thus, nicotinic

acid is not a true vitamin by the classic definition of the term.)

PRODUCTS

Niacin, USP. Niacin, nicotinic acid, 3-pyridine carboxylic acid, vitamin B₃, occurs as white crystals or as a crystalline powder. It is odorless or may have a slight odor. One gram of nicotinic acid dissolves in 60 mL of water. It is freely soluble in boiling water, boiling alcohol, and solutions of alkali hydroxides and carbonates but is almost insoluble in ether. A 1% aqueous solution has a pH of 6. Nicotinic acid has a pK_a of 4.85. Nicotinic acid is stable under normal storage conditions. It sublimates without decomposition.

Serious deficiency of niacin or tryptophan may lead to pellagra (from the Italian, *pelle agra*, for "rough skin"). The major systems affected are the gastrointestinal tract (diarrhea, enteritis, stomatitis), the skin (dermatitis), and the central nervous system (headache, dizziness, depression). Severe cases may result in delusions, hallucinations, and dementia. In the United States, pellagra has become rare because flour is supplemented with nicotinic acid. Chronic alcoholism is the chief cause of pellagra and is associated with multiple vitamin deficiency. The symptoms of pellagra are completely reversed by niacin; therefore, it is indicated for the treatment and prevention of the deficiency.

Adverse effects of niacin are most commonly seen when this vitamin is used at pharmacological doses above 1 g/day in the treatment of dyslipidemia. Notable adverse effects include flushing due to vasodilatation; dermatological effects including dry skin pruritus and hyperkeratosis; gastrointestinal effects including peptic ulcer, stomach pain, nausea, and diarrhea; elevations in serum uric acid and glucose; and hepatotoxicity.^{122, 124}

Niacin (but not niacinamide) is also indicated in hyperlipidemia to lower triglycerides and cholesterol. Triglycerides, VLDLs, and LDLs are reduced; HDLs are increased. The exact mechanism is not known. Because niacin at high doses has a direct vasodilatory effect believed to be mediated through the prostaglandins, the dose required (1 to 3 g 3 times daily) often limits the usefulness.

Niacin is absorbed readily from the gastrointestinal tract and distributed widely. At physiological doses, little niacin is excreted unchanged. Most is excreted as *N*-methylniacin or the glycine conjugate (nicotinuric acid). After administration of large doses, niacin can be found in the urine unchanged.

Niacinamide, USP. Niacinamide, nicotinamide, nicotinic acid amide, is prepared by the amidation of esters of nicotinic acid or by passing ammonia gas into nicotinic acid at 320°C. Nicotinamide is a white crystalline powder that is odorless, or nearly so, and bitter. One gram is soluble in about 1 mL of water, 1.5 mL of alcohol, and about 10 mL of glycerin. Aqueous solutions are neutral to litmus. For occurrence, action, and uses, see nicotinic acid. Niacinamide has pK_a values of 0.5 and 3.35.

Like niacin, niacinamide is indicated in the treatment and prevention of deficiency states. Unlike niacin, niacinamide has no vasodilatory effect, which may be of therapeutic importance for compliance reasons. Niacinamide has no effect on triglycerides and lipoproteins. This product is formulated with potassium iodide and used as an iodine supplement.

Niacinamide hydrochloride is also available. It is more stable in solution and more compatible with thiamine chloride in solution.

Riboflavin (Vitamin B₂)

Although crystalline riboflavin was not isolated until 1932, interest in this compound as a pigment dates back to 1881 in connection with the color in the whey of milk. In 1932, riboflavin was isolated as a coenzyme-enzyme complex from yeast by Warburg and Christian and was designated *yellow oxidation ferment*.

Riboflavin is synthesized by all green plants and by most bacteria and fungi. Although yeast is the richest source, eggs, dairy products, legumes, and meats are the major sources in the diet. The precursor is a guanosine phosphate derivative, but the exact synthetic steps leading to the vitamin are not understood completely.

In higher mammals, riboflavin is absorbed readily from the intestines and distributed to all tissues. It is the precursor in the biosynthesis of the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). The metabolic functions of this vitamin involve these two coenzymes, which participate in numerous vital oxidation-reduction processes. FMN (riboflavin 5'-phosphate) is produced from the vitamin and ATP by flavokinase catalysis. This step can be inhibited by phenothiazines and the tricyclic antidepressants. FAD originates from an FMN and ATP reaction that involves reversible dinucleotide formation catalyzed by flavin nucleotide pyrophosphorylase. These coenzymes function in combination with several enzymes as coenzyme-enzyme complexes, often characterized as *flavoproteins*.

These flavoproteins function in aerobic or anaerobic conditions as oxidases and dehydrogenases. Examples include glucose oxidase, xanthine oxidase, cytochrome reductase, and acyl-CoA dehydrogenase. The riboflavin moiety of the complex is considered a hydrogen-transporting agent (carrier) functioning as a hydrogen acceptor; the hydrogen donors may be NADH, NADPH, or some suitable substrate. The isoalloxazine rings accept two hydrides stepwise to form the dihydriboflavin derivative.

PRODUCTS

Riboflavin, USP. Riboflavin, lactoflavin, vitamin B₂, vitamin G, is a yellow to orange-yellow, crystalline powder with a slight odor. It is soluble in water 1:3,000 to 1:20,000 mL, with the variation in solubility being due to differences in internal crystalline structure, but it is more soluble in an isotonic solution of sodium chloride. A saturated aqueous solution has a pH of 6. Riboflavin has a pK_a of 10.5. It is less soluble in alcohol and insoluble in ether or chloroform. Benzyl alcohol (3%), gentisic acid (3%), urea in varying amounts, and niacinamide are used to solubilize riboflavin when relatively high concentrations of it are needed for parenteral solutions. Gentisic ethanol amide and sodium 3-hydroxy-2-naphthoate also solubilize riboflavin effectively.

When dry, riboflavin is not affected appreciably by diffused light; it deteriorates, however, in solution in the presence of light. This deterioration is very rapid in the presence of alkalis, producing lumiflavin. This deterioration may be retarded by buffering on the acid side, but under acid conditions, light can produce lumichrome. Neither of these decomposition products possesses biological activity.

The vitamin is commercially available as riboflavin, riboflavin 5-phosphate, and riboflavin 5-phosphate sodium. The phosphate esters are used commercially only in multivitamin preparations, and they are hydrolyzed before absorption occurs. Absorption occurs through an active transport system in which riboflavin is phosphorylated by the intestinal mucosa during absorption. Food and bile enhance absorption. Riboflavin is distributed widely in the body, with limited stores in the liver, spleen, heart, and kidneys. Conversion to FAD occurs primarily in the liver. FMN and FAD circulate primarily protein bound. Only small amounts (~9%) are excreted in the urine unchanged. Larger amounts can be found after administration of large doses.

Severe riboflavin deficiency is known as *ariboflavinosis*. Its major symptoms include cheilosis, seborrheic dermatitis, and vascularization of the cornea. Ariboflavinosis occurs in chronic alcoholism in combination with other vitamin deficiencies. It has also resulted from phenothiazine, tricyclic antidepressant, and probenecid therapy. Riboflavin has no pharmacological action and is relatively nontoxic. The only approved indication is in the treatment and prevention of ariboflavinosis.

Pyridoxine

In 1935, the term *vitamin B₆* was applied to the principle that cured dermatitis in rats fed a vitamin-free diet supplemented with thiamine and riboflavin. Three years later, vitamin B₆ was isolated from rice paste and yeast. In 1935, P. Gyorgy showed that rat pellagra was not the same as human pellagra but that it resembled a particular disease of infancy known as "pink disease" or acrodynia. This rat acrodynia is characterized by a symmetric dermatosis affecting first the paws and the tips of the ears and the nose. These areas become swollen, red, and edematous, with ulcers developing frequently around the snout and on the tongue. Thickening and scaling of the ears are noted, and there is weight loss; fatalities occur 1 to 3 weeks after the appearance of the symptoms. Gyorgy was able to cure these conditions with a supplement obtained from yeast, which he called *vitamin B₆*. In 1938, this factor was isolated from rice paste and yeast in a crystalline form in a number of laboratories. A single dose of about 100 μ g produced healing in 14 days in a rat with severe vitamin B₆-deficiency symptoms.

Chemical tests, electrometric titration determinations, and absorption spectrum studies gave clues to its composition. These were substantiated by the synthesis of vitamin B₆ (1938 and 1939). Two additional chemical forms, pyridoxal (an aldehyde) and pyridoxamine (a primary amine), have been isolated from natural sources. These three compounds are interrelated metabolically and functionally. The interconversion between the different forms is shown below.

Gyorgy proposed the term *pyridoxine* for the original compound isolated. Soon it became synonymous with *vitamin B₆*. In 1960, IUPAC recommended using the term *pyri-*

doxine as a generic descriptor for all forms of the vitamin and *pyridoxol* as the trivial name for the alcohol form of the vitamin. In 1973, IUPAC revised its recommendations. Presently, the term *vitamin B₆* is the approved descriptor for all forms of the vitamin, and the term *pyridoxine* refers to the alcohol form. The term *pyridoxol* is no longer recommended. IUPAC further recommends that the phosphate esters be called *pyridoxine 5'-phosphate*, *pyridoxal 5'-phosphate*, and *pyridoxamine 5'-phosphate*. These may be abbreviated to *pyridoxine 5'-P*, *pyridoxine-P*, etc. when no ambiguity arises.

Pyridoxine is available from whole-grain cereals, peanuts, corn, meat, poultry, and fish. Up to 40% of the vitamin may be destroyed, however, during cooking. Food sources contain all three forms, either in their free form or phosphorylated. Plants contain primarily pyridoxol and pyridoxamine, while animal sources provide chiefly pyridoxal. Many plants also contain a glycoside of pyridoxol, which is included in vitamin content determinations. Although this conjugate is absorbed, it is not used well.⁵ This may explain the lower bioavailability of the vitamin from plant sources than from animal sources.

Vitamin B₆ is absorbed via passive diffusion, chiefly in the jejunum, and transported to the liver. The liver is a major organ of storage (16 to 27 mg), metabolism, and interconversion between the three forms. Excess B₆ is oxidized to 4-pyridoxic acid. This acid is the primary form found in the urine, accounting for up to 60% of ingested vitamin B₆.

In the liver, all three forms are converted to pyridoxal 5-phosphate, which circulates in the blood bound to albumin.

Before entry into cells, the phosphate must be dephosphorylated. Inside the cells, pyridoxal kinase rephosphorylates the vitamin. This kinase is found in many cell types, although other enzymes involved in the interconversions are not expressed in all cells.¹²⁵ Although large amounts of the vitamin are found in the liver, the muscles contain higher amounts in the form of glycogen phosphorylase.¹²⁶ This vitamin B₆ is not readily available, however, during deficiency states.¹²⁷

Pyridoxal 5-phosphate is a coenzyme^{128, 129} that performs many vital functions in human metabolism. It functions in the transaminations and decarboxylations that amino acids generally undergo. For example, it functions as a cotransaminase in the transamination of alanine to form pyruvic acid and as a codecarboxylase in the decarboxylation of dopa to form dopamine. Other biological transformations^{123, 128} of amino acids in which pyridoxal can function are racemization, elimination of the α-hydrogen together with a β-substituent (i.e., OH or SH) or a γ-substituent, and probably the reversible cleavage of β-hydroxyamino acids to glycine and carbonyl compounds.

An electromeric displacement of electrons from bonds *a*, *b*, or *c* (see diagram below) would result in the release of a cation (H, R', or COOH) and, subsequently, lead to the variety of reactions observed with pyridoxal. The extent to which one of these displacements predominates over others depends on the structure of the amino acid and the environment (pH, solvent, catalysts, enzymes, and such). When this mechanism applies in vivo, the pyridoxal component is linked to the enzyme through the phosphate of the hydroxymethyl group.

Metals such as iron and aluminum, which markedly catalyze nonenzymatic transaminations in vitro, probably do so by promoting formation of the Schiff base and maintaining planarity of the conjugated system through chelate ring formation, which requires the presence of the phenolic group. This chelated metal ion also provides an additional electron-

heterocyclic nitrogen atom (or nitro group), thereby increasing the electron displacements from the α -carbon atom as shown above.

Certain hydrazine derivatives, when administered therapeutically (e.g., isoniazid), can induce a deficiency of the coenzyme (pyridoxal 5-phosphate) by inactivation through the mechanism of hydrazone formation with the aldehyde functional group. Another hydrazine derivative, hydralazine, when administered in high doses to control hypertension, can cause similar B_6 deficiency, conceivably through a similar mechanism involving hydrazone formation.

Hypochromic anemias caused by familiar-type pyridoxine dependency respond to pyridoxine therapy. Similarly, this vitamin has been useful in the treatment of hypochromic or megaloblastic anemias that are not due to iron deficiency and do not respond to other hematopoietic agents.²

A review by Rose¹³⁰ summarizes studies on the effects of certain hormones on vitamin B_6 nutrition in humans, on the biochemical interrelationship between steroid hormones and pyridoxal phosphate-dependent enzymes, and on the role of vitamin B_6 in regulating hypothalamus–pituitary functions. Some of these studies have important clinical implications. The use of estrogen-containing oral contraceptives has been investigated as a factor leading to an abnormality of tryptophan metabolism. This abnormality resembles dietary vitamin B_6 deficiency and responds favorably to treatment with the vitamin. For some time, there has been clinical interest in the relationship between certain hormones and vitamin B_6 function because abnormal urinary excretion of tryptophan metabolites was observed during pregnancy and in patients with hyperthyroidism.

Estrogens and tryptophan metabolism have been studied because estrogen administration occasionally leads to the excretion of abnormally large amounts of xanthurenic acid, a metabolic product of tryptophan. This metabolic malfunction

has been related to the inhibitory effect of estrogen sulfate conjugates on another pathway of tryptophan metabolism—the transamination of kynurenine from tryptophan. Consequently, xanthurenic acid formation appears to be abnormally high because of this estrogen effect or B_6 deficiency.

In vitro studies have been conducted to determine the effect of estrogens on kynurenine aminotransferase, which catalyzes the B_6 -dependent transamination of kynurenine to kynurenic acid. Some estrogen conjugates (e.g., estradiol disulfate and diethylstilbestrol sulfate) interfere with this transamination, apparently by reversible inhibition of the aminotransferase apoenzyme. Apparently, the estrogen sulfate competes with pyridoxal 5-phosphate for interaction with the apoenzyme. In contrast, free estradiol and estrone do not possess this inhibitory property.

Some women suffer from mental depression when taking estrogen-containing oral contraceptives, and this depression could be due to another malfunction in tryptophan metabolism, leading to 5-hydroxytryptamine (serotonin). Some evidence indicates that the decarboxylation of 5-hydroxytryptophan is inhibited (in vitro) by estrogen conjugates competing with pyridoxal phosphate for the decarboxylase apoenzyme.

Other endocrine systems are interrelated. Both corticosteroids and thyroid hormones may increase the requirement for pyridoxine and affect pyridoxal 5-phosphate-dependent metabolic processes. Moreover, there appear to be associations between vitamin B_6 and anterior pituitary hormones that seem to involve the hypothalamus, 5-hydroxytryptamine, and dopamine. The latter two neurotransmitters are synthesized by metabolic processes that require pyridoxal 5-phosphate.

Interestingly, studies have shown that vitamin B_6 , in turn, influences the function of steroid hormones.²⁵ Pyridoxal 5-phosphate binds to lysine residues on the steroid receptors.

doxine as a generic descriptor for all forms of the vitamin and *pyridoxol* as the trivial name for the alcohol form of the vitamin. In 1973, IUPAC revised its recommendations. Presently, the term *vitamin B₆* is the approved descriptor for all forms of the vitamin, and the term *pyridoxine* refers to the alcohol form. The term *pyridoxol* is no longer recommended. Other endocrine systems are interrelated. Both corticosteroids and thyroid hormones may increase the requirement for pyridoxine and affect pyridoxal 5-phosphate-dependent metabolic processes. Moreover, there appear to be associations between vitamin B_6 and anterior pituitary hormones that seem to involve the hypothalamus. 5-Hydroxytryptamine, and dopamine. The latter two neurotransmitters are synthesized by metabolic processes that require pyridoxal 5-phosphate.

Interestingly, studies have shown that vitamin B_6 , in turn, influences the function of steroid hormones.²⁵ Pyridoxal 5-phosphate binds to lysine residues on the steroid receptors.

It has been proposed that the lysine residues are found at the site where the steroid binds to the receptor and where the receptor binds DNA.¹²⁵ Thus, pyridoxal 5-phosphate decreases the number of receptors able to bind with the steroids and the number of steroid-receptor complexes binding to DNA. The overall result is decreased expression of DNA.

PRODUCTS

Pyridoxine Hydrochloride, USP. Pyridoxine hydrochloride, 5-hydroxy-6-methyl-3,4-pyridinedimethanol hydrochloride, vitamin B₆ hydrochloride, rat antidermatitis factor, is a white, odorless, crystalline substance that is soluble 1:5 in water and 1:100 in alcohol and insoluble in ether. It is relatively stable to light and air in the solid form and in acid solutions at a pH no greater than 5, at which pH it can be autoclaved at 15 pounds at 120°C for 20 to 30 minutes. Pyridoxine is unstable when irradiated in aqueous solutions at pH 6.8 or above. It is oxidized readily by hydrogen peroxide and other oxidizing agents. Pyridoxine is as stable in mixed vitamin preparations as riboflavin and nicotinic acid. A 1% aqueous solution has a pH of 3. The pK_{a1} values for pyridoxine, pyridoxal, and pyridoxamine are 5.00, 4.22, and 3.40, respectively, and their pK_{a2} values are 8.96, 8.68, and 8.05, respectively.

Pyridoxine deficiencies have been studied by the use of antivitamin such as 4-desoxypyridoxal. As with the other B vitamins, dietary deficiencies are rare and are associated mainly with alcoholism. The symptoms involve the skin, nervous system, and erythropoiesis.

Because of inadequate diets, some infants suffer from severe vitamin B₆ deficiencies that can lead to epilepsy-like convulsive seizures, and the convulsions can be controlled by treatment with pyridoxine.¹ The convulsions are believed to be due to below-normal availability of the central nervous

system neurohormone γ -aminobutyric acid (GABA), from glutamic acid decarboxylation, which is effected by the coenzyme pyridoxal 5-phosphate.

Pyridoxine hydrochloride is indicated in the treatment and prevention of vitamin deficiency. It is also approved for concurrent administration with isoniazid and cycloserine to decrease their toxicity. Concurrent administration of pyridoxine hydrochloride and levodopa is not recommended. The decarboxylation of levodopa to dopamine in the periphery is increased by pyridoxine, so that less levodopa reaches the central nervous system.

Peripheral neuropathy can occur following ingestion of high doses of pyridoxine. Doses of 2 g/day can produce paresthesia and alter proprioception.¹³¹ Some studies suggest the dose required may be as low as 50 to 500 mg/day. Symptoms may actually increase for several weeks after discontinuing pyridoxine, a phenomenon called *coasting*.¹³²

Cobalamins

Vitamin B₁₂, cyanocobalamin, occurs in nature as a cofactor that originally was isolated as cyanocobalamin and vitamin B_{12b} (hydroxocobalamin). In April 1948, Rickes et al.¹³³⁻¹³⁵ isolated from clinically active liver fractions, minute amounts of a red crystalline compound that was also highly effective in promoting the growth of *Lactobacillus lactis*. This compound was called vitamin B₁₂, and in single doses as small as 3 to 6 μ g, it produced positive hematological activity in patients with addisonian pernicious anemia. Evidence indicates that its activity is comparable with that of Castle's extrinsic factor and that it can be stored in the liver.

Vitamin B₁₂ is found in commercial fermentation processes of antibiotics, such as those of *Streptomyces griseus*, *S. olivaceus*, *S. aureofaciens*, sewage, millorganite, and others. Some of these fermentations furnish a commercial source of vitamin B₁₂. Excellent dietary sources are meats, eggs, seafood, dairy, and fermented products. De novo synthesis of vitamin B₁₂, however, is restricted to microorganisms. Animals depend on intestinal flora synthesis or, as in humans, consumption of products from animal that have already obtained vitamin B₁₂. The only dietary plant prod-

ucts containing the vitamin are legumes, because of their symbiosis with microorganisms.

Because dietary vitamin B₁₂ is protein bound, the first step in absorption is its release in the stomach. Release is enhanced by gastric pH and pancreatic proteases. The freed vitamin is bound immediately to a glycoprotein, the *intrinsic factor*, secreted by parietal cells of the gastric mucosa. The vitamin B₁₂–intrinsic factor complex is carried to the intestines, where it binds with receptors in the ileum. Absorption is mainly by an active process, which can be saturated by 1.5 to 3 μ g of vitamin B₁₂. Excess amounts may be absorbed passively.

In the intestinal cells, the complex is broken and vitamin B₁₂ is absorbed into the blood, where it binds to transcobalamin II, a β -globulin, for distribution. In the liver, the vitamin is converted to the active form and stored as such. Up to 90% of the vitamin (5 to 11 mg) is stored in the liver. Vitamin B₁₂ is excreted through the bile and undergoes extensive reabsorption.

In the biosynthesis of the coenzymes^{1,36} derived from vitamin B₁₂, cobalt is reduced from a trivalent to a monovalent state before the organic anionic ligands are attached to the structure. The two types of cobamide that participate as coenzymes in human metabolism are the adenosylcobamides and the methylcobamides. These coenzymes perform vital functions in methylmalonate–succinate isomerization and in methylation of homocysteine to methionine.

Methylcobalamin is the major form of the coenzyme in the plasma, and 5-deoxyadenosylcobalamin is the major form in the liver and other tissues. The enzyme system methylmalonyl-CoA mutase requires 5'-deoxyadenosylcobamide; this enzyme system catalyzes the methylmalonyl-CoA transformation to succinyl-CoA, which is the major pathway of propionyl-CoA metabolism. Propionyl-CoA from lipid metabolism must be processed through this pathway by succinyl-CoA to enter the Krebs citric acid cycle to be either converted to γ -oxaloacetate, leading to gluconeogenesis, or oxidized aerobically to CO₂, with production of ATP. The methylation of homocysteine to form methionine requires methylcobalamin and is catalyzed by a transmethylation that also requires 5-methyltetrahydrofolic acid and reduced FAD.¹³⁶

A deficiency of vitamin B₁₂ leads to anemia. Pernicious anemia is due to a lack of the intrinsic factor. The symptoms involve systems that have rapidly dividing cells and the nervous system. Herbert and Das¹³⁶ reviewed the biochemical roles of vitamin B₁₂ and folic acid in hematopoiesis and other cellular development. They emphasize that vitamin B₁₂ and folic acid are essential for normal growth and proliferation of all human cells. Vitamin B₁₂ also functions to maintain myelin throughout the nervous system. Deficiency of either vitamin leads to megaloblastic anemia involving below-normal DNA synthesis. Interference with DNA synthesis results in the inability of cells to mature properly. These symptoms are readily reversed by vitamin B₁₂ supplementation; the nerve damage, however, is irreversible. It has been postulated that the myelin damage results from low levels of S-adenosylmethionine caused by a methionine synthetase deficiency.¹³⁷ Most vitamin B₁₂ deficiencies are due to malabsorption (lack of intrinsic factor, alcoholism) or increased need (pregnancy). It has been postulated that vitamin B₁₂ deficiency is largely a conditioned folic acid deficiency

caused by below-normal transformation of 5-methyltetrahydrofolic acid to tetrahydrofolic acid (THFA) by the B₁₂-dependent homocysteine methyl transferase reaction and defective cellular uptake of 5-methyl-THFA in vitamin B₁₂ deficiency. This so-called methyl-THFA trap hypothesis seems to rationalize a mechanism for the pathogenesis of megaloblastic anemia in vitamin B₁₂ deficiency, and investigations continue to provide evidence that supports this rationalization.

High doses of vitamin B₁₂ are not associated with toxicity. Rare anaphylactic reactions and mild diarrhea have occurred, although vitamin B₁₂ therapy has involved adverse events that result more from problems with resolution of the disease being treated (usually megaloblastic anemia) than from the high doses of B₁₂ used. For example, after B₁₂ therapy for megaloblastic anemia, serious hypokalemia has resulted from increased potassium requirements for erythropoiesis.¹³⁸

PRODUCTS

Cyanocobalamin, USP. Cyanocobalamin, vitamin B₁₂, is a cobalt-containing substance usually produced by the growth of suitable organisms or obtained from liver. It occurs as dark red crystals or an amorphous or crystalline powder. The anhydrous form is very hygroscopic and may absorb about 12% water. One gram is soluble in about 80 mL of water. It is soluble in alcohol but insoluble in chloroform and in ether.

Vitamin B₁₂ loses about 1.5% of its activity per day when stored at room temperature in the presence of ascorbic acid; vitamin B_{12b} (hydroxocobalamin) is very unstable (completely inactivated in 1 day). This loss in activity is accompanied by release of cobalt and a loss of color. The greater stability of vitamin B₁₂ is attributed to the increased strength of the bond between cobalt and the benzimidazole nitrogen by cyanide. Unusual resonance energy is imputed to the cobalt–cyanide complex, giving a positive charge to the cobalt atom and, thereby, strengthening the Co–N bond. The protective action of certain liver extracts of vitamin B_{12b} toward ascorbic acid and its sodium salt is, no doubt, due to the presence of copper and iron. Iron salts protect vitamin B_{12b} in 0.001% concentration. Catalysis of the oxidative destruction of ascorbate by iron is well known. On exposure to air, liver extracts containing B₁₂ lose most of the B₁₂ activity in 3 months. The most favorable pH for a mixture of cyanocobalamin and ascorbic acid appears to be 6 to 7. Niacinamide can stabilize aqueous parenteral solutions of cyanocobalamin and folic acid at a pH of 6 to 6.5; it is, however, unstable in B-complex solution. Cyanocobalamin is stable in solutions of sorbitol and glycerin but not in dextrose or sucrose.

Aqueous solutions of vitamin B₁₂ are stable to autoclaving for 15 minutes at 121°C. It is almost completely inactivated in 95 hours by 0.015 N sodium hydroxide or 0.01 N hydrochloric acid. Cyanocobalamin is most stable at pH 4.5 to 5.0 and is stable in a wide variety of solvents.

Hydroxocobalamin, USP. Hydroxocobalamin, cobinamide dihydroxide, dihydrogen phosphate (ester) mono(inner salt), 3'-ester with 5,6-dimethyl-1- α -D-ribofuranosylbenzimidazole, vitamin B_{12b}, is cyanocobalamin in which the CN group is replaced by an OH group. It occurs as dark

red crystals or a red crystalline powder that is sparingly soluble in water or alcohol and practically insoluble in the usual organic solvents. Under the usual conditions, in the absence of cyanide ions, only the hydroxo form of cobalamin is isolated from natural sources. It has good depot properties but is less stable than cyanocobalamin.

Cyanocobalamin Radioactive Cobalt (^{57}Co) Capsules, USP. Cyanocobalamin ^{57}Co capsules contain cyanocobalamin in which some of the molecules contain radioactive cobalt (^{57}Co). Each microgram of this cyanocobalamin preparation has a specific activity of not less than 0.02 MBq (0.5 μCi). The USP cautions that in making dosage calculations one should correct for radioactive decay. The radioactive half-life of ^{57}Co is 270 days.

Cyanocobalamin ^{57}Co Solution, USP. Cyanocobalamin ^{57}Co solution has the same potency, dosage, and use as described under Cyanocobalamin Radioactive Cobalt (^{57}Co) Capsules, USP. It is a clear, colorless to pink solution that has a pH range of 4.0 to 5.5.

Cyanocobalamin Radioactive Cobalt (^{60}Co) Capsules, USP. Cyanocobalamin ^{60}Co capsules are the counterpart of cyanocobalamin ^{57}Co capsules in potency, dosage, and use. They differ only in radioactive half-life, which is 5.27 years.

Cyanocobalamin Radioactive Cobalt (^{60}Co) Solution, USP. Cyanocobalamin ^{60}Co solution has the same potency, dosage, and use as cyanocobalamin ^{60}Co capsules. It is a clear, colorless to pink solution with a pH range of 4.0 to 5.5.

These four preparations must be labeled "Caution—Radioactive Material" and "Do not use after 6 months from date of standardization."

Cobalamin Concentrate, USP. Cobalamin concentrate, derived from cultures of *Streptomyces* spp. or of other cobalamin-producing microorganisms, contains 500 μg of cobalamin per gram of concentrate. A cyanocobalamin–zinc tannate complex can be used as a repository form for the slow release of cyanocobalamin when it is administered by injection.

Commercial products containing liver extract for oral and parenteral use are available. Liver extract is assayed to con-

tain 10 to 20 μg of cyanocobalamin activity per mL. Crude liver extract contains 2 μg of activity per mL.

Vitamin B₁₂ with intrinsic factor is a mixture whose potency is expressed in terms of oral units of hematopoietic activity. One unit has no more than 15 μg of cyanocobalamin activity. The intrinsic factor is obtained from dried hog stomach, pylorus, or duodenum. One unit contains not more than 300 mg of dried product.

Folic Acid

In the early 1940s, R. J. Williams et al.^{139, 140} used the term *folic acid* in referring to a vitamin occurring in leaves and foliage of spinach, from the Latin for leaf (*folium*). Previously, it was called *vitamin M* and *vitamin B₉*. Since then, folic acid has been found in whey, mushrooms, liver, yeast, bone marrow, soybeans, and fish meal, all of which are excellent dietary sources. The structure (see diagram) has been proved by synthesis in many laboratories (e.g., see Waller et al.^{141, 142}).

Folic acid is a pteridine derivative (rings A and B constitute the pteridine heterocyclic system) synthesized by bacteria from GTP, *p*-aminobenzoic acid, and glutamic acid. Accordingly, the structure of folic acid is composed of three moieties: the pteridine moiety derived from GTP, the *p*-aminobenzoic acid moiety, and the glutamic acid moiety. (Antibacterial sulfonamides [see Chapter 8] compete with *p*-aminobenzoic acid and, thereby, interfere with bacterial folic acid synthesis.) Humans cannot synthesize folic acid.

In the human, dietary folic acid must be reduced metabolically to THFA to exert its vital biochemical actions. This reaction, which proceeds through the intermediate dihydrofolic acid, is catalyzed by a reductase. This reductase enzyme system has been implicated as the catalyst in both reaction steps—folic acid reduction and dihydrofolic acid reduction. The coenzyme THFA is converted to other cofactors by formulation of the N-10 and/or N-5 nitrogen.

These coenzymes derived from folic acid participate in many important reactions, including conversion of homocysteine to methionine, synthesis of glycine from serine, purine synthesis (C-2 and C-8), and histidine metabolism.

N ⁵ — CH ₃	N ⁵ -Methyltetrahydrofolic acid
N ⁵ — CHO	N ⁵ -Formyltetrahydrofolic acid (folinic acid)
N ¹⁰ — CHO	N ¹⁰ -Formyltetrahydrofolic acid
N ⁵⁻¹⁰ = CH —	N ⁵⁻¹⁰ -Methenyltetrahydrofolic acid
N ⁵⁻¹⁰ — CH ₂ —	N ⁵⁻¹⁰ -Methylenetetrahydrofolic acid
N ⁵ — CH=NH	N ⁵ -Formiminotetrahydrofolic acid
N ⁵ — CH ₂ —OH	N ⁵ -Hydroxytetrahydrofolic acid

The most critical “one-carbon” transfer involved in DNA synthesis requires N⁵,N¹⁰-methylene-THFA as the methylating coenzyme responsible for converting uridylic acid to thymidylic acid. Interestingly, some folic acid antagonists useful in cancer chemotherapy (e.g., methotrexate [see Chapter 12]) interfere with DNA synthesis by inhibiting this methylation step.¹⁴³

There is a fundamental relationship between folic acid metabolism and vitamin B₁₂. The reduction of methylene-THFA to 5-methyl-THFA is essentially irreversible; hence, there is only one pathway for the regeneration of THFA from 5-methyl-THFA. THFA is regenerated by the B₁₂-dependent methyl group transfer from 5-methyl-THFA to homocysteine. This biochemical interrelationship has been implicated in the etiology of megaloblastic anemia (see corresponding discussion under vitamin B₁₂).¹³⁶

PRODUCTS

Folic Acid, USP. Folic acid, N-[[[(2-amino-4-hydroxy-6-pteridiny)methyl]amino]benzoyl]glutamic acid, pteroylglutamic acid (Folacine, Folvite), occurs as a yellow or yellowish-orange powder that is only slightly soluble in water (1 mg/100 mL). It is insoluble in the common organic solvents. The sodium salt is soluble (1:66) in water. Aqueous solutions of folic acid or its sodium salt are stable to oxygen of the air, even on prolonged standing. These solutions can be sterilized by autoclaving at a pressure of 15 pounds in the usual manner. Folic acid in the dry state and in very dilute solutions is decomposed readily by sunlight or UV light. Although folic acid is unstable in acid solutions, particularly below a pH of 6, the presence of liver extracts has a stabilizing effect at lower pH levels than are otherwise possible. Iron salts do not materially affect the stability of folic acid solutions. The water-soluble vitamins that have a deleterious effect on folic acid are (in descending order of effectiveness) as follows: riboflavin, thiamine hydrochloride, ascorbic acid, niacinamide, pantothenic acid, and pyridox-

ine. This deleterious effect may be largely overcome by inclusion of approximately 70% sugar in the mixture.

Folic acid in foods is destroyed more readily by cooking than are the other water-soluble vitamins. These losses range from 46% in halibut to 95% in pork chops and from 69% in cauliflower to 97% in carrots.

Folic acid occurs in the diet as pteroylpolylglutamates that must be hydrolyzed to the monoglutamates before absorption. The hydrolysis is catalyzed by pteroyl-γ-glutamyl carboxypeptidase, found in the membrane of the intestinal mucosa. The monoglutamates are absorbed actively in the jejunum and upper duodenum. This absorption is pH sensitive and is facilitated by the slightly acidic conditions found in these regions. The vitamin is transported as monoglutamates bound to albumin.

Although the mucosa in these regions possesses dihydrofolate reductase, most reduction and methylation occur in the liver. THFA is distributed to all tissues, where it is stored as polyglutamates. The N⁵-methyl derivative is the main transport and storage form in the body. The body stores 5 to 10 mg, approximately 50% in the liver. The major elimination pathway for the vitamin is biliary excretion as the N⁵-methyl derivative. Extensive reabsorption occurs. Only trace amounts are found in the urine. Large doses that exceed the tubular reabsorption limit, however, result in substantial amounts in the urine.

As with vitamin B₁₂, folic acid deficiencies mainly result from malabsorption or alcoholism. No neurological abnormalities are associated with folic acid deficiency. The resulting megaloblastic anemia is indistinguishable from that caused by vitamin B₁₂ because both vitamins are involved in the critical biochemical step. Folic acid can correct the anemia caused by vitamin B₁₂ deficiency, but it has no effect on the neurological damage. Thus, only small amounts are found in over-the-counter preparations.

Folic acid administered to healthy adults in a daily dose of 15 mg for 1 month resulted in gastrointestinal disturbances (including anorexia, nausea and pain) and central nervous system effects (including sleep disturbances, vivid dreams, malaise, irritability and increased excitability).¹⁴⁴

Leucovorin Calcium, USP. Leucovorin calcium, N[[4-[[[(2-amino-5-formyl-1,4,5,6,7,8-hexahydro-4-oxo-6-pteridiny)methyl]amino]benzoyl]-L-glutamic acid, calcium salt, calcium 5-formyl-5,6,7,8-tetrahydrofolate, calcium folinate, occurs as a yellowish-white or yellow, odorless, microcrystalline powder that is insoluble in alcohol and very soluble in water.

This product is used in chemotherapy concurrently with dihydrofolate reductase inhibitors to prevent damage to normal cells. It is not indicated for use in folic acid deficiencies.

Ascorbic Acid

The historical significance of vitamin C was summarized eloquently by the eminent medicinal chemist and pharmacist Professor Ole Gisvold, and the following direct quotation from the 7th edition of this textbook is an appropriate introduction to the significance of ascorbic acid in medicinal chemistry and basic biochemistry:

The disease scurvy, which now is known as a condition due to a deficiency of ascorbic acid in the diet, has considerable historical significance.¹⁴⁵ For example, in the war between Sweden and Russia (most likely the march of Charles XII into the Ukraine in the winter of 1708–1709) almost all of the soldiers of the Swedish army became incapacitated by scurvy. But further progress of the disease was stopped by a tea prepared from pine needles. The Iroquois Indians cured Jacques Cartier's men in the winter of 1535–1536 in Quebec by giving them a tea brewed from an evergreen tree. Many of Champlain's men died of scurvy when they wintered near the same place in 1608–1609. During the long siege of Leningrad, lack of vitamin C made itself particularly felt, and a decoction made from pine needles played an important role in the prevention of scurvy. It is somewhat common knowledge that sailors on long voyages at sea were subject to the ravages of scurvy. The British used supplies of limes to prevent this, and the sailors often were referred to as "limeys."

Holst and Frolich,¹⁴⁶ in 1907, first demonstrated that scurvy could be produced in guinea pigs. A comparable condition cannot be produced in rats.

Although Waugh and King^{147–152} (1932) isolated crystalline vitamin C from lemon juice and showed it to be the antiscorbutic factor of lemon juice, Szent-Gyorgyi¹⁵³ had isolated the same substance from peppers in 1928, in connection with his biological oxidation–reduction studies. At the time, he failed to recognize its vitamin properties and reported it as a hexuronic acid because some of its properties resembled those of sugar acids. Hirst et al.¹⁵⁴ suggested that the correct formula should be one of a series of possible tautomeric isomers and offered basic proof that the formula now generally accepted is correct. The first synthesis of L-ascorbic acid (vitamin C) was announced almost simultaneously by Haworth et al.¹⁵⁵ and Reichstein¹⁵⁶ in 1933. Since that time, ascorbic acid has been synthesized in a number of different ways.

This vitamin is now better known as ascorbic acid because of its acidic character and its effectiveness in the treatment and prevention of scurvy. The acidic character is due to the two enolic hydroxyls; the C-3 hydroxyl has a pK_a value of

4.1, and the C-2 hydroxyl has a pK_a of 11.6. The monobasic sodium salt is the usual salt form (e.g., Sodium Ascorbate, USP).

Ascorbic acid can be synthesized by nearly all living organisms, plants, and animals; but primates, guinea pigs, bats, and some other species cannot produce this vitamin. The consensus is that organisms that cannot synthesize ascorbic acid lack the liver microsomal enzyme L-gulonolactone oxidase, which catalyzes the terminal step of the biosynthetic process. Sato and Udenfriend¹⁵⁷ summarized studies of the biosynthesis of ascorbic acid in mammals and the biochemical and genetic basis for the incapability of some species to synthesize the vitamin. Because humans are one of the few animal species that cannot synthesize ascorbic acid, the vitamin has to be available as a dietary component.

Ascorbic acid performs important metabolic functions, as evidenced by the severe manifestations of its deficiency in humans. This vitamin is involved in metabolic hydroxylations in numerous important metabolic processes (e.g., the synthesis of steroids and of neurotransmitters and in collagen and drug metabolism). Ascorbic acid has also been implicated as important in other critical oxidation–reduction processes in human metabolism.¹

Although ascorbic acid is an effective reducing agent and antioxidant, the biochemical functions of this vitamin are not well understood. It is controversial to consider ascorbic acid an antiviral agent, but some scientists argue that ascorbic acid is an effective cure or preventative of "common colds."^{158, 159} One study provides some evidence that ascorbic acid appears to help the organism recover from viral infections through an indirect mechanism on the body's immune system.¹⁶⁰ Ascorbic acid has also received attention as a possible anticancer agent. In cell culture studies, ascorbic acid, both alone and in combination with copper ions, is selectively toxic to melanoma cancer cells.¹⁶¹

PRODUCTS

Ascorbic Acid, USP. Ascorbic acid, vitamin C, L-ascorbic acid (Cevitamic Acid, Cebione), occurs as white or slightly yellow crystals or powder. It is odorless and, on exposure to light, gradually darkens. One gram dissolves in about 3 mL of water and in about 30 mL of alcohol. A 1% aqueous solution has a pH of 2.7. Aqueous solutions are not very stable. The ascorbic acid in such preparations undergoes oxidation, particularly under aerobic conditions. Oxidation to dehydroascorbic acid is followed by hydrolytic cleavage of the lactone. The effect of pH on the aerobic degradation of ascorbic acid aqueous solutions has been studied by various investigators. Rogers and Yacomini¹⁶² found that the degradation rate shows a maximum near pH 4 and a minimum near pH 5.6. Further, if a preparation of ascorbic acid with an initial pH between 5 and 5.6 develops

acidity on storage, the rate of degradation will increase as the pH decreases; hence, an initial pH in the range of 5.6 to 6 is recommended.

Dietary sources of ascorbic acid include citrus fruits, tomatoes, and potatoes. Although the sources of some commercial products are rose hips and citrus fruits, most ascorbic acid is prepared synthetically.

Ascorbic acid is readily absorbed by an active process. Large doses can saturate this system, limiting the amounts absorbed. Once absorbed, it is distributed to all tissue. The vitamin is metabolized to oxalic acid before excretion. Ascorbic acid-2-sulfate is also a metabolite found in the urine. Large doses result in the excretion of substantial amounts of unchanged ascorbic acid. The resultant acidification of the urine is the basis for most of the vitamin's adverse effects.

High doses of vitamin C (ascorbic acid) can lead to renal, bone, hematological and gastrointestinal effects.³² Renal calculi due to oxalate or urate result from enhanced renal excretion of these compounds in the presence of high doses of vitamin C. Increased release of calcium and phosphorus from bone have been observed. Hematological effects include increased absorption of nonheme iron without significant increases in total body iron stores. Diarrhea, likely resulting from an osmotic effect, has been reported following large doses, and ascorbic acid tablets that lodge in the esophagus can cause local erosion. Finally, ascorbic acid has been shown to interfere with a number of laboratory tests because of its ability to act as a reducing agent and interfere with colorimetric redox assays.

The vitamin is indicated for the treatment and prevention of ascorbic acid deficiency. Although scurvy occurs infrequently, it is seen in the elderly, infants, alcoholics, and drug users. Ascorbic acid (but not the sodium salt) frequently is administered with methenamine to improve the effectiveness of this antibacterial agent. Because ascorbic acid increases iron chelation by deferoxamine, it is used in the treatment of chronic iron toxicity. It is also a useful adjunct in the treatment of methemoglobinemia.

Ascorbic Acid Injection, USP. Ascorbic acid injection is a sterile solution of sodium ascorbate that has a pH of 5.5 to 7.0. It is prepared from ascorbic acid with the aid of sodium hydroxide, sodium carbonate, or sodium bicarbonate. It may be used for intravenous injection; ascorbic acid is too acidic for this purpose.

Sodium Ascorbate, USP. Sodium ascorbate is a white crystalline powder that is soluble 1:1.3 in water and insoluble in alcohol.

Ascorbyl Palmitate, NF. Ascorbyl palmitate, ascorbic acid palmitate (ester), is the C-6 palmitic acid ester of ascorbic acid. It occurs as a white to yellowish-white powder that is very slightly soluble in water and in vegetable oils. It is freely soluble in alcohol. Ascorbic acid has antioxidant properties and is a very effective synergist for the phenolic antioxidants such as propylgallate, hydroquinone, catechol, and nordihydroguaiaretic acid, when they are used to inhibit oxidative rancidity in fats, oils, and other lipids. Long-chain, fatty acid esters of ascorbic acid are more soluble and more suitable for use with lipids than is ascorbic acid.

Biotin

Biotin was discovered, isolated, and identified structurally in the 1930s. Previously, it was known also as vitamin H. Since then, it has been noted that small amounts of biotin can be detected in almost all higher animals. The D isomer possesses all of the activity. The highest concentrations have been found in liver, kidney, eggs, and yeast, as a water-insoluble complex. Considerable quantities are found both free and in the complex form in vegetables, grains, and nuts. Alfalfa, string beans, spinach, and grass are fair sources of this vitamin.

Microorganisms synthesize biotin from the fatty acid oleic acid. The biosynthetic process involves numerous complex reactions that remain to be better understood. The final reaction step requires formation of the sulfur heterocycle, but the source of the sulfur is not yet known.

Although this vitamin is known to perform essential metabolic functions in the human, the minimal nutritional requirement has not been established because it has been difficult to quantify the amounts of the vitamin made available by intestinal microorganisms. Nevertheless, deficiency states may develop as a result of prolonged feeding of large quantities of raw egg white. Raw egg white contains avidin, a protein that complexes biotin and minimizes its absorption from the gastrointestinal tract. The symptoms of biotin deficiency include dermatitis, hyperesthesia, and glossitis.

Biotin performs vital metabolic functions in important carboxylation processes in the form of carboxybiotin, which is in combination with a carboxylase, as represented below.

The oxygen for ATP cleavage is derived from bicarbonate and appears in the Pi.

Purified preparations of acetyl-CoA carboxylase contain biotin (1 mole of biotin per 350,000 g of protein [enzyme]). It catalyzes the first step in palmitate synthesis as follows:

Biotin also appears to be associated intimately in carboxylation by β -methylcrotonyl-CoA carboxylase, propionyl-CoA carboxylase, pyruvate carboxylase, and methylmalonylmalic transcarboxylase.

Biotin is also joined in an amide linkage to the ϵ -amino group of a lysine residue of carbamyl phosphate synthetase (CPS) to form biotin-CPS, which participates with two ATPs, HCO_3^- , and glutamine in the synthesis of carbamyl phosphate. This takes place stepwise as follows:

1. Biotin CPS + ATP + $\text{HCO}_3^- \rightarrow$ carbonic phosphoric anhydride biotin-CPS (CPA biotin-CPS) + ADP
2. CPA biotin-CPS \rightarrow OOC-biotin-CPS + P_i
3. OOC-biotin-CPS + glutamine \rightarrow $\text{H}_2\text{NOC-biotin-CPS}$ + ATP \rightarrow biotin-CPS + carbamyl phosphate + ADP

Carbamyl phosphate can participate in amino acid metabolism and some nucleic acid syntheses.

Biotin is absorbed readily from the gastrointestinal tract. The body appears unable to break the fused imidazolidine and tetrahydrothiophene ring system. Biotin appears in the urine, predominantly as the unchanged molecule. Only small amounts of the metabolites biotin sulfoxide and bisnorbiotin appear in the urine.

MISCELLANEOUS CONSIDERATIONS

Some dietary components are difficult to characterize as essential nutritional factors in human metabolism because the organism can produce these compounds from other dietary components. (Consider vitamin D and nicotinic acid, which are discussed above.) Vitamin D and nicotinic acid, however, generally are considered among the classic vitamins. Moreover, there is no clear consensus on the necessity for inositol, choline, and *p*-aminobenzoic acid. Nevertheless, such dietary components do perform important metabolic functions; hence, a brief characterization of these follows.

Inositol. Inositol, 1,2,3,5-*trans*-4,6-cyclohexanhexol, *i*-inositol, *meso*-inositol (*myo*-inositol, mouse antialopeia factor), is prepared from natural sources such as corn steep liquors and is available in limited commercial quantities. It is a white crystalline powder that is soluble in water 1:6 and in dilute alcohol. It is slightly soluble in alcohol, the usual organic solvents, and fixed oils. It is stable under normal storage conditions.

Inositol is one of nine different *cis-trans* isomers of hexahydrocyclohexane and is usually assigned the following configuration:

Inositol has been found in most plant and animal tissues. It has been isolated from cereal grains, other plant parts, eggs, blood, milk, liver, brain, kidney, heart muscle, and other sources. The concentration of inositol in leaves reaches a maximum shortly before the fruit ripens. Good sources of this factor are fruits, especially citrus fruits,¹⁶¹ and cereal grains. Inositol occurs free and combined in nature. In plants, it is present chiefly as the well-known phytic acid, which is inositol hexaphosphate. It is also present in the phosphatide fraction of soybean as a glycoside. In animals, much of it occurs free.¹⁶⁴ Inositol in the form of phosphoinositides is almost as widely distributed as inositol, and some of these forms are more active metabolically. Phosphatidylinositol (monophosphoinositide) is the most widely distributed of the inositides, and the chief fatty acid residue is stearic acid.

Phosphoinositides serve as storage forms for secondary messengers. Phosphoinositides compose only a minor fraction (2-8%) of the lipids in cell membranes, yet they can be converted to at least three intracellular messenger molecules: arachidonic acid, inositol 1,4,5-trisphosphate (IP_3), and 1,2-diacylglycerol (DAG). The functions of arachidonic acid derivatives are discussed in Chapter 24. IP_3 releases intracellular calcium, and DAG is an essential cofactor in the activation of protein kinase C.¹⁶⁵

The binding of many different hormones, neurotransmitters, and growth factors to the cell surface results in activation of the polyphosphoinositide receptor system.¹⁶⁶ Binding to the specific receptor activates the enzyme phospholipase C through the intermediacy of a G protein. Phospholipase C converts phosphatidylinositol 4,5-bisphosphate (PIP_2) into IP_3 and DAG. IP_3 releases calcium ion, which in turn affects many cellular responses in the target cells.

IP_3 is also converted to inositol 1,3,4,5-tetrakisphosphate (IP_4). IP_4 also acts as an intracellular messenger, resulting in an influx of extracellular calcium. IP_4 is converted to IP_3 (1,3,4), which is dephosphorylated stepwise to inositol 1,4-diphosphate, inositol 1-phosphate, then inositol. The inositol is then incorporated into DAG to form phosphatidylinositol (PI). PI is sequentially phosphorylated to form phosphatidylinositol 4-phosphate (PIP) and PIP_2 .

The DAG released has several possible fates. It can be converted to PI, as mentioned, or it can be hydrolyzed further to release the arachidonic acid component. DAG in conjunction with calcium ion stimulates protein kinase C. By phosphorylating proteins, kinases regulate many cellular activities. The cycle is completed by the phosphorylation of DAG to phosphatidic acid, which in turn is converted to PI. The complete system remains to be fully understood. Cyclic phosphoinositol derivatives appear also to be secondary messengers.

Inositol is a growth factor for a wide variety of human cell lines in tissue culture. It is considered a characteristic

component of seminal fluid, and the content is an index of the secretory activity of the seminal vesicles.

Evidence is accumulating that inositol will reduce elevated blood cholesterol levels. This in turn may prevent or mitigate cholesterol depositions in the intima of blood vessels in humans and animals and, therefore, be of value in atherosclerosis. Inositol has also been considered a lipotropic agent. Because humans can synthesize inositol, the need for it as a nutritional requirement has not been proved.²

Methionine, USP. An adequate diet should provide the methionine necessary for normal metabolism in the human. Methionine is considered an essential amino acid in humans. It is the precursor in the biosynthesis of *S*-adenosylmethionine, which is an important methylating coenzyme involved in a variety of methylations (e.g., *N*-methylation of norepinephrine to form epinephrine and *O*-methylation of catecholamines catalyzed by catechol-*O*-methyltransferases). Adenosylmethionine also participates in the methylation of phosphatidylethanolamine to form phosphatidylcholine, but this pathway is not efficient enough to provide all of the choline required by higher animals; hence, adequate dietary availability of choline is necessary.²

Choline. Choline is a component of many biomembranes and plasma phospholipids. Dietary sources include eggs, fish, liver, milk, and vegetables. These sources provide choline primarily as the phospholipid lecithin. Lecithin is hydrolyzed to glycerophosphorylcholine by the intestinal mucosa before absorption. The liver liberates choline. Choline can be biosynthesized by humans; consequently, it cannot be considered a true vitamin. Biosynthesis involves methylation of ethanolamine. The methyl groups are provided by methionine or by a reaction involving vitamin B₁₂ and folic acid. Therefore, deficiencies can occur only if all methyl donors are excluded from the diet.

The therapeutic uses of choline depend on its physiological functions. Because it is involved in the formation of plasma phospholipids, it is used as a lipotropic agent to alleviate fatty infiltration of the liver, cirrhosis. It has been used, in large doses, in certain central nervous system disorders (e.g., tardive dyskinesia, presenile dementia) because it is a precursor of acetylcholine. Choline also serves as a methyl donor in some reactions after it is converted to betaine.

***p*-Aminobenzoic Acid, USP.** *p*-Aminobenzoic acid (PABA) has been mentioned as a biosynthetic component of folic acid in bacteria, but higher mammalian organisms cannot synthesize folic acid from its precursors. Nevertheless, PABA appears to perform certain metabolic functions in some animals. In the early 1950s, PABA was reported to be an essential factor in the normal growth and life of the chick.

Since these original developments in this field, various claims¹⁶⁷ have been made for the chromotrichial value of PABA in rats, mice, chicks, minks, and humans. The problem of nutritional achromotrichia is a complex one that may involve several vitamin or vitamin-like factors and is complicated by the synthesis and absorption from the intestinal tract of several factors produced by bacteria.

PABA is a white, crystalline substance that occurs widely in the plant and animal kingdoms. It occurs both free and combined¹⁶⁸ and has been isolated¹⁶⁹ from yeast, of which it is a natural constituent. It is soluble 1:170 in water and 1:8 in alcohol and freely soluble in alkali.

PABA is thought to play a role in melanin formation and to influence or catalyze tyrosine activity.¹⁷⁰ It inhibits oxidative destruction of epinephrine and stilbestrol, counteracts the graying of fur attributable to hydroquinone in cats and mice, exhibits antisulfanilamide activity, and counteracts the toxic effects of carbarsone and other pentavalent phenylarsonates.¹⁷¹

When given either parenterally or in the diet to experimental animals, PABA protects them against otherwise fatal infections of epidemic or murine typhus, Rocky Mountain spotted fever, and tsutsugamushi disease.¹⁷² These diseases have been treated clinically with most encouraging results

by maintaining blood levels of 10 to 20 mg/100 mL for Rocky Mountain spotted fever and tsutsugamushi disease. The mode of action of PABA in the treatment of these diseases appears to be rickettsiostatic rather than rickettsicidal, and the immunity mechanisms of the host finally overcome the infection.

PABA appears to function as a coenzyme in the conversion of certain precursors to purines.¹⁷³ It has been suggested as an effective sunscreen as a 5% solution in 55 to 75% ethyl alcohol on excessive sunlight-exposed areas of the skin.¹⁷⁴

The historical significance of the effect of PABA on the antimicrobial action of sulfonamides and sulfones has been reviewed by Anand.¹⁷⁵

An Introduction to the Medicinal Chemistry of Herbs

JOHN M. BEALE, JR.

According to the World Health Organization, approximately 80% of the world's population uses herbal drugs as part of their normal health care routine.¹ The United States is no exception. In the United States, herbal medicines represent the fastest growing segment of pharmacy trade.² Self-medication with herbs cuts across all educational and affluence levels. Senior citizens as well as young, health-conscious persons are using herbs at an incredible rate. The reasons for herbal use are many and certainly cannot be fully enumerated here. Possibly, herbal users desire to assume control over their own health care needs. Perhaps the large, "impersonal" health care system is unpalatable to many, and they turn to herbal medicines as an alternative. Patients may feel alienated by increasingly busy physicians who have less time to spend with them, and they may turn to herbal drugs because they feel that they can gain some control.

Obviously, if people are going to use herbals as part of their health care routine, they must find out about the herbs and what they do. There is no doubt that a definite major factor affecting herbal use is advertising targeted very successfully to specific populations, such as the young professional or the senior citizen. Such advertising is mere pseudoscience, but its flamboyance is a big drawing factor. Herbal ads often convey an attitude that self-medication is safe and effective, and this makes people feel good and as if they do not need the physician who just saw them for 5 minutes. People also tend to believe that natural products are inherently better than synthetic drugs. The natural drugs somehow contain the "vital force" that is going to improve their health. This is actually a belief in the vitalism principle, which Wöhler disproved in 1828.³ Tyler puts this issue into clear terms: "If it comes in a shrinkwrap, safety-sealed box, or a bottle with a childproof lid, it is not harvested freshly from the earth. It is a manufactured industrial product, no matter how many flowers adorn the wrapper, no matter how many times the label invokes the word 'nature'."⁴

Certainly, the cost of medical care cannot be overlooked when considering the reasons for interest in alternative forms of medicine. Most herbal medicines are far less expensive than prescription drugs. There is danger, however, in self-medicating with herbal drugs. The old adage that "he who tries to diagnose himself has a fool for a physician" becomes very apropos with herbal medicine. When prescription drugs are dispensed, a patient has access to the information that is available from the physician or pharmacist. This is often not the case with herbal medicinals. In the United States, training of health care professionals in the use of herbal

drugs has been nearly nonexistent for years. Hence, herbal users are left to their own devices regarding choice, safety, and quality of the herb chosen.

Until 1882,⁵ a number of drugs were monographed and described in *The United States Pharmacopoeia*. Ginseng, for example, was clearly characterized as a drug and could be labeled and described to patients as such. Today, the Food and Drug Administration (FDA) calls ginseng, legally, a "food for beverage use." Outside the United States, it is common to find ginseng recommended for many different medical conditions.⁶ At the time of the 1882 *United States Pharmacopoeia* and into the early 1900s, pharmacists were well trained in the use, preparation, and dispensing of herbals and could advise patients on their herbal selection. This is not always the case today.

The convoluted regulatory efforts that began in 1906 and continue today are well described by Tyler.⁷ A group of herbs had been grandfathered against the Federal Food, Drug, and Cosmetic Act of 1938 and the Kefauver-Harris amendments of 1962. Most purveyors of herbs assumed that these herbs would continue to be salable with the indications on the label—in other words, marketed as drugs. The FDA declared that all of these grandfathered drugs would be considered misbranded and subject to confiscation if any claims of efficacy were not in accordance with the evaluations of 1 of 17 over-the-counter (OTC) drug evaluation panels that had operated between 1972 and 1990. The net result was that it became possible to sell herbal drugs only if no statements regarding prevention or treatment of a disease state were on the label. The FDA assigned three categories into which herbs were placed. Category I⁸ (effective) contains only a select few herbal drugs. These are mostly laxatives such as cascara bark and senna leaf (although as Tyler points out, prune juice is excluded). Category II (unsafe or ineffective) contained 142 herbs, and category III (insufficient evidence to judge) contains 116. As applied to herbs and, in fact, the entire OTC classification, the judgments of the FDA have been harmful and nonscientific.

For the most part, herbal manufacturers decided not to fight the FDA and merely removed the disease- or condition-specific information from the labels and continued to sell the herbs as foods or nutritional supplements. With regard to using herbs as food additives, the FDA has maintained a list of substances "generally recognized as safe" (the GRAS list).⁹ The list contains about 250 herbs, primarily relating to their use in beverages and cooking and as food additives. The list, of course, contains no references to herbs as drugs.

In 1990, the Nutrition Labeling and Education Act required consistent, scientifically based labeling on all processed foods. Herbal medicines were still left in limbo. Finally, in 1994, the Dietary Safety Health and Education Act included herbal medicines in the definition of dietary supplements. The act ensures consumers' access to supplements on the market as long as they are safe, and it allows structure and function claims on the label. Despite all of these legislative efforts, herbal drugs have been relegated to the grocery shelf as dietary supplements. They are sold with little or no instruction, and the public has no way of ascertaining purity, standardization, or legitimacy of the use for which the product is sold. Indeed, there is more information on the label of a tube of toothpaste than on a bottle of an herbal drug. Herbal manufacturing companies are making efforts to improve products along these lines, but there is a long way to go. Until testing can be done to prove that herbs are safe and effective, they will probably remain in their present circumstances.

For many years, medicinal chemistry was paired with a science called *pharmacognosy*,¹⁰ a course of study of plants with medicinal uses and analytical techniques for detecting active ingredients. Pharmacognosy was an important science because many of the pharmaceuticals used in the treatment of disease are discovered through the study of ethnobotanical leads and laboratory research. This course of study gave pharmacists the training required to understand, recommend, and counsel on herbs. Today, pharmacognosy is no longer required in most schools, and most practicing pharmacists and physicians have little understanding of herbs.

Medicinal herbs are unlike anything else that appears in the chapters of this book. Although they are unquestionably drugs (a fact that many sellers of herbs will dispute), they are not pure substances. Indeed, most herbal preparations contain many different constituents. Ephedra complex, or *Ma huang*, is a sympathomimetic that contains five or six different β -phenethylamine derivatives. At least one of these, (+)-norpseudoephedrine, is a Schedule IV compound. The alkaloid content¹¹⁻¹³ varies widely in commercial ephedra-containing preparations. In one study, for one single product, lot-to-lot variations in the content of (-)-ephedrine, (+)-pseudoephedrine, and (-)-methylephedrine exceeded 180, 250, and 1,000%, respectively.¹¹ Total alkaloid content among 20 products ranged from 0.0 to 18.5 mg/dosage unit, and discrepancies were exhibited between the labeled contents and actual measurements.¹² Another study assayed 9 products and found that total alkaloid levels ranged from 0.3 to 56 mg/g of ephedra.¹³

Unlike the situation with ephedra, in many cases we simply have no idea what the components do. The constituents of some herbal drugs seem to work synergistically and cannot be separated without loss of activity of the preparation. Herbal preparations are most often used as crude mixtures and are not standardized or analyzed for the content of the active principle(s). Hence, the chemistry of medicinal herbs cannot be treated in the same way as that of, say, a pure antibiotic or a calcium channel blocker. The medicinal chemistry of the actions, interactions, and side effects of herbal products is complex and difficult to assess clinically and chemically. Frequently, some of the compounds present

in a given herb can be identified, but there may be no obvious way to correlate chemical structure with function. Often, assessment of structure–function relationships with herbal products involves a lot of guessing.

WHAT IS AN HERB?

An herb is a substance of plant origin that, according to one's desires, can be used for culinary or medicinal purposes.¹⁴ Obviously, some are more suited to culinary than medicinal uses, but most herbal substances have some identifiable medicinal use. As mentioned in the previous section, a typical herb may contain dozens of different compounds, so it has rarely been advantageous to separate an herb into its component parts. In fact, doing so may completely inactivate the drug. In an herbal mixture, some compounds can reinforce others and vice versa. It is impossible to predict what will happen. In relatively few cases has the active ingredient of an herb been isolated, characterized thoroughly, and tested for activity. We are left with a situation in which herbs are used in crude form as powders, fluid extracts, and teas. The above should not be misconstrued to mean that analysis of herb components is useless. On the contrary, it is essential but just is not done often enough.

HERBAL PURITY AND STANDARDIZATION

In the United States, the issues of herbal purity and adulteration have been neglected for years. Because herbs are not regulated in the United States the same way they are in other countries, the pressure to ensure lot-to-lot standardization and to screen out plant adulterants has been less than optimal. Instances have been reported in the literature¹¹ in which several bottles of an herb purchased in the same location possessed different concentrations of active ingredient. Ephedra and ginseng are notable examples. Another example is echinacea. This herb is occasionally adulterated with a plant that looks very similar to *Echinacea angustifolia* but has none of the activity of echinacea. Plant parts, insect parts, soil, etc. can all be adulterants. Fortunately, pressure on the herb-producing industry has caused a markedly increased effort to screen and standardize herbs for trade. Possibly, simple high-performance liquid chromatography (HPLC) methods could be used to verify the herb's quality if the time were taken to obtain them. A chromatogram could be supplied to the purchaser to show the purity of the herb. Nevertheless, remember that an herb is a crude material containing multiple pharmacologically active compounds.

AN HERB IS A DRUG

Despite the regulations, an herbal preparation possesses the properties of a drug, albeit a mild one in many cases, and should be treated as such. It is pharmacologically active. It interacts with prescription drugs. It affects the health of the

persons taking it. Advertisers often tout herbs as "nondrugs" in an attempt to lure consumers. Pharmacists should be cognizant of the truth that herbs are real drugs and that their patients may be self-medicating with them. This practice may affect the outcome of therapy with prescription drugs. For example, suppose a patient is stabilized on Coumadin and starts to take ginkgo. Ginkgo affects platelet-activating factor (PAF)¹⁵ and can effectively cause an overdose effect with Coumadin, and the patient can bleed. Or, suppose a patient taking a monoamine oxidase inhibitor (MAOI) decides to take St. John's wort; the patient may have a toxic reaction.¹⁶ Because pharmacists often do not see what their patients are buying, this is a complex problem.

The herbal drugs available to consumers are far too numerous to discuss in this chapter. This section presents a few of the more commonly used herbs along with their chemistry. Information on other herbs can easily be found in the literature.

TYPES OF HERBS

Echinacea

The medicinal herb that we call *echinacea*, or the purple coneflower, is indigenous to the Great Plains of the United States and, indeed, can be found in much of the Western Hemisphere. The plant gets its name (coneflower) from the narrow florets, which project downward in a conical array from a prominent center toward a substantial stem that bears one flower. Today, the herb is used as an immunostimulant,¹⁷ as a means of lessening the symptoms and duration of a cold or the flu, and sometimes as a wound healer. Recent reports show that echinacea is the best-selling herb in the United States.³ Folklore¹⁸ tells us that Native Americans used *Echinacea angustifolia* to treat superficial wounds, snakebite, and the common cold. In the latter part of the 19th century, settlers exchanged information about medicines with the Indians and added echinacea to their own "pharmacopoeia." Echinacea even became one of the first patent medicines, sold by a huckster in Missouri at midcentury. In the early 1900s, echinacea was introduced to the European continent, where it occupies a special place in medical therapy. One estimate stated that in Germany alone there are 800 echinacea-containing drugs, including a number of homeopathic preparations.¹⁹

Three species are identified as echinacea:²⁰ *Echinacea angustifolia*, *E. pallida*, and *E. purpurea*. All are used for medicinal purposes, and they have similar properties. There are slight differences among the species with regard to the anatomical distribution of active constituents.

CHEMISTRY

There is no doubt that echinacea has immunomodulating properties. The chemistry of the constituents of the plant has been studied extensively, but it is difficult to correlate a major activity with any plant fraction. Indeed, no single component appears to be responsible for the activity of echinacea. Standardization of echinacea preparations has also proved to be a problem. The consumer is presented with three potential preparations sold under the name "echina-

cea": *E. purpurea*, *E. angustifolia*, and *E. pallida*. Some medicinal preparations are from the roots (all three species), some from the aerial parts (*E. purpurea*), and some from the whole plant (homeopathic mother tinctures of *E. angustifolia* and *E. pallida*).²⁰ Another factor that affects the composition of echinacea preparations is the way in which they are extracted. Expressed juices, teas, hydroalcoholic extracts, and tinctures in alcohol are used, as well as solids. It is rarely possible to obtain reproducibility in these preparations.

In 1916, the National Formulary of the United States listed the roots of both *E. angustifolia* and *E. pallida* as official, and the distinction between the two began to be forgotten. In about 1950, *E. purpurea* was introduced as the primary medicinal plant in Europe. Of the three species, *E. pallida* is the most widely cultivated, the tallest, and has the largest flowers. This is considered the official preparation in the United States. *E. purpurea* root preparations are sometimes adulterated with a similar-looking plant called *Parthenium integrifolium*. HPLC analysis can easily detect the adulteration.²¹ The above shows how difficult it is to standardize echinacea preparations. Additionally, opinions differ about which plant component is the best for analytical standardization of the drug. Echinacea contains a series of phenylpropanoid glycosides, echinacoside, verbascoside, and 6-*O*-caffeoyl echinacoside.^{22, 23} These compounds possess no immunostimulating activity. Some argue that the caffeoyl glycoside echinacoside should be the standard, since it is easy to detect and quantitate; others feel that it makes little sense to standardize the echinacea preparation to a compound that has no medicinal activity.

Echinacoside R=Glucose (1,6-) R'=Rhamnose (1,3-)
Verbascoside R=H R'=Rhamnose (1,3-)
6-*O*-Caffeoylglycoside R=6-*O*-caffeoylglucose R'=Rhamnose (1,3-)

Several fractions of echinacea have been isolated according to polarity and studied for pharmacological activity. The most polar components, the polysaccharides, yielded two immunostimulatory polysaccharides, PS1 and PS2.²⁴ These stimulate phagocytosis in vivo and in vitro and cause a burst of production of oxygen radicals by macrophages in a dose-dependent way. PS1 is a 4-*O*-methylglucuronarabinxyran with a molecular weight (MW) of 35,000. PS2 is an acidic arabinorhamnogalactan with an average MW of 45,000. Luetig et al.²⁵ have shown that different concentrations of polysaccharides from *E. purpurea* could stimulate macrophages to release tumor necrosis factor- α (TNF- α). These constituents also activate B cells and stimulate the production of interleukin-1. Three glycoproteins have also been isolated that exhibit B-cell-stimulating activity and induce

the release of interleukin-1, TNF- α , and interferon (IFN) from macrophages, both in vitro and in vivo.²²

Alcoholic tinctures of the aerial parts and roots of echinacea contain caffeic acid derivatives and lipophilic, polyacetylenic compounds. The roots of *E. angustifolia* and *E. pallida* contain 0.3 to 1.7% echinacoside²⁶ as the principal conjugate in the plant. *E. angustifolia* contains 1,5-*O*-dicaffeoyl quinic acids (quinic, chlorogenic, and cynarin)²⁷ in the root tissue, allowing distinction by HPLC. Echinacoside has low bacterial and viral activity but does not stimulate the immune system. The most important set of compounds that seem to be found throughout the tissues of all of the echinacea species are the 2,3-*O*-dicaffeoyl tartaric acids, castaric acid and chicoric acid.²⁸ Chicoric acid possesses phagocytic stimulatory activity in vitro and in vivo, while echinacoside lacks this activity. Chicoric acid also inhibits hyaluronidase and protects collagen type III from free radical degradation.

Quinic Acid	R ₁ =H	R ₂ =H	R ₃ =H
Chlorogenic Acid	R ₁ =H	R ₂ =R	R ₃ =H
Cynarin	R ₁ =R	R ₂ =R	R ₃ =H

Shikimate (Quinic Acid) Derivatives

Castaric Acid	R ₁ =H	R ₂ =H	R ₃ =OH	R ₄ =H
Chicoric Acid	R ₁ =H	R ₂ =R	R ₃ =OH	R ₄ =H

The alkamides²⁹ from the roots and flowers of *E. angustifolia* and *E. purpurea* stimulate phagocytosis in model animal systems. There are a host of these compounds distributed throughout the aerial parts of some *Echinacea* species and the roots of most. One such compound, echinacein,²⁸ displays sialogogue and insect repellent properties and is believed to be the main immunostimulant in echinacea. The alkamides and ketoalkynes^{29,30} may very well possess activity. One notable effect is the anti-inflammatory effect of a high-molecular-weight arabinogalactan that is about as po-

tent as indomethacin.²⁵ The lipophilic fractions, the alkamides, stimulate phagocytosis and inhibit 5-lipoxygenase and cyclooxygenase (COX), blocking the inflammatory process.

It is clear that echinacea can stimulate components of the innate immune system, but no single component seems to be responsible for the effect. Echinacea, if taken at the onset of symptoms of a cold or flu, will lessen the severity of the disease. It is not recommended that one use echinacea longer than 10 to 14 days, however, and persons under the age of 12 and those who are immunocompromised should never use this herb.

Feverfew

Feverfew, *Tanacetum parthenium* (L.) Schultz Bip.³¹ is an herb that was used in antiquity to reduce fever and pain. The literature is replete with anecdotal evidence of the usefulness of the herb, and recent clinical studies have added more support. Feverfew is a member of the aster/daisy family. The plant tissues have a pungent smell and very bitter taste. The medicinal principle of feverfew is concentrated in hairy trichomes on the chrysanthemum-like leaves.³² The plant displays clusters of daisy-like flowers with yellow centers and radiating white florets. Recent uses of feverfew are for migraine and arthritis, although the indication for arthritis is disputable. The anecdotal evidence that an herb could successfully treat a condition such as migraine headache naturally begged for some scientific proof.

Two prospective clinical studies using dried whole feverfew leaf have been performed^{33,34} to assess the value of the herb in migraine. The two leaf studies on migraine provided good supportive evidence for activity of the herb against migraine. Both studies were double blinded, placebo controlled, and standardized on 0.54 mg parthenolide per capsule. In both studies, the feverfew group demonstrated significant decreases in frequency, severity of attacks, and

nausea and vomiting. No adverse effects were observed of the nonsteroidal anti-inflammatory drug (NSAID) type.

MECHANISM OF ACTION

Feverfew inhibits prostaglandin synthesis, but not through an effect on COX.³⁵ The herb also inhibits the synthesis of thromboxane, again by a COX-independent mechanism. Additionally, feverfew inhibits the synthesis of phospholipase A₂ in platelets,^{36, 37} preventing the liberation of arachidonic acid from membrane phospholipids for subsequent conversion to prostaglandins and thromboxane. Feverfew also inhibits the ADP-, collagen-, and thrombin-induced aggregation of platelets, suggesting that the herb has a greater thrombotic effect. In another, similar study, dried leaves of feverfew inhibited prostaglandin and thromboxane synthesis in platelets and inhibited platelet aggregation initiated by ADP and collagen.³⁸ Surprisingly, this study showed that feverfew inhibited the platelet-release reaction by which intracellular storage granules are released.³⁹ These storage granules contain serotonin, a positive effector in migraine headache. Some of the more surprising findings for feverfew are that it appears to be a selective inhibitor of inducible COX-2,⁴⁰ and it has clear effects on vascular tone in animal models.

The pharmacologically active constituent in feverfew has typically been considered to be parthenolide,⁴¹ an amphiphilic sesquiterpene lactone that is biosynthesized from the germacranolide cation. Parthenolide is present in much greater quantities than any of the other constituents, and its presence does seem to correlate with activity, at least in dried leaves. Parthenolide is an α -methylene lactone,⁴² an α,β -unsaturated molecule that can serve as an acceptor in the Michael reaction. In the Michael reaction, a donor nucleophile such as a thiol can attack the acceptor to form a covalent adduct. If parthenolide functions this way, a biological nucleophile such as a thiol on an enzyme could be bound, inactivating that enzyme. The likelihood of this mechanism has been shown by successfully forming adducts with parthenolide itself *in vivo*.^{43, 44} The other components—canin, artec-

3- β -Hydroxyparthenolide

nin, secotanaparthenolide, and 3- β -hydroxyparthenolide—are present in lower concentrations.⁴⁵ Their effects may be important to the activity of feverfew, but this is impossible to judge at present. One study that used an extract of the leaf with known parthenolide content failed to show activity, so questions still remain.

Saint John's Wort

Saint John's wort (*Hypericum perforatum*) is a medicinal herb that has been used since the time of Paracelsus (1493–1541) to treat a variety of psychiatric disorders. Today, the herb remains one of the most important psychotropic drugs in Germany and Western Europe for the treatment of depression, anxiety, and nervousness.⁴⁶ The drug has recently become popular among consumers in the United States. The demand for the drug in the United States has been fueled by German studies that reported that St. John's wort was equieffective with fluoxetine in the treatment of depression.

Some interesting circumstances give the herb its name. The plant is a low-growing shrub that grows wild in Europe and Western Asia with yellow flowers that bloom around June 24, the traditional birthdate of St. John. If the flowers are rubbed, a red pigment is released. This red substance has traditionally been associated with the blood of St. John released at his beheading.

The medicinal components of St. John's wort are derived from the flowering tops. A 2001 study in *JAMA*, however, negates about 30 previously published trials and showed that St. John's wort failed to improve major depressive disorder in the first large-scale, multicenter, randomized, placebo-controlled trial in patients diagnosed with major depressive disorder. The herb has a definite mild sedative effect, and in 10 years of controlled clinical trials it has proved effective in the treatment of *mild* depression.

CHEMISTRY⁴⁷

The red components of Saint John's wort are the anthracene derivatives hypericin, present in about 0.15%, and pseudohypericin. Flavonoids present are quercetin, hyperoside, quercitrin, isoquercitrin, and rutin. Two C–C-linked biflavins, amentoflavone and biapigenin, are present, as is the acylphloroglucinol derivative hyperforin. Procyanidin, a chiral flavone dimer, adds to the list of flavones. Some terpenes and *n*-alkanes are present as minor components. The primary active ingredients have traditionally been held to be the hypericins and the flavone/flavonols, especially the hypericins. In fact, the German Commission E Monograph specifies that the herb should be standardized to hypericin content.

Despite the evidence of efficacy, the mechanism of action of St. John's wort remains unclear. Several possibilities have been put forth. Probably the most popular one is the MAOI/

R=CH₃, Hypericin
R=CH₂OH, Pseudohypericin

R=H, Quercetin
R=Gal, Hyperoside

COMT hypothesis. According to this hypothesis, St. John's wort increases the levels of catecholamines at the brain synapses by inhibiting their inactivation by oxidative deamination (MAOI) and by catechol functionalization (catechol-*O*-methyltransferase [COMT]).⁴⁷ Recent studies have shown that hypericins possess such activities only at pharmacologically excessive concentrations. If true, these effects at normal doses are small and do nothing to alleviate depression. Other hypotheses suggest hormonal effects or effects on the dopaminergic system. Hyperforin has become a candidate for the major antidepressant constituent of St. John's wort,

supposedly inhibiting serotonin reuptake by elevating free intracellular sodium.

St. John's wort also exhibits anti-inflammatory and antibacterial activity. Reports of antiviral activity are unsubstantiated. The main adverse effect with St. John's wort is severe phototoxicity. A sunburn-like condition may occur at normal dosages. St. John's wort should never be taken with MAOIs because of the risk of potentiation of the effects. Selective serotonin reuptake inhibitors (SSRIs) likewise should not be taken with St. John's wort because of the risk of serotonergic syndrome.

Dose (capsules standardized to 0.3% hypericin): 300 mg of standardized extract 3 times daily.

The FDA considers St. John's wort unsafe.

Capsicum (Capsaicin, Chili Pepper, Hot Pepper)

Pepper plants have been used for years as herbal remedies for pain.⁴⁸ The therapeutically useful pepper plants are members of the *Solanaceae* family. There are two primary species whose dried fruit is commonly used: *Capsicum frutescens* and *C. annuum*. The actual active ingredient, capsaicin, is extracted from an oleoresin that represents up to 1.5% of the plant. Two major components in the oleoresin (among several) are capsaicin and 6,7-dihydrocapsaicin. Volatile oils and vitamins A and C occur in large quantities. The amount of ascorbic acid in the capsaicin oleoresin is reportedly 4 to 6 times that in an orange.⁴⁹

Capsaicin is supplied pharmaceutically as a cream, gel, or lotion. The first application of the preparation produces intense pain and irritation at the site of application, but usually no skin reaction occurs. Repeated applications cause desensitization, and eventually analgesic and anti-inflammatory effects occur. Stimulation of afferent nerve tracts causes a heat sensation.

There are several potential explanations for the alleviation of pain by capsaicin. There is believed to be a compound called *substance P* that mediates pain stimuli from the periphery to the spinal cord. One theory is that capsaicin depletes the neuronal supply of substance P so that pain stimuli cannot reach the brain.⁵⁰ Additionally, the methoxyphenol portion of the capsaicin molecule may fit the COX receptor site and inhibit the lipoxygenase and cyclooxygenase pathways.⁴⁹

Capsaicin is extremely potent, so topical preparations are compounded in percentage strengths of 0.025 to 0.25%. The preparations deplete substance P most effectively if used 3 to 4 times a day. Capsaicin has been suggested as a remedy for postsurgical pain (postamputation and postmastectomy), postherpetic neuralgia, and a variety of other complex pain situations. Relief of pain may occur as quickly as 3 days or may require up to 28 days.

Patients should be instructed to wash their hands well after

applying capsaicin. Contact with mucous membranes and the eyes should be avoided. If contact occurs, one should wash with cool running water.

Capsaicin as the oleoresin is used as a "pepper spray" for self-defense. Spraying into the eyes causes immediate blepharospasm, blindness, and incapacitation for up to 30 minutes.

Garlic

Garlic (*Allium sativum*)⁵¹ is an herbal drug with references to medicinal properties that date back thousands of years. Of all the herbal remedies available to consumers, garlic is probably the most extensively researched.⁵² Publications about the effects and benefits of garlic occur with great frequency. Garlic is a bulb. It may be used as such, but it is typically dried, powdered, and compressed into a tablet. Usually, the tablets are enteric coated.

CHEMISTRY

Garlic⁵³ contains a key component, alliin or *S*-methyl-L-cysteine sulfoxide. Additionally, methiin (methylcysteine sulfoxide), cycloalliin, several γ -L-glutamyl-S-alkyl-L-cysteines, and alkyl alkanethiosulfonates are present. The tissues also contain enzymes (alliinase, peroxidase, myrosinase), as well as additional sulfur-containing compounds, ajoene, and other minor components. Garlic itself has the highest sulfur content of all of the *Allium* species. When the garlic clove is crushed, the enzyme alliinase is released, and alliin is converted to allicin. Allicin gives garlic its characteristic odor and is believed to be the pharmacologically active ingredient from the herb. Alliinase will not survive the acidic environment of the stomach, so enteric-coated tablets are used.

Garlic is most often studied for its lipid-lowering and anti-thrombotic⁵⁴ effects. A cholesterol-lowering effect is well documented in both animals and humans. Garlic lowers serum cholesterol, triglycerides, and low-density lipoprotein (LDL) while increasing high-density lipoprotein (HDL). Jain reported mean reductions of 6% in total serum cholesterol and 11% in LDL. Methylallyltrisulfide in garlic oil poten-

tially inhibits ADP-induced platelet aggregation, and ajoene inhibits platelet aggregation for short periods.

Compared with the statin drugs, there is a paucity of human research data for garlic. There have been no morbidity and mortality studies for garlic, for instance. All that we can really gather from the literature is that there *may* be an effect on patient lipid profiles, but for every positive response, a negative one can be found. Garlic is certainly not harmful and can be used safely as part of a lipid-reduction program, but this should be done under a physician's supervision.

Chamomile

The herb known as chamomile⁵⁵ is derived from the plants *Matricaria chamomilla* (German, Hungarian, or genuine chamomile) and *Anthemis nobilis* (English, Roman, or common chamomile). Plants from the two genera have similar activities. The medicinal components are obtained from the flowering tops. The flowers are dried and used for chamomile teas and extracts. Chamomile has been used medicinally for at least 2,000 years. The Romans used the herb for its medicinal properties, which they knew were antispasmodic and sedative. The herb also has a long history in the treatment of digestive and rheumatic disorders.

The activity of chamomile is found in a light blue essential oil that composes only 0.5% of the flower. The blue color is due to chamazulene, 7-ethyl-1,4-dimethylazulene. This compound is actually a by-product of processing the herb. The major component of the oil is the sesquiterpene (–)- α -bisabolol. Also present are apigenin, angelic acid, tiglic acid, the terpene precursors (farnesol, nerolidol, and germacranolide) coumarin, scopoletin-7-glucoside, umbelliferone, and herniarin. Much of the effect of chamomile is due to bisabolol. Bisabolol is a highly active anti-inflammatory agent in a variety of rodent inflammation and arthritis tests. In addition, bisabolol shortens the healing time of burns and ulcers in animal models.

The gastrointestinal (GI) antispasmodic properties of bisabolol and its oxides are well known. In fact, bisabolol is said to be as potent as papaverine in tests of muscle spasticity. Besides bisabolol, the flavone and coumarin components have antispasmodic activities. The blue compound chamazulene possesses both anti-inflammatory and antiallergenic activities, as do the water-soluble components (the flavonoids). Apigenin and luteolin possess anti-inflammatory potencies similar to that of indomethacin. These flavonoids possess acidic phenolic groups, a spacer, and an aromatic moiety that could fit into the COX receptor. None of these effects has been unequivocally documented in humans. The essential oil possesses low water solubility, but teas used over a long period of time provide a cumulative medicinal effect. Typically, 1 teaspoon (3 g) of flower head is boiled in hot water for 15 minutes, 4 times a day.

Apigenin

Luteolin

DRUG INTERACTIONS

Chamomile contains coumarins and may enhance the effect of prescription anticoagulants. The herb is an antispasmodic and slows the motility of the GI tract. This action might decrease the absorption of drugs. Chamomile preparations may be adulterated with chamomile pollen. This may cause allergy, anaphylaxis, and atopic dermatitis.

Ephedra

The varieties of ephedra (*Ephedra sinica*, *E. nevadensis*, *E. trifurca*, *Ma huang*, natural ecstasy, ephedrine, *Herba Ephedrae*) that possess medicinal activity grow in Mongolia or along the Mongolian border region with China. The plant itself, an evergreen with a pine odor, consists of green cane-like structures with small, reddish-brown basal leaves. In the fall, the canes, root, and rhizome are harvested and dried in the sun. The dried material furnishes the active ingredients.

ACTIVITY

Ma huang is a sympathomimetic agent. The active principles are β -phenethylamines.^{11–13} These agents can stimulate the release of epinephrine and norepinephrine from nerve endings. Ma huang is a sympathomimetic stimulant in the periphery as well as in the central nervous system (CNS). It has positive inotropic and positive chronotropic effects on the heart; hence, the herb may be dangerous to people with cardiac disease. The amounts of ephedra-type compounds and the relative composition differ so widely that it is difficult to be certain what one is getting in any given preparation. Ma huang's main active ingredient is the β -phenethylamine compound (–)-ephedrine. Plants grown in China may contain 0.5 to 2.5% of this compound. Many ephedrine congeners are represented in the plant,¹¹ and many of these possess considerable pharmacological activity. Some are as follows: (–)-ephedrine, (+)-pseudoephedrine, norephedrine, norpseudoephedrine, ephedroxane, and pseudoeephedroxane.

Ma huang's principal active ingredient is (–)-ephedrine. This compound is the *erythro*-*n*(–) isomer with the 2(*S*),3(*R*) configuration. The less potent (+)-pseudoephedrine has the *threo* 2(*S*),3(*S*) structure. Ephedrine acts as a mixed agonist on both α and β receptors.

PHARMACOLOGICAL EFFECTS

Ephedrine's actions occur through mixed stimulation of the α - and β -adrenergic receptors. The drug is a CNS stimulant that increases the strength and rate of cardiac contraction. Additionally, ephedrine decreases gastric motility, causes bronchodilation, and stimulates peripheral vasoconstriction with the predicted increase in blood pressure. The *threo* isomer (+)-pseudoephedrine causes similar effects but is much less potent than (–)-ephedrine. The claims that ephedra causes increased metabolism and "fat burning" are certainly false, and ephedra lacks anorectic effects. Any reports of successful use of ephedra preparations in weight loss probably reflect the stimulant or "energizing" effect and increased physical activity. In the United States, ephedra has been used as a recreational CNS stimulant (natural ecstasy).

E. nevadensis and *E. trifurca* are typically used in teas. The FDA prohibits preparations with more than 8 mg/dose and advises that one should not take an ephedra product more often than every 6 hours and no more than 24 mg/day. Ephedra should not be used for more than 7 days. Dosages over the recommended amount may cause stroke, myocardial infarction, seizures, and death.

Ephedra has been closely linked to methamphetamine production. There are movements in many localities to outlaw the herb. There are many drug interactions with Ma huang. β -Blockers may enhance the sympathetic effect and cause hypertension. MAOIs may interact with ephedra to cause hypertensive crisis. Phenothiazines might block the α effects of ephedra, causing hypotension and tachycardia. Simultaneous use of theophylline may cause GI and CNS effects. In pregnancy, ephedra is absolutely contraindicated (uterine stimulation). Persons with heart disease, hypertension, and diabetes should not take ephedra.

Cranberry

The cranberry plant (*Vaccinium macrocarpon*, *V. oxycoccus*, and *V. erythrocarpum*) is a trailing evergreen that grows primarily in acidic swamp areas. The whole berries are di-

vested of seeds and skins, and the rest of the fruit is used as a drink or in capsule form. Cranberry juice has been used for many years as a urinary tract disinfectant. In 1923,⁵⁶ a report said that the urine of persons who consumed cranberry juice became more acidic. Because an acidic medium hinders the growth of bacteria, it was thought that acidification of the urine inhibited bacterial growth.

An analysis of cranberry juice shows that it contains many different compounds. Citric, malic, benzoic, and quinic acids are present as carboxylic acid components. With pK_a s of 3.5 to 5, these compounds should exist in the ionized form in the urine at pH 5.5, thus lowering the pH. We now know that acidification of the urine is not the entire story. In fact, drinking the cocktail does not appreciably acidify the urine. Two other constituents exist in the juice: mannose and a high-molecular-weight polysaccharide.^{57–59} With bacteria that use fimbrial adhesins in infecting the urinary tract, mannose binds and inhibits adhesion of the type 1 mannose-sensitive fimbriae, while the high-molecular-weight polysaccharide inhibits binding of the P-type fimbriae. Hence, adhesion of many *Escherichia coli* strains, which cause over half of all urinary tract infections, is inhibited. This inhibition has the effect of blocking infection.

Dosage: Drink between 10 and 16 ounces of juice daily.

Ginkgo biloba

Ginkgo biloba (L.), also known as the maidenhair or Kew tree, has survived essentially unchanged in China for 200 million years.⁶⁰ There is a Chinese monograph describing the use of ginkgo leaves dating from 2800 bc. Today, ginkgo is extracted by an extremely complex multistep process that concentrates the active constituents and removes the toxic ginkgolic acid.⁶¹

The ginkgo extract is a complex mixture of both polar and nonpolar components. The more polar fractions contain flavonol and flavone glycosides. The more nonpolar fractions contain some diterpene lactones, known as ginkgetin, ginkgolic acid, and isoginkgetin, and some interesting caged diterpenes known as ginkgolide A, B, C, J, and M.⁶² There is also a 15-carbon sesquiterpene (bilobalide) and other minor components. *Ginkgo biloba* extract is prepared by picking the leaves, drying them, and constituting them into an acetone-water extract that is standardized to contain 24% flavone glycosides and 6% terpenes.⁶⁴

Ginkgolide C

Ginkgotoxin

Ginkgo biloba produces vasodilating effects on both the arterial and venous circulation.^{60, 61} The result is increased tissue perfusion (i.e., in the peripheral circulation) and cerebral blood flow. The extract produces arterial vasodilatation (rodent models), dampens arterial spasticity, and decreases capillary permeability, capillary fragility,⁶⁰ erythrocyte aggregation, and blood viscosity. There are several possible explanations for these effects. One possibility is that the compounds in *Ginkgo biloba* extract inhibit prostaglandin and thromboxane biosynthesis. It has also been speculated that *Ginkgo biloba* extract has an indirect regulatory effect on catecholamines. Ginkgolide B is reportedly a potent inhibitor of PAF.¹⁵ In any case, the effects are due to a mixture of the constituents, not a single one.

Ginkgo biloba has become popular because of its putative abilities to increase peripheral and cerebral circulation. The herb is called an *adaptogen*,⁶³ a drug that helps persons handle stress. In the periphery, the herb has been compared to pentoxifylline. If the properties are true, the herb could be used for intermittent claudication. If cerebral blood flow can be increased with *Ginkgo biloba*, the herb might be useful

for disorders of memory that occur with age and Alzheimer's disease. The popular use for the herb is to help people think better under stress and to increase the length of time that someone (e.g., a student) can handle mental stress.

Ginseng

Ginseng is the root of the species *Panax quinquefolius*. This form is commonly known as American, or Western, ginseng. The shape of the root is important to many and may make it highly prized. *Panax* means "all" or "man." Sometimes, the root is shaped like the figure of a human. The doctrine of signatures would say that this root would benefit the whole person. Another species of ginseng, *P. ginseng*, is commonly called Asian, or Korean, ginseng. Chemically, the two species are very similar. Major components are named the *ginsenosides*.⁶⁴

The chemical constituents of ginseng are called *ginsenosides* or *panaxosides*. A total of 12 of these have been isolated but are present in such small quantities that purification is difficult. Sterols, flavonoids, proteins, and vitamins (B₁, B₂, B₁₂, pantothenic acid, niacin, and biotin) are also components with pharmacological activity. The chemistry of ginseng gives a good example of how different compounds in one herb can have opposing pharmacological effects.⁶⁵ Ginsenoside Rb-1 acts as a CNS depressant, anticonvulsant, analgesic, and antipsychotic, prevents stress ulcers, and accelerates glycolysis and nuclear RNA synthesis. Ginsenoside Rg-1 stimulates the central nervous system, combats fatigue, is hypertensive, and aggravates stress ulcers. Additionally, ginsenosides Rg and Rg-1 enhance cardiac performance, while Rb depresses that function. Some of the other ginsenosides display antiarrhythmic activity similar to that of the calcium channel blocker verapamil and amiodarone.

Ginseng is popularly believed to enhance concentration, stamina, alertness, and the ability to do work. Longer term use in elderly patients is claimed to enhance "well-being." There are few data from human studies. Clinical studies comparing ginseng to placebo on cognitive function tests showed statistically insignificant improvement. Neverthe-

Ginsenoside R_g

20 (R) Ginsenoside

less, ginseng is a popular herbal product recommended by the German Commission E.

Milk Thistle

Milk thistle (*Silybum marianum*) is a member of the Asteraceae, a family that includes daisies, asters, and thistles. The plant has a wide range around the world and is found in the Mediterranean, Europe, North America, South America, and Australia. The seeds of the milk thistle plant have been used for 2,000 years as a hepatoprotectant.^{66, 67} This usage can be traced to the writings of Pliny the Elder (AD 23–79) in Rome, who reported that the juice of the plant could be used for "carrying off bile." Culpepper in England reported that milk thistle was useful in "removing obstructions of the liver and spleen and against jaundice."

CHEMISTRY

Milk thistle contains as an active constituent silymarin,⁶⁸ which is actually a mixture of three isomeric flavanolignans: silybin (silibinin), silychristin, and silydianin. Silybin is the most active hepatoprotectant and antioxidant compound of the mixture. Also present in the plant are the flavanolignans dehydrosilybin, silyandrin, silybinone, and silyhermin. Other lipid-soluble components are apigenin, silybonol, and linoleic, oleic, myristic, stearic, and palmitic acids.

Silymarin

MECHANISM OF ACTION

The silymarin complex is aptly suited for its hepatoprotective actions.⁶⁸ Silymarin undergoes enterohepatic cycling, moving from intestine to liver and concentrating in liver cells. Protein synthesis is induced in the liver by silybin,

whose steroid structure stimulates both DNA and RNA synthesis. Through these activities, the regenerative capacity of the liver is activated. Silymarin is reported to alter the outer cell membrane structure of liver cells, blocking entrance of toxic substances into the cell. This blockage is so pronounced that it can reduce the death rate from *Amanita phalloides* poisoning. Silymarin's effect can be explained by its antioxidant properties; it scavenges free radicals. By this effect, the level of intracellular glutathione rises, becoming available for other detoxification reactions. Silybin inhibits enzymes like lipoxygenase,⁶⁶ blocking peroxidation of fatty acids and membrane lipid damage. Studies also show that silymarin protects the liver from amitriptyline, nortriptyline, carbon tetrachloride, and cisplatin. When treated, patients with alcoholic cirrhosis showed increased liver function as measured by enzymes. In patients with acute viral hepatitis, silymarin shortened treatment time and improved aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels.

In liver disease, silymarin appears to have an immunomodulatory effect. The activities of superoxide dismutase (SOD) and glutathione peroxidase are increased, which probably accounts for the effect on free radicals. Silymarin, however, has an anti-inflammatory effect on human platelets. Silybin retards release of histamine from human mast cells and inhibits activation of T lymphocytes. The chemical appears capable of reducing the levels of all immunoglobulin classes and enhances the motility of lymphocytes. Milk thistle extract and its components have shown efficacy in treating hepatotoxin poisoning, cirrhosis, and hepatitis. It also plays a role in blood and immunomodulation and in lipids and biliary function. The overall effect is due to the electron-scavenging properties of flavanolignans, the enhanced regenerative capacity of the liver, and the alteration of liver cell membranes that blocks toxin entry.

Valerian

Valerian (*Valeriana officinalis*) is found in temperate regions of North America, Europe, and Asia. The dried rhizome of valerian contains an unpleasant-smelling volatile oil that is attributed to isovaleric acid. Despite the odor, valerian is a safe and effective sleep aid.

CHEMISTRY

Three classes of compounds have been linked to the sedative properties of valerian. The rhizome contains monoterpenes

and sesquiterpenes (valericic acid and its acetoxy derivative), iridoids (valepotriates), and pyridine alkaloids.^{69, 70} At present, it is not possible to state which class of compound is responsible for the sedative activity. Most researchers believe that the valepotriate is the active component, but some studies have shown that valericic acid is more potent.

Aqueous and hydroalcoholic extracts of valerian induce the release of [³H]γ-aminobutyric acid (GABA) from synaptosome preparations. The extracts appear to have much the same effects as benzodiazepines, except that valerian does not act on the Na⁺/K⁺-ATPase. Valericic acid inhibits the GABA transaminase. This effect would increase the inhibitory effect of GABA in the CNS.

There is no doubt that valerian is safe and effective as a sleep aid. Used properly, it is one of the more recommendable herbs.

Dose: 400 to 900 mg standardized extract $\frac{1}{2}$ to 1 hour before bedtime.

Pennyroyal

Pennyroyal (*Hedeoma pulegioides*, *Mentha pulegium*) is an example of an extremely toxic herb. The plant is a member of the mint family, Labiatae. The dried leaves and flowering tops of the plant contain from 16 to 30% oil, consisting of

the monoterpene pulegone.⁷¹ The oil also contains tannins, α- and β-pinenes, other terpenes, long-chain alcohols, piperitenones, and paraffin.

The toxicity of pennyroyal is believed to be due to the pulegone⁷¹ in the oil. Cytochrome P-450 catalyzes the metabolism of pulegone to yield the toxic metabolite menthofuran. Possibly, some of the other terpenes undergo oxidation to active metabolites as well. Menthofuran, metabolites of other terpenes, and pulegone itself deplete hepatic glutathione, resulting in liver failure. This mechanistic hypothesis is supported by the fact that administration of acetylcysteine reverses the toxicity.

Pennyroyal has been used as an abortifacient since the time of Pliny the Elder,⁷² an insect repellent (the terpenes in the oil have citronellal-like properties), an aid to induce menstruation, and a treatment for the symptoms of premenstrual syndrome. It has also been used as a flea repellent on dogs and cats.

When used as an abortifacient, the drug often causes liver failure and hemorrhage, leading to death. Pennyroyal is sometimes used with black cohosh to accelerate the abortifacient effect. Coma and death have been reported. Pennyroyal is an example of an herb that has no safe uses. It should not be sold.

Herbal Drugs Used in the Treatment of Cancer

Anticancer drugs derived from biological sources are fairly common and are among the most important in the therapeutic armamentarium. Drugs like doxorubicin, mitomycin C, mithramycin, and bleomycin have been around for a long time and have shed much light on the treatment of cancer. Three plant-derived drugs that have found their way through clinical trials deserve mention here. Two of the most famous are vincristine and vinblastine. These are compounds isolated from the periwinkle plant *Catharanthus roseus*. The Vinca alkaloids bind tightly to tubulin in cells and interfere with its normal function in spindle formation. The Vinca alkaloids make the tubulin less stable. The net result is metaphase arrest of cell division. Paclitaxel (Taxol) was originally isolated from the needles or bark of the Pacific yew. Because it occurs in vanishingly small concentration in the plant, a semisynthetic method for its production was developed. Taxol binds to tubulin like the Vinca alkaloids, but it makes the tubulin structure hyperstable so that it cannot function. Again, the net result is metaphase arrest.

sucrose. Concentrated aqueous extracts may contain 10 to 20% glycyrrhizin. When the herb is ingested, the intestinal flora catalyze the conversion of glycyrrhizin into glycyrrhetic acid, the pharmacologically active compound. Glycyrrhizin and glycyrrhetic acid possess mild anti-inflammatory properties. Glycyrrhizin appears to stimulate gastric mucus secretion. This may be the origin of the antiulcer properties of licorice. Glycyrrhizin and glycyrrhetic acid do not act directly as steroids. Instead, they potentiate, rather than mimic, endogenous compounds.

R=Glucuronyl-(1,2)-glucuronate : Glycyrrhizin
R=H : Glycyrrhetic Acid

There is some interesting folklore relating to the use of licorice. During World War II, a Dutch physician⁷³ noticed that patients with peptic ulcer disease improved dramatically when treated with a paste containing 40% licorice extract. The physician treated many patients in this way, but during the course of his work he noticed that there was a serious side effect from the herbal drug. About 20% of his ulcer patients developed a reversible edema of the face and extremities. Since these original observations, many studies have been conducted with licorice root. The findings have remained the same: licorice is useful for peptic ulcer disease, but potentially serious mineralocorticoid side effects are possible (lethargy, edema, headache, sodium and water retention, excess excretion of potassium, and increased blood pressure).

Licorice exerts its protective effects on the gastric mucosa by inhibiting two enzymes, 15-hydroxyprostaglandin dehydrogenase and Δ^{13} -prostaglandin reductase. Inhibition of these enzymes causes their substrates to increase in concentration, increasing the levels of prostaglandins in the gastric mucosa and causing a cytoprotective effect. The acid also inhibits 11- β -hydroxysteroid dehydrogenase,⁷⁴ thus increasing the glucocorticoid concentration in mineralocorticoid-responsive tissues, causing increased sodium retention, potassium excretion, and blood pressure.

In the 1960s, a semisynthetic compound based on glycyrrhetic acid, 4-*O*-succinylglycyrrhetic acid (carbenoxolone), was introduced in Europe. It proved effective against peptic ulcer disease, but it was later shown to be inferior to the H_2 -receptor antagonists.

Licorice is also an effective demulcent, soothing a sore throat, and is an expectorant and cough suppressant.

Licorice can cause serious adverse reactions. These are mineralocorticoid effects (pseudoprimary aldosteronism), muscle weakness, rhabdomyolysis, and heart failure. Poisoning by licorice is insidious. Long-term high doses are ex-

Licorice

When we think of licorice, we typically think of the popular candy. Licorice, however, has an important history in herbal medicine. Licorice is a perennial shrub that is indigenous to the Mediterranean and is cultivated in the Middle East, Spain, northern Asia, and the United States. The most common variety used for medicinal purposes is *Glycyrrhiza glabra* var. *typica*. Licorice has been used since Roman times and was described in early Chinese writings.

CHEMISTRY

The root and rhizomes of the licorice plant contain approximately 5 to 9% of a steroidal glycoside called *glycyrrhizin*. In the glycoside form, glycyrrhizin is 150 times sweeter than sugar. Also present are triterpenoids, glucose, mannose, and

tremely toxic. Licorice can potentiate the digitalis glycosides and cause toxicity. With cardiovascular agents that prolong the QT interval, the effects may be additive.

Computational Chemistry and Computer-Assisted Drug Design

J. PHILLIP BOWEN

The advent of powerful and inexpensive computers has revolutionized science and medicine. Medicinal chemistry is no exception. Today, drug design methods are widely used in both industrial and academic environments. Through the use of computer graphics, structures of organic molecules can be entered into a computer and manipulated in many ways. Computational chemistry methods are used to calculate molecular properties and generate pharmacophore hypotheses. Once a pharmacophore hypothesis has been developed, structural databases (commercial, corporate, and/or public) of three-dimensional (3D) structures can be searched rapidly for "hits" (i.e., existing compounds that are available with the required functional groups and permissible spatial orientations as defined by the search query). It has become popular to carry out *in silico* screening of drug-receptor candidate interactions, known as *virtual* high-throughput screening (vHTS), for future development. The realistic goal of vHTS is to identify potential lead compounds. The drug-receptor fit and predicted physicochemical properties are used to "score" and "rank" compounds according to penalty functions and information filters (molecular weight, number of hydrogen bonds, hydrophobicity, etc.). Although medicinal chemists have always been aware of absorption, distribution, metabolism, elimination, and toxicity (ADMET or ADME/Tox), in recent years, a much more focused approach addresses these issues in the early design stages. This is logical when one considers the compelling statistics associated with clinical evaluations of the safety and efficacy of new drugs. Only approximately 20% of compounds entering clinical trials emerge as marketable drugs. Increased efforts to develop computer-based absorption, distribution, metabolism, and elimination (ADME) models are being pursued aggressively. Many of the *predictive* ADME models use quantitative structure activity relationships (QSAR). In general, understanding what chemical space descriptors are critical for drug-like molecules helps provide insight into the design of chemical libraries for biological evaluation.

With the aid of molecular modeling software, pharmaceutical scientists can modify the structural features of a potential drug candidate *in silico* and make predictions about its physicochemical properties prior to laboratory synthesis. Crystallographic information about the receptor has allowed scientists to use structure-based drug design approaches with tangible benefits (i.e., marketable drugs). Given the difficulty in preparing organic compounds, one can immediately appreciate the power that computer-based methods offer. Obviously, the computer-generated models must be accurate enough to give scientists a high degree of confidence in

them. This means that the computer results must be compared with experimental data. Regardless of the intellectual appeal of computer-assisted drug design (CADD), the methods must be validated for known cases to give confidence in the many situations when the methods will be applied to unknown cases. The inherent differences between a *model* and *reality* should always be appreciated, whether computer simulations are being used for drug design, weather forecasting, or economic prognostication.

The ability to calculate molecular properties, coupled with visualization of molecular structures, has greatly benefited scientists involved in drug discovery. Computer models of drug molecules and drug-receptor interactions are commonly found in the scientific literature. One would be hard-pressed these days to find a journal devoted to drug discovery without one paper showing computer graphics representations of drug molecules. Drug-like molecules can be displayed with molecular surfaces and color-coded according to solvent accessibility, electrostatic potentials, or other properties. With molecular modeling software, it is easy to superimpose two or more molecules. Even pharmaceutical industry marketing campaigns have brightly colored representations of drugs and their molecular surfaces splashed onto magazine ads or swirling across television screens.

In the 1980s, skeptics of the use of computer-based methods for drug discovery often asked the question: what compounds were designed by molecular modeling methods? Few convincing examples could be provided during this period, since CADD had only been in existence for a few years. Furthermore, because it is not uncommon for a drug to take 10 or more years from the design stage to final approval, the fruits of CADD would not be revealed until about a decade later. Unquestionably, many of the major advances in medicinal chemistry have used *rational* drug design but without computers. In some respects, the question regarding CADD success stories is fundamentally flawed, in that no one typically asks how many drugs were designed by a single scientific technique (e.g., nuclear magnetic resonance [NMR] spectroscopy). The NMR analogy was the often-quoted response by computational chemists. In reality, drug discovery is so undeniably complicated that no one single method generally can be credited for the complete design of a drug. An arsenal of methods from diverse scientific areas is brought to bear on drug discovery problems. The scientists involved have to interpret the data. Although molecular modeling methods are just another tool to help scientists make informed decisions on what lead compounds to pursue and what structural features should be modified to

enhance biological activity, there is an inherent appeal associated with visualization and predictions. In the final analysis, scientists, not computers, "design" drugs. CADD has two fundamental roles to play in drug research: *lead discovery* and *lead development*.

During the late 20th century, there were many case histories of accurate predictions of *in vitro* biological activity based on so-called *rational* drug design approaches. In the 1970s, Corwin Hansch demonstrated that simple regression statistics could be used to correlate biological activity indirectly to molecular structure through physical properties such as hydrophobicity ($\log P$), electronic (σ), and steric (E_s) effects (Chapter 2). The seminal contributions of Hansch demonstrated the power of QSAR and helped to usher in the era of computer-based modeling for molecular design. Beginning in the 1980s, there were many reports of computer-based predictions of *in vitro* biological activity. This is not unreasonable, since there are fewer pharmacodynamic and pharmacokinetic variables to be considered with *in vitro* testing than with *in vivo* testing. The use of structure-based design has grown in importance since the early 1980s. Today, there are many examples of drugs on the market or in clinical trials for which computer-based methods, particularly structure-based drug design, have played central roles in their development.

No single chapter can provide all the detailed information necessary to master this specialty, which ranges from quantum physics to 3D database searching. Many of the subtopics discussed have had entire books or series of books devoted to them, and a complete discussion of each topic is simply beyond the scope of this chapter and the purpose of the book. Instead, the goal of this chapter is to provide a brief and accurate overview of a select set of computational chemistry and CADD methods, highlighted with examples when appropriate. In some cases, the concepts are simplified or generalized to make sense of them in a few pages, but this is done without sacrificing accuracy so that the interested reader can continue future studies with a solid foundation in the fundamentals. Finally, computer-based methods do not replace experimental methods. In fact, the purpose of CADD is to aid pharmaceutical scientists in the discovery process, whether through simple visualization or the complex formulation of a pharmacophore model and statistical modeling.

COMPUTER GRAPHICS AND MOLECULAR VISUALIZATION

Ever since chemists have recognized that molecules are made up of atoms, there have been efforts to represent molecular structures accurately. One of the first attempts to develop molecular models can be traced to the early 1800s when John Dalton used wooden spheres drilled with holes to accept metal rod linkers as representations of atoms and chemical bonds, respectively. The original mechanical models are on display at the London Museum of Science.^{1,2}

Prior to computer graphics, the fundamental principles now associated with CADD (or molecular modeling) were used for some landmark discoveries in structural biology. Unquestionably, one of the most widely recognized scien-

tific achievements was the construction of a DNA model proposed by Watson and Crick in 1953.³ The structure has withstood the test of time, leading to a shared Nobel Prize for Watson and Crick and setting the stage for the age of biotechnology. Initially, crude models were crafted from cardboard. Once a better understanding of the structural requirements of the nucleic acids was developed, more accurate physical models were prepared from metal. Originally, the incorrect tautomeric forms of the heterocyclic bases were used. The incorrect tautomeric forms did not lead to any viable models of DNA, but once Watson and Crick learned that the older literature was in error, they had new nucleic acid models prepared based on the new structural data. With the correct physical models, coupled with their knowledge of the experimental data associated with DNA, they were able to construct the double helical structure⁴—an excellent example of the power of Tinkertoy sets in the right hands.

The modeling principles used by Watson and Crick to arrive at the correct representation of DNA were previously used by Linus Pauling, who correctly predicted that proteins would adopt α -helix or β -sheet conformations.⁵ Pauling suggested that solid molecular models would assist in understanding molecular structure, particularly protein structures. Solid models, in which the atomic sizes of the constituent atoms are designed accurately to reflect the relative sizes (the van der Waals radii), were prepared according to International Union of Pure and Applied Chemistry (IUPAC) guidelines. These space-filling molecular models, known as CPK models,⁶ became commercially available. They have been used around the world to help understand the molecular shapes of proteins and nucleic acids and their interactions with small drug-like molecules.

Commercially available handheld mechanical models became popular after the impressive structural predictions of the α -helix and β -sheet conformations for proteins, as well as the double helix for DNA. During this time, building on the work of earlier generations, Sir Derek Barton, Ernest Eliel, and others demonstrated the importance of conformational and stereochemical effects for small organic molecules. Medicinal chemists used these models and empirically derived rules to develop hypotheses for drug-receptor interactions. Wooden ball-and-stick models were used by high school and college students to help visualize organic structures. Accurate metal Dreiding and Kendrew models are still useful.^{7,8} These physical models have the advantage that medicinal chemists can hold them, manipulate them, and get a better feel for the structural flexibility. Nevertheless, large macromolecular models usually had to be supported by scaffolding, and they were notoriously troublesome to modify and manipulate. Imagine the difficulties associated with modeling the intercalation of small potential lead structures into DNA. The DNA structure would have to be cranked open mechanically, and the small potential intercalators would have to be inserted and manipulated by hand to get the best fit as determined by visual inspection.

Manipulation of computer models is much superior to the use of traditional physical models (as long as the electricity is flowing). Mathematical models using quantum mechanics or force field methods (see below) better account for the inherent flexibility of molecules than do hard sphere physical models. In addition, it is easy to superimpose one or more molecular models on a computer and to color each structure

separately for ease of viewing. Medicinal chemists use the superimposed structures to identify the necessary structural features and the 3D orientation (pharmacophore) responsible for the observed biological activity. The display of the multiple conformations available to a single molecule can provide valuable information about the conformational space available to drug-like molecules. Rather than measuring bond distances with a ruler, as was done years ago with handheld models, it is relatively easy to query a computer-generated molecular display. Because the coordinates for each atom are stored in computer memory, rapid data retrieval is achieved. Moreover, the shape and size of a molecular system can be visualized and quantified, unlike the situation with handheld models, when only visual inspections are possible. Exactly how much energy does it cost to rotate torsion angles from one position to the next? Understanding drug volumes and molecular shapes is critically important when defining the complementary (negative volume image) receptor sites needed to accommodate the drug molecule.

In the 1970s, major advances were made by computer scientists because of increasing computer speeds, which allowed the generation of computer models analogous to the handheld mechanical models. Interestingly, the growth of computer graphics software was driven by the need to have computer-assisted design (CAD) tools for the aircraft manufacturing industry. In the early 1980s, software companies emerged that developed and sold model-building software to the pharmaceutical and agrochemical industries. Today, there are many different software companies that specialize in the interactive manipulations of computer-based molecular images.

High-resolution computer graphics have revolutionized the way drug design is carried out. Once a molecular structure has been entered into a molecular modeling software program, the structure can be viewed from any desired perspective. The dihedral angles can be rotated to generate new conformations, and functional groups can be eliminated or modified almost effortlessly. As indicated above, the molecular features (bond lengths, bond angles, nonbonded distances, etc.) can be calculated readily from the stored 3D coordinates. Significant work by computer scientists has been invested into giving the illusion that flickering computer images are physical 3D objects. With special viewing glasses, 3D computer images can be seen. These are relatively inexpensive and lead to impressive results. The basic idea is that the computer generates two colored images (most commonly green and red) and each structure can only be viewed by one eye. Alternatively, viewing headgear may be worn such that each lens in the glasses is synchronized with the computer monitor to open and shut. To give the illusion of 3D representations, a special optical technique known as depth cueing is used. In this method the brain is tricked into believing that slightly dimmer objects are farther away, while brighter objects are closer. Another approach is to have the molecular structure slowly rock back and forth.

Since the 1970s, the cost of hardware has decreased and the power of computers has increased dramatically. These impressive hardware advances, coupled with advances in software and more efficient algorithms, have made computer-based modeling accessible to anyone. At one time, CADD was the exclusive domain of industry and some specialized academic laboratories. Expensive computer graph-

Figure 28-1 ■ Dorzolamide (Trusopt), the first FDA-approved drug to be designed by structure-based methods, is a carbonic anhydrase inhibitor that is used to lower ocular pressure in glaucoma patients.

ics workstations dominated. Today, the power of personal computers makes them an appealing and affordable alternative. Many standard molecular modeling software packages are being ported to run on personal computers, and the cost of computer graphics technology is decreasing because of the demand of the video game market.

Molecular structures can be represented in many different ways, depending on the properties one decides to highlight. Dorzolamide (Fig. 28-1) is a good example of a drug that involved CADD methods in its development.⁹ Figure 28-2 shows a standard representation of dorzolamide from a molecular modeling software package. The atoms can be color-coded in various ways according to the different properties that one might want to highlight. The representation in Figure 28-2 shows the connectivity of the atoms in dorzolamide that one might use during molecular modeling. As noted above, however, it is important to know the size and shape of the molecule. Various representations are possible. One is a CPK solid representation, but insight into the atomic

Figure 28-2 ■ A computer-generated representation of dorzolamide (Trusopt). Rather than a ball-and-stick representation, dorzolamide is shown as a tube representation with color-coded atom types. The structure has been energy minimized with the MMFF94 force field in the Sybyl (Tripos, Inc.) molecular modeling software package.

connectivity is difficult with opaque surfaces. Another convenient visualization technique is to have the atoms and bonds displayed simultaneously with the van der Waals surface represented by an even distribution of dots. These dot surfaces are convenient, in that the atomic connectivity is shown along with the appropriate size and shape of the molecular surface. As computer graphics technology has improved, it has become possible to represent the surface as a translucent volume, shown in Figure 28-3, in which the molecular structure appears to be embedded in a clear gelatin material.

Finally, computer graphics images of drug-receptor interactions, whether taken from x-ray crystal data or *in silico* generated, provide insight into the binding interactions, as shown in Figure 28-4. A full display of all the atomic centers in a protein structure gives too much detail. Most commonly, as shown in Figure 28-4, a ribbon structure traces the backbone of the protein main chain.¹⁰ The Richardson approach is another commonly used display to highlight secondary structural features, in which cylinders denote α helices, arrows denote β sheets, and tubes are used for coils and turns.¹¹

Because drug molecules make contact with solvents and receptor sites through surface contacts, it is paramount to have accurate methods to represent molecular surfaces correctly. Algorithms have been developed for such purposes, and they continue to be improved. The most straightforward way to represent a molecular shape is by the so-called van der Waals surface, in which each constituent atom contributes its exposed surface to the overall molecular surface. Each atom is assigned a volume corresponding to its van der Waals radius, and only the union of atomic spheres con-

Figure 28-3 ■ Another computer-generated representation of dorzolamide (Trusopt). The structure has been energy minimized with the MMFF94 force field in the Sybyl (Tripos, Inc.) molecular modeling software package and is displayed with a superimposed translucent van der Waals surface. Such representations have the advantages of showing both the atomic connectivity of the molecular structure and its 3D shape and size.

tributes. These van der Waals surfaces have small crevices and pockets that cannot make contact with solvent molecules. Another surface, known as the solvent-accessible or Connolly surface, can be generated.¹² The algorithm takes the van der Waals surface and rolls a sphere, having the volume of a water molecule with a radius of 1.4 Å, across it. Wherever the sphere makes contact with the original surface, a new surface is created. This expanded surface is a more realistic representation of what water molecules contact. Another similar solvent-accessible surface is known as the Lee and Richards surface.¹³ This surface is constructed in an analogous way, with a sphere rolled over the van der Waals surface, but the boundary is taken as a line connecting the center of mass of the sphere from point to point. Also, it is possible to calculate the solvent-excluded surface. The polar and nonpolar surface areas can be used as QSAR descriptors (Chapter 2), and many computer models for solvation use solvent-accessible surface areas (SASA). Commonly, the electrostatic density may be displayed on the surface of a molecular structure, providing an easily recognized color-coded grid that may be used to infer the complementary binding functional groups of the putative receptor.

COMPUTATIONAL CHEMISTRY OVERVIEW

Colorful molecular graphics images are based on the foundations of computational chemistry. Computational chemistry methods, which may be defined as the use of theory and computer technology to calculate molecular properties, are widely used in academia and industry to gain insights into complex problems. In many cases, computational chemistry

is used to rationalize experiments and to help make sense of the massive amount of data generated. Such practices are important to answer the *why* of chemical and biological phenomena. The greatest potential power of computational chemistry, however, is in the domain of making *predictions* prior to experimental work. Computer experiments are ideally suited to help answer questions that are difficult—and sometimes impossible—to answer by experiments alone. Just what kind of predictions can be made? Energy-based calculations have been used to predict and to understand molecular geometry, chemical conditions, chemical reaction pathways, and transition states, as well as physical, ADME, and biological properties. Usually, computer simulations are less expensive and require less time than carrying out physical experiments.

In general, *computational chemistry* refers to energy-based methods. *CADD* is a more all-encompassing term, including not only energy-based calculations but also QSAR, database searching, and pharmacophore perception methods. Computational chemistry approaches can be divided into two broad categories: quantum mechanics-based and classical mechanics-based. The former covers the areas of semiempirical, *ab initio*, and density functional theory. The latter refers to force field (molecular mechanics) calculations and molecular dynamics simulations. Each method has its strengths and weaknesses, and it is important to be aware of these. From the practical standpoint of a pharmaceutical scientist, whichever approach gives reliable answers in the shortest time is typically used. The trick, obviously, is knowing when it is appropriate to use one method over another. This understanding comes in time through practice, just as an organic chemist can “push” electrons to solve or rationalize complex reaction mechanisms almost instinctively.

The Born-Oppenheimer theorem is a good starting point.¹⁴ The theorem basically states that electrons move in a stationary field of nuclei; and therefore, the electron and nuclear motions can be considered separately. This approximation is valid in most cases of interest to medicinal chemists, since on the time scale of electron motion, the nuclei do not move. The difference in speed is a consequence of the differences in mass of the electron and the particles within the nucleus. It is analogous to speedboats circling a heavy aircraft carrier. On the time scale of the speedboats, during a brief snapshot of time, the aircraft carrier is motionless relative to the lighter craft. These facts, summarized in the Born-Oppenheimer theorem, enable successful use of the various mathematical models used in quantum mechanics and force field-based methods.

Quantum mechanics involves optimizing the electron distributions within molecules. Theoretical physicists first proposed the foundations of quantum mechanics in the 1920s.¹⁵ There were only a few cases where exact solutions existed. More typically, approximate methods had to be used.¹⁶ Although the theory has developed and improved, greater attention began to be placed on computational quantum chemistry in the 1950s when the first commercially available computers were introduced. Once computers became more available to the scientific community, solving problems with computational chemistry became realistic.^{17, 18} Force field methods, on the other hand, ignore the electronic distribution and concentrate on the motion of nuclei as if they behaved

like a ball-and-spring model, with potential energy functions used to describe the forces holding nuclei together. These methods were shown to be viable in the 1940s.^{19–21}

For several reasons, this chapter focuses on force field rather than quantum mechanics methods. First, most medicinal chemistry applications are more amenable to this treatment. Second, most energy-based methods used in molecular modeling software are based on force fields—from conformational searching to scoring functions for drug–receptor fits—and it is critical to have a grasp of the fundamentals. Third, force field methods are conceptually easier to understand, and the mathematics is not as complicated. Finally, for large macromolecular systems with solvation, force field calculations are the only practical way to proceed, given the differences in computer time between classical-based and quantum-based computations.

FORCE FIELD METHODS

Force field methods are not a recent development; in fact, they have a long history. Three independent groups working on different problems reported the first calculations in 1946.^{19–21} Of the three papers, the description of biphenyl derivatives examined by Frank H. Westheimer most effectively showed how to solve a problem convincingly.¹⁹ In the early years, the force field or molecular mechanics calculations were known as the *Westheimer method*. Westheimer is considered the father of molecular mechanics. Force field methods were not actively developed until the 1960s and 1970s, as commercial computers were becoming more common. A number of academic research groups began to explore force field calculations as a way to help solve problems of interest. The investigations ranged from small strained organic structures to protein simulations. Most of the current force fields can trace their roots to common sources developed in the 1970s.^{22–24}

Force field calculations rest on the fundamental concept that a ball-and-spring model may be used to approximate a molecule.^{25, 26} That is, the stable relative positions of the atoms in a molecule are a function of through-bond and through-space interactions, which may be described by relatively simple mathematical relationships. The complexity of the mathematical equations used to describe the ball-and-spring model is a function of the nature, size, and shape of the structures. Moreover, the fundamental equations used in force fields are much less complicated than those found in quantum mechanics. For example, small strained organic molecules require greater detail than less strained systems such as peptides and proteins. Furthermore, it is assumed that the total energy of the molecule is a summation of the individual energy components, as outlined in Equation 28-1. In other words, the total energy (E_{total}) is divided into energy components, which are attributed to bond stretching ($E_{\text{stretching}}$), angle bending (E_{bending}), nonbonded interactions ($E_{\text{nonbonded}}$), torsion interactions (E_{torsion}), and coupled energy terms ($E_{\text{cross-terms}}$). The cross-terms combine two interrelated motions (bend–stretch, stretch–stretch, torsion–stretch, etc.). The division of the total energy into terms associated with distortions from equilibrium values is the way most chemists and biological scientists tend to think about molecules.

$$\begin{aligned}
 E_{\text{total}} = & \sum_{\text{bonds}} E_{\text{stretching}} + \sum_{\text{angles}} E_{\text{bending}} \\
 & + \sum_{\text{nonbonded}} (E_{\text{VDW}} + E_{\text{electrostatics}}) \\
 & + \sum_{\text{dihedrals}} E_{\text{torsion}} + \sum E_{\text{cross-terms}} \quad (\text{Eq. 28-1})
 \end{aligned}$$

In the 1600s, Robert Hooke, the scientific rival of the famous Sir Isaac Newton (who among his many scientific contributions invented the calculus, developed a theory of gravitation, and formulated classical mechanics), proposed that if an ideal spring with an attached mass m was compressed or stretched from its equilibrium position by an external force (\vec{F}_{ext}), the spring would exert a restoring force ($\vec{F}_{\text{spring}} = -\vec{F}_{\text{ext}}$) of equal magnitude but in the opposite direction of the distortion. This is an example of Newton's third law: For every action, there is an equal and opposite reaction. For simplicity, it may be assumed that the spring lies along the x axis, where the equilibrium length corresponds to x_0 . The position x_0 may be considered the "natural length" of the relaxed spring. Figure 28-5 shows the setup for the classic one-dimensional harmonic oscillator.

Hooke's law for a one-dimensional oscillator oriented along the x axis may be written in mathematical form according to Equation 28-2, where x and x_0 are the distorted and the equilibrium positions, respectively. (Note that in Equation 28-2, \vec{x} is used to symbolize that the displacement is a vector quantity, which alternatively could be represented as $\hat{x}\hat{i}$, where \hat{i} is a unit vector in the x axis.) If there are no frictional forces present, then the kinetic and potential energies are said to be *conserved*. As shown in Equation 28-3, if we can express the force, \vec{F} , as the first derivative of the potential energy, E , with respect to the displacement, then we have a conservative system (i.e., the kinetic and potential energy equal a constant).

$$\vec{F} = -k(\vec{x} - \vec{x}_0) \quad (\text{Eq. 28-2})$$

$$\frac{dE}{dx} = -\vec{F} \quad (\text{Eq. 28-3})$$

From elementary physics, the dot product of the force and displacement is defined as the applied work from the surroundings. This external work is the energy required to distort the spring, Equation 28-4. An extension of Newton's third law implies that the spring requires an equal amount of work to be restored, Equation 28-5. Note that work is a scalar quantity. The negative and positive signs assigned to the work reflect whether the surroundings are doing work

Figure 28-5 ■ A simple one-dimensional ball-and-spring (x axis) oscillator serves as a model for bond vibrations.

on the system (positive) or whether the system is doing work on the surroundings (negative).

According to Hooke's law, the restoring force is proportional to the displacement $-k(\vec{x} - \vec{x}_0)$. Therefore, substitution of Equation 28-2 into Equation 28-5 yields Equation 28-6. Recognizing that the work applied to the system is now the total energy of the system, we generate Equation 28-7.

$$W_{\text{surroundings} \rightarrow \text{system}} = \vec{F}_{\text{external}} \cdot d\vec{x} \quad (\text{Eq. 28-4})$$

$$W_{\text{system} \rightarrow \text{surroundings}} = \vec{F}_{\text{internal}} \cdot d\vec{x} = -\vec{F}_{\text{external}} \cdot d\vec{x} \quad (\text{Eq. 28-5})$$

$$W_{\text{system} \rightarrow \text{surroundings}} = -[k(\vec{x} - \vec{x}_0)] \cdot d\vec{x} \quad (\text{Eq. 28-6})$$

$$dE_{\text{system}} = k(\vec{x} - \vec{x}_0) \cdot d\vec{x} \quad (\text{Eq. 28-7})$$

Taking the integral of Equation 28-7, where the displacement goes from x_0 to x , with a corresponding energy change E_1 to E_2 , gives Equation 28-8.

$$\int_{E_1}^{E_2} dE = k \int_{x_0}^x (x - x_0) dx \quad (\text{Eq. 28-8})$$

Integration of Equation 28-8 yields Equation 28-9, where c is the integration constant.

$$\Delta E = E_2 - E_1 = \frac{1}{2}k(x - x_0)^2 + c \quad (\text{Eq. 28-9})$$

Equation 28-9 can be simplified by noting that E_2 is the energy corresponding to the distorted spring at position x , whether this is stretching or compression. The energy E_1 can be defined as our zero potential energy when $x = x_0$ relative to any distortion. This means that by our choice of zero potential energy, the integration constant must be zero, $c = 0$, which can clearly be seen if no distortion, $E_2 - E_1 = 0$, occurs. Finally, Equation 28-10 is the generalized one-dimensional potential energy function for stretching and compression of a spring. Note that the ΔE notation has been dropped, since E_1 is defined as the zero energy position. Equation 28-10 is a quadratic function. Figure 28-6 shows the plot of a simple quadratic function with

$$E = -\frac{1}{2}k(x - x_0)^2 \quad (\text{Eq. 28-10})$$

Figure 28-6 ■ A plot of $f(x) = x^2$. This function, in the form of Hooke's law, has been applied successfully in force field calculations to model bond distortions (stretching and compressing).

The distortion of a one-dimensional ball-and-spring model along the x axis can be generalized into the 3D case, where in effect we have replaced x with r and x_0 with r_0 . With Equation 28-11, the spring does not depend on being placed along one axis; it may be oriented in any direction. As pointed out above, Equation 28-11 is a quadratic function, used to describe stretching motions in most of the macromolecular force fields (e.g., AMBER^{27–30} and CHARMM⁴¹).

$$E_{\text{stretching}} = \frac{1}{2} k_{\text{stretch}} (r - r_0)^2 \quad (\text{Eq. 28-11})$$

The use of a quadratic equation to mimic a chemical bond means that distortion and compression are equivalent in terms of an energy penalty. Think about what the quadratic model suggests: Compression and stretching result in equal increases in energy. This does not make sense physically, since for a diatomic molecule, compression brings the two atoms together, while distortion separates them. It is well known that bond distortion is anharmonic, so immediately we see a flaw in our model, which becomes more obvious in trying to reproduce bond distortions for strained molecules. The energy associated with bond stretching is described by a Morse curve, which is similar to a quadratic function only in the region close to the r_0 (Fig. 28-7). The relatively nondistorted bond lengths, which are characteristic of proteins, fall in the region where the Morse and quadratic functions overlap reasonably well. This is why simple quadratic terms may be acceptable as a first approximation in macromolecular calculations. In fact, given the complexity of nature, it is remarkable that a simple Hooke's law potential energy function works as well as it does.

For small strained organic molecules, more complex equations are usually necessary. Morse curves typically are not used in force field calculations. One approach that takes into

account the anharmonicity associated with bond stretching relies on power series approximation. The Morse curve may be expanded into a power series function around the equilibrium position. Such expansions follow a well-known mathematical stratagem embodied in the Taylor series expansion, shown in Equation 28-12, where the expansion occurs about the position a . Complex curves may be approximated by power series. There are many advantages to having a function expressible as $(x - a)^n$, including ease of computation and ease in taking derivatives, which is why a Morse curve is not used directly via force field calculations.

$$f(x) = f(a) + \frac{f'(a)}{1!} (x - a) + \frac{f''(a)}{2!} (x - a)^2 + \dots + \frac{f^{(n)}(a)}{n!} (x - a)^n \quad (\text{Eq. 28-12})$$

Expanding the Morse curve into a Taylor series using the formula outlined in Equation 28-12 generates Equation 28-13. The first term in the series is a constant, and this may be set equal to zero. The second term in the series may be recognized as the gradient, which stated above without proof and shown in Equation 28-3, is defined as the negative force for conserved systems. At the equilibrium bond length, r_0 , the force is equal to zero, which means that the second term is also zero. Therefore, the first two terms in this expansion vanish. The first nonvanishing term in the series is the third term, which is a quadratic term, equivalent to Hooke's law. The fourth and fifth terms correspond to cubic and quartic terms, respectively, in Equation 28-13.

$$E = k_0 + \frac{k_1}{1} (r - r_0) + \frac{k_2}{2} (r - r_0)^2 + \frac{k_3}{6} (r - r_0)^3 + \frac{k_4}{24} (r - r_0)^4 + \dots \quad (\text{Eq. 28-13})$$

The higher terms can be considered corrections to the quadratic term, which is only a first approximation to bond distortion. New force constants, $k_3^* = k_3/3$ and $k_4^* = k_4/12$, can be defined, giving Equation 28-14. The use of the quadratic function alone is known as the harmonic approximation.

$$E_{\text{stretching}} = \frac{k_2}{2} (r - r_0)^2 + \frac{k_3^*}{2} (r - r_0)^3 + \frac{k_4^*}{2} (r - r_0)^4 \quad (\text{Eq. 28-14})$$

Figure 28-7 ■ In force field calculations, different levels of approximations are used to reproduce the stretching and compression of chemical bonds. The plot shows a Morse potential energy function superimposed with various power series approximations (quadratic, cubic, and quartic functions). Note that the bottoms of the curves, representing the bond length for most chemical bonds of interest to medicinal chemists, almost overlap exactly. This nearly perfect fit in the bonding region is the reason simple harmonic functions can be used to calculate bond lengths for unstrained molecular structures in the force field method.

MMFF94,^{32–36} developed by Thomas Halgren at Merck, is currently one of the most widely available force fields. It was developed with medicinal chemistry applications in mind and can be found in various molecular modeling software packages, including Syhyl (Tripos, Inc.),³⁷ Spartan (Wavefunction, Inc.),³⁸ PCMODEL (Serena Software),³⁹ and MacroModel (Schrödinger, Inc.).⁴⁰ The force field is robust and can deal with many diverse functional groups found in drug-like molecules, giving accurate answers for small molecules as well as macromolecules. MMFF94 rivals the accuracy of MM3,^{41–43} which is known as an excellent small organic molecule force field, as well as those results published for MM4.^{44–47} MM3, however, is restricted in its usefulness for medicinal chemistry applications because of limited parameterization. The MM4 force field, a subsequent version of MM3, has modified potential energy functions and an expanded number of cross-terms.⁴⁸ These additions should make MM4 more accurate than its predecessor. MM4 will probably suffer from shortcomings similar to those of

MM3, in terms of its ability to calculate diverse drug-like structures, because of the lack of parameters. Interestingly, MM4 has yet to be released publicly, even though it and MMFF94 were reported in 1996, at the same time, in back-to-back publications within the same journal volume. Because MMFF94 is so widely available, it is arguably the standard small molecule force field of choice at this time.

The MM3 and MMFF94 stretching functions may be written as outlined in Equation 28-15, where $\Delta r = r - r_0$, k_{stretch} is the force constant parameter, c_1 is a constant used to modify k_{stretch} , and 143.9325 is a conversion factor. Note that Equation 28-14 and Equation 28-15 are essentially the same but written in a different form. Equation 28-15 demands that the cubic and quartic force constants be scaled quadratic stretching constants.

$$E_{\text{stretching}}^{\text{MMFF94}} = 143.9325 \frac{k_{\text{stretch}}}{2} (\Delta r)^2 [1 + c_1(\Delta r) + c_2(\Delta r)^2] \quad (\text{Eq. 28-15})$$

Bending strains are treated in an analogous way in force field calculations. Any distortion in bond angles $\theta - \theta_0$ results in a rise in the energy. The increase in energy associated with angle bending may be treated effectively with simple quadratic terms (Eq. 28-16). Equations similar to 28-16 are found in AMBER, CHARMM, and related macromolecular force fields. The use of quadratic terms is just a first approximation applicable to unstrained systems, as seen in the case of bond stretching. Many small molecules require a more complex function. Equation 28-17 is the bending function used in the MMFF94 force field. Again, one can see that the first term is quadratic, while the second term is cubic. The latter may be considered a correction factor.

$$E_{\text{bending}} = \frac{1}{2} k_{\text{bend}} (\theta - \theta_0)^2 \quad (\text{Eq. 28-16})$$

$$E_{\text{bending}}^{\text{MMFF94}} = 0.043844 \frac{k_{\text{bend}}}{2} (\Delta \theta) [1 + c_3(\Delta \theta)^2] \quad (\text{Eq. 28-17})$$

To keep C_{sp^2} -hybridized centers planar, a special out-of-plane potential energy function is used. This is necessary because force fields are mechanically based and do not treat electrons explicitly. A simple solution regarding out-of-plane bending, found in some force fields, makes use of quadratic potential functions. The idea is simple and effective: Keep the central atom planar. For example and the sake of simplicity, consider formaldehyde. Because by definition three points define a plane, the two hydrogen atoms and oxygen atom (bonded to a carbonyl carbon) form a plane. Without some constraint, the carbonyl carbon will tend to move out of the plane defined by the two hydrogen atoms and the oxygen atom. The projection of the carbonyl carbon onto the plane forms a direct imaginary line, as shown in Figure 28-8. The incorporation of an energy penalty term using a simple quadratic function will achieve the desired purpose of keeping the center atom in the plane. The higher the out-of-plane bending constant, the less puckering will be observed. Equation 28-18 shows the simple form used, where k_{COP} is the out-of-plane bending constant and $d - d_0$ is the distance from the projection of the atom on the plane to the atom itself.⁴⁸

$$E_{\text{out of plane}} = \frac{k_{\text{COP}}}{2} (d - d_0)^2 \quad (\text{Eq. 28-18})$$

Figure 28-8 ■ To reproduce the out-of-plane bending motions for sp^2 -hybridized atoms, a quadratic penalty function is used to constrain the system to be planar. The sp^2 -hybridized atom forms a projection onto the plane defined by the three atoms directly bonded to it. For formaldehyde, the two H atoms and the O atom define a plane. The C_{sp^2} is constrained to be in the plane by the use of a quadratic function.

Some force fields use an improper torsion angle concept to constrain the central atom of a trigonal planar group. In the case of formaldehyde (Fig. 28-8), the improper torsion angle may be defined as $\text{H}-\text{C}_{\text{sp}^2}-\text{O}_{\text{sp}^2}-\text{H}$. Note the fact that there is no covalent bond between the oxygen and hydrogen; hence, the name *improper* torsion angle. The use of an improper torsion is an equivalent mathematical method and has the same effect of constraining the central atom to be in the plane as a function of $(\phi - \phi_0)^2$.

Atoms have size and shape. With handheld mechanical models, the size of an atom is invariant regardless of its chemical environment, whereas in reality the van der Waals radii behave as if they were soft spheres rather than hard spheres (i.e., more like marshmallows than wooden balls). One advantage of using computer-based energy calculations is the ability to treat the van der Waals radii more realistically by providing greater flexibility than one can achieve with physical models. Certainly, this approach differs significantly from any hard sphere model. The other important nonbonded energy term arises from electrostatic interactions. Having a good electrostatic model is important, particularly when one considers the significance of electrostatic forces in drug-receptor interactions. Equation 28-19 describes the nonbonded terms.

$$E_{\text{nonbonded}} = \epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - 2 \left(\frac{\sigma_{ij}}{r_{ij}} \right)^6 \right] + \frac{1}{4\pi\epsilon_0\epsilon} \left(\frac{q_i \cdot q_j}{r_{ij}} \right) \quad (\text{Eq. 28-19})$$

The first two terms within brackets define the van der Waals repulsions, which vary as $1/r^{12}$, and the London dispersion attractions, which vary as $1/r^6$.⁴⁹⁻⁵¹ The constant σ_{ij} is related to the size of the atom pair being considered, r_{ij} is the distance between the atom pairs, and ϵ_{ij} refers to the depth of the potential energy well. It is based on the Lennard-Jones 6-12 potential. Many force fields use functions of this type to describe steric interactions (Fig. 28-9). Only atoms with a 1.4 nonbonded relationship to one another (i.e., with three chemical bonds separating them) are included in these calculations. The bending and stretching terms include 1,3 nonbonded attractive and repulsion terms implicitly.

Hydrogen bonding may be treated as a special situation requiring a modified Lennard-Jones potential. The nonbonded calculations are the most time consuming, particularly if more complex terms are substituted for the $1/r^{12}$ repulsive part of the Lennard-Jones 6-12 potential, as found in MM3.

Figure 28-9 ■ When two atoms *i* and *j* are separated by infinite distance, there are no interactions between them. As two nonbonded atoms approach one another, two forces have to be considered. Attractive dispersion forces (London forces) result from the interaction of instantaneous dipoles on each atom *i* and *j*. As the nonbonded atoms continue to approach one another, a repulsive interaction overwhelms the attractive interaction, and the energy curve rises sharply. The two nonbonded atoms can reach an equilibrium position where repulsive and attractive forces balance. Different mathematical relationships have been used in force field calculations to reproduce the nonbonded steric interactions.

The third term in Equation 28-19 is Coulomb's law, where q_i and q_j are the charges on two nonbonded atoms *i* and *j*. The two charged atomic centers are not connected via a chemical bond and do not have a common single atom attached to atoms *i* and *j*. In other words, we are talking about 1,4- or greater relationships, as shown in Figure 28-10. The dielectric constant ϵ basically dampens the charge-charge interactions and is a function of the solvent. The greater the

Figure 28-10 ■ Two partially charged atoms *i* and *j*, not directly connected to each other or connected to a common atom (1,4-interactions or greater), exert an attractive or repulsive electrostatic interaction (depending on the charge) on each other. A Coulomb potential energy function is the most common way used in force field methods to calculate the charge-charge electrostatic energy. Coulomb's law is used in virtually all force fields with the exceptions of the original MM2 and MM3 codes. MM2* and MM3*, improved versions of the original codes, are found in the popular molecular modeling software program MacroModel developed by Clark Still and use charge-charge interaction terms.

value of the dielectric constant, the less electrostatic interaction exists between the atom pair. In a vacuum, the dielectric constant is 1.0; in water, the dielectric constant is approximately 80.

One of the major limitations of force fields has to do with the assignment of charges to each atomic center. There is no atomic charge operator in quantum mechanics. Atomic charges are determined quantum mechanically by using a population analysis. Consequently, there are many ways charges may be assigned. One popular way is to generate an electrostatic potential from high-level *ab initio* calculations (discussed below) and then fit the optimal point charge distribution on the atoms via least-squares methods. This approach has been used in AMBER.³⁰

As discussed above, most force fields assign point charges to atomic centers and use Coulomb's law. The most notable exception is MM2 and MM3; in both versions, a dipole-dipole scheme for uncharged molecular structures is used.⁵² For systems with a net charge, MM3 introduces functions capable of dealing with the additional charge-charge and charge-dipole interactions. Although there should be no difference between the two electrostatic schemes, having dipole-dipole, charge-charge, and charge-dipole terms requires more parameterization time. Improved MM2 and MM3 implementations found in MacroModel have eliminated the dipole-dipole scheme in favor of using point charges and Coulomb's law.

If the stretching, bending, and nonbonded terms were summed over all appropriate pairwise atom contributions within a structure, many important conformational effects in the simplest of hydrocarbons would not be reproduced. For example, Figure 28-11 shows the energy (kcal/mol) versus torsion angle ϕ profile for butane. The energy rises and falls during the rotation around the central $C_{sp^3}-C_{sp^3}$ bond as a function of the relative positions of the methyl groups. The peaks on the curve correspond to energy maxima, while

Figure 28-11 ■ Potential energy for butane. The energy (kcal/mol) is plotted on the *y* axis versus the torsion angle $C_{sp^3}-C_{sp^3}-C_{sp^3}-C_{sp^3}$, which is plotted on the *x* axis. There are three minima. The two *gauche* conformers are higher in energy than the *anti* conformer by approximately 0.9 kcal/mol.

the valleys correspond to energy minima. For butane, there are two different types of minima: one is for the *anti* butane conformation, and the other two correspond to the *gauche* butane conformations. The *anti* conformation is the global minimum, meaning it has the absolute lowest energy of the three possible low-energy conformations. The differences in the conformational energies cannot be attributed to steric interactions alone. Structures with more than one rotatable bond have multiple minima available. Knowing the permissible conformations available to drug-like molecules is important for design purposes. It turns out that another nonmechanical effect is needed to reproduce the potential energy curve for butane and other structures.

It has long been known that it requires energy for rotation about single bonds. One of the first conformational effects presented in organic chemistry courses involves the favorable H-C_{sp3}-C_{sp3}-H torsional orientations for ethane. The torsion angles are either *eclipsed* or *staggered*. In 1891, Bischoff proposed that ethane has a preference for a staggered conformation and the rotation in substituted ethanes was restricted.⁵³⁻⁵⁵ The H/H steric interactions alone cannot explain the energy difference. If restricted rotation was considered, Pitzer demonstrated that the calculated and observed entropies for ethane were identical.^{56, 57} The *staggered* conformation, where the C_{sp3}-H bonds are not aligned, is preferred because the electron densities in each bond are as far apart as possible. This energetically preferred orientation is reproduced by quantum mechanics calculations, but force field calculations need some equivalent function, since electrons are not treated explicitly but are treated indirectly via classical potential energy functions. For other saturated hydrocarbons, the potential energy terms are just extensions of the fundamental ethane curve with other nonbonded terms superimposed, according to Equation 28-1. In some cases, the energy required to rotate about single bonds is too great, locking structures into chiral conformations (atropisomers). Christie and Kenner first demonstrated restricted rotation in 1922 by resolving 2,2'-dinitrophenyl-6,6'-dicarboxylic acid into optically active isomers.⁵⁸

A solution successfully implemented to reproduce the ethane phenomena, as well as other effects, was accomplished with the introduction of a truncated Fourier series.^{59, 60} Although C_{sp3}-C_{sp3}-C_{sp3}-C_{sp3} and H-C_{sp3}-C_{sp3}-H dihedral angles prefer to be staggered, some torsion combinations prefer to be eclipsed.⁶¹ Molecular orbital theory has been used to explain the underlying chemical reasons. Carbonyl oxygens prefer to eclipse the α hydrogens or α carbons of alkyl groups (O_{sp2}=C_{sp2}-C_{sp3}-H or O_{sp2}=C_{sp2}-C_{sp3}-C_{sp3}), and the acyl oxygens of esters prefer to have the O-R groups aligned with the C=O bond (O_{sp2}=C_{sp2}-O_{sp3}-C_{sp3}). These bond alignment effects are reproduced adequately in force field calculations using a three-term truncated Fourier series (Eq. 28-20). Essentially, this torsion function introduces quantum mechanical effects into a classical ball-and-spring system, which transforms our model into a much more powerful tool, with a fraction of the computer costs in terms of CPU cycles compared with using quantum chemical calculations.

$$E_{\text{torsion}} = \frac{V_1}{2} (1 - \cos\phi) + \frac{V_2}{2} (1 - \cos 2\phi) + \frac{V_3}{2} (1 + \cos 3\phi) \quad (\text{Eq. 28-20})$$

Figure 28-12 ■ A plot of Equation 28-20 with $V_1 = V_2 = 0$, and V_3 is a positive number. Note that this curve has threefold symmetry. The third term in Equation 28-20 is used to reproduce ethane-like torsion profiles about single bonds.

It is illustrative to look at each of the three terms in Equation 28-20 for a full appreciation of how a three-term Fourier series can be used to affect conformational equilibria. Figure 28-12 shows the plot of energy versus dihedral angle rotation with the V_1 and V_2 constants set to zero, and V_3 assigned a positive value. The curve has threefold symmetry. The maxima occur at dihedral angles of 0°, 120°, and 240°; the minima occur at dihedral angles of 60°, 180°, 300°, and 360°. Inspection of Figure 28-12 shows the similarity between it and the ethane torsion curve. Consequently, the third term describes the ethane effect without resorting to any complex calculations.

If the V_1 and V_3 terms are set to zero, plotting the second term shown in Figure 28-13, where V_2 is assigned a positive value in the truncated Fourier series, reveals its physical significance. There are minima at 0°, 180°, and 360° and maxima at 90° and 270°. Therefore, the second term in Equ-

Figure 28-13 ■ A plot of Equation 28-20 with $V_1 = V_3 = 0$, and V_2 is a positive number. Note that this curve has twofold symmetry. The second term in Equation 28-20 is used to reproduce ethylene-like torsion profiles about double bonds.

Figure 28-14 ■ A plot of Equation 28-20 with $V_2 = V_3 = 0$, and V_1 is a positive number. Note that this curve has onefold symmetry. The interpretation is less straightforward than the second and third terms in Equation 28-20. The first term in Equation 28-20 is used to help reproduce torsion curves of the following type, $X-C_{sp^2}-C_{sp^2}-X$ and $X-C_{sp^3}-C_{sp^3}-X$, where X is usually an electronegative element.

tion 28-20 is used to describe the torsional energy profile (arising about $C_{sp^2}=C_{sp^2}$ double bonds), which has twofold symmetry. The true underlying chemical explanation for the sharp energy rise observed in rotating about carbon-carbon double bonds may be attributed to the breaking of the weak π bond. The π bond is a consequence of the overlap of two adjacent coplanar p-orbitals. Any rotation about the $C_{sp^2}=C_{sp^2}$ bond shifts the orientation of the p-orbitals, with a reduction in the overlap and a concomitant rise in energy. For example, ethylene, the simplest alkene, prefers a flat conformation with the $H-C_{sp^2}-C_{sp^2}-H$ dihedral angles at either 0° or 180° . When the $H-C_{sp^2}-C_{sp^2}-H$ dihedral angle is 90° , the p-orbitals are orthogonal, and there is no overlap. Therefore, the energy is a maximum along the one-dimensional potential energy curve when $H-C_{sp^2}-C_{sp^2}-H$ is 90° .

The physical significance of the V_1 term is less intuitive. Setting the V_2 and V_3 terms to zero and assigning the V_1 term a positive value yields the curve shown in Figure 28-14. The V_1 term is used primarily as an additional way to increase the repulsive interactions between atoms that have a 1,4 relationship that are not fully accounted for by the nonbonded terms. This situation is commonly found for electron-withdrawing groups X and Y , with torsion combinations $X-C_{sp^3}-C_{sp^3}-Y$ and $X-C_{sp^2}-C_{sp^2}-Y$.

Radom, Hehre, and Pople were the first to give physical interpretations of these torsional terms.⁶² For maximum flexibility in developing force fields, it should be noted that the V_1 , V_2 , and V_3 terms may be either positive or negative. Although the discussion above focuses on carbon-carbon or carbon-hydrogen torsion angles, Equation 28-20 also applies to any other combination $i-j-k-l$, with any other elements from the periodic table used for i , j , k , and l . Given the number of drugs that have heterocycles, a force field useful for drug design has to address many torsion angle combinations.

Additional energy interaction terms may be added to im-

prove the accuracy of the force field description. Many of these additional terms fall into the category of cross-terms, in which two motions or interactions are connected or correlated. For example, in small molecule force fields one might find stretch-torsion, stretch-bend, bend-bend, torsion-bend, and other interactions. Equation 28-21 shows a stretch-bend function. Some of these cross-terms have been shown to be more important than others. The purpose of cross-terms is to give better geometric results, and they are particularly important in calculating the vibrational spectra.

$$E_{\text{stretch-bend}} = \frac{k_{sb}}{2} [(r - r_0) + (r' - r'_0)] (\theta - \theta_0) \quad (\text{Eq. 28-21})$$

Force field methods are fast and accurate if the potential energy functions and parameters within the potential energy functions have been carefully developed. In addition to calculating molecular geometry, force field calculations are used to determine the energy between conformations.

GEOMETRY OPTIMIZATION

It is important to be able to take a molecular structure in silico and subject it to energy minimization. This is the first step for force field and quantum mechanics calculations and for molecular dynamics simulations. Once a molecular structure finds a stable conformation, the physical and chemical properties can then be calculated. The goal of energy minimization (or geometry optimization) is to take a high-energy state, which is a function of the atomic coordinates, and to reduce the energy by optimizing the geometry. In other words, minimizing the potential energy functions with respect to the coordinates reduces the steric and electrostatic interactions. This is a type of calculus problem familiar to students who have ever had to locate the stationary points of a given equation. Recall that the extrema (maxima and minima) of a mathematical function $f(x)$, with one independent variable x , have first derivatives equal to zero, $f'(x) = 0$. The second derivative $f''(x)$ will be positive if it is a minimum and negative if it is a maximum. Figure 28-15 shows

Figure 28-15 ■ An arbitrary mathematical function with maxima and minima. The first derivative of a function is zero at a maximum or minimum, $f'(x) = 0$. The second derivative is positive ($f''(x) = +\text{value}$) if the stationary point is a minimum, or is negative ($f''(x) = -\text{value}$) if the stationary point is a maximum.

an example of a function, $f(x)$, with two minima and two maxima.

Typically, a molecular structure is entered into a molecular modeling software package by template fragments or through a sketching mode. It is also possible to download structures from structural databases. Structures built or downloaded do not have an optimum geometry based on the force field potential energy equations; i.e., they are not occupying the lowest energy state in vacuo. Minimization algorithms are written to take a starting structure and minimize the energy, which translates into the structure dropping into the nearest potential energy well on the conformational hyperenergy surface. The more complex the structure, usually the more minima are available in conformational space. Butane, a simple hydrocarbon, is an informative example. It has three minima available. Energy minimization requires a series of iterations because of the nonlinear nature of the force field potential energy functions. The general stratagem is to transform the full nonlinear optimization into a series of local iterative linearizations, and this approach works well. Atoms within a molecular structure are moved in small steps in the direction that results in a decrease in the energy of the system. The size and direction of the steps are determined by the specific method being used, based on Equation 28-3, and illustrated for a one-dimensional case in Figure 28-16.

Geometry optimization may be divided into two broad categories: first-order methods and second-order methods. The former uses first derivatives to determine the step size and direction, while the latter uses both first and second derivatives. First-order methods include *steepest descent* (SD) and *conjugate gradient* (CG). The second-order method discussed below is known as the Newton-Raphson (NR) geometry optimization approach; there are many variations of this method. Again, the concepts of minimizing a function are not new; they were developed years ago. (The "Newton" in Newton-Raphson is Sir Isaac Newton.) The immediate goal of an energy minimization is finding a suitable displacement δ_n , which, as stated above, is opposite to the potential energy gradient. In other words, the atoms are moved in the direction of the forces. The displacement is

added to the coordinates at each step and is updated by a quick recalculation of the force field total energy.

SD is the simplest approach.⁶³⁻⁶⁵ The step size in SD δ_n is simply taken as a scaled negative gradient as shown in Equation 28-22, where ∇ (del), a vector operator, is the gradient as defined by Equation 28-23 and λ is a scaling constant. The SD algorithm is inefficient when the potential energy curve is not very steep. So as the minimum is approached, where the slope of the curve is flatter, SD algorithms become inefficient compared with other methods.

$$\delta_n = -\lambda(\nabla_n E_{total}) \quad (\text{Eq. 28-22})$$

$$\nabla = \left(\frac{\partial}{\partial x} \hat{i} + \frac{\partial}{\partial y} \hat{j} + \frac{\partial}{\partial z} \hat{k} \right) \quad (\text{Eq. 28-23})$$

The CG method, outlined in Equation 28-24, is widely used.⁶⁶⁻⁶⁷ It gives better convergence than SD algorithms. As the name implies, the previous step size along with the current gradient as determined by the total force field energy is used to determine the next step size. An additional scaling factor c is found to improve results.

$$\vec{r}_{n+1} = \vec{r}_n + c\delta_n \quad (\text{Eq. 28-24})$$

The Newton-Raphson method uses information obtained by taking the first and second derivatives of the energy with respect to the coordinates.^{22,63} The combination of both first and second derivatives provides a powerful method to locate minima. This may be a time-consuming process because of the matrix manipulations that must be undertaken for a 3N system, where N is the number of atoms. In Equation 28-25, ∇^2 is the dot product of ∇ multiplied by itself. Note that ∇^2 is a scalar operator.

$$\delta_n = -\frac{1}{\nabla^2 E} (\nabla E) \quad (\text{Eq. 28-25})$$

$$\begin{aligned} \nabla^2 &= \nabla \cdot \nabla = \left(\frac{\partial}{\partial x} \hat{i} + \frac{\partial}{\partial y} \hat{j} + \frac{\partial}{\partial z} \hat{k} \right) \cdot \left(\frac{\partial}{\partial x} \hat{i} + \frac{\partial}{\partial y} \hat{j} + \frac{\partial}{\partial z} \hat{k} \right) \\ &= \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \quad (\text{Eq. 28-26}) \end{aligned}$$

None of the geometry optimization methods discussed finds the global minimum.

Figure 28-16 ■ The direction of the step size in an energy minimization is toward the minimum value.

CONFORMATIONAL SEARCHING

As indicated above, it is important to be able to explore conformational space to determine what arrangements of atoms (conformations) are energetically feasible. Observed physical properties (e.g., heats of formation) are statistical averages of all the conformations available. Most organic molecules have multiple energy minima. In the case of drug design, it may be important to sample the possible number of conformations a drug molecule can adopt. Usually, a drug in the drug-receptor complex adopts a *bioactive conformation* that differs from any of the local minima or the global minimum. From the analysis of many lead and drug pairs, the average drug-like molecule has more degrees of freedom (i.e., is more flexible) than lead-like compounds. Initially, this may seem counterintuitive, since the mission of a drug is to have its functional groups bind to complementary functional groups of the receptor. It turns out that a flexible drug is superior to one with a locked conformation because the exact orientation in a conformationally constrained molecule

may not be optimal for interactions with the receptor. Moreover, the potential superiority of a flexible drug can be understood when one considers that both receptor and small molecule must mold themselves to form the drug–receptor complex. A flexible drug can contort itself more easily to reach the binding pocket and then adjust itself accordingly to form the necessary interactions. A rigid drug with its functional groups locked into place may be more limited in its ability to get to the target site and, once there, to position itself correctly. Of course, based on the Koshland induced fit hypothesis, it is known that both small molecules and macromolecules adjust themselves to form protein–ligand complexes.

Before conformational searching is discussed in any detail, it is critical to have a common vocabulary. The terms *conformer* and *conformation* can be defined in reference to the butane potential energy curve (Fig. 28-11). There are an infinite number of conformations on the curve, since the distance between any two points on any curve may be as small as desired. *Conformations* refer to both maxima and minima and all positions in between. A *conformer*, on the other hand, refers to the conformation at the bottom of the potential energy well, which is a minimum. Looking at the simple case of butane, it is easily seen that there are three potential energy wells. Every molecular structure has a global minimum, the absolute lowest energy, but there are many minima. For butane, the global minimum corresponds to the *anti* conformer. One speaks of energy minimization, not energy optimization (discussed above), because the potential energy functions are being minimized, not the geometry. *Geometry optimization* is the equivalent term, for the structure is being *optimized* according to the force field equations.

Why is it necessary to explore conformational space? First, as discussed above, energy minimization algorithms are designed to seek the nearest minimum to the starting position. So for butane, if we had an initial input geometry in which the $C_{sp^3}-C_{sp^3}-C_{sp^3}-C_{sp^3}$ dihedral angle was 90° , the molecular structure would be energy minimized to the *gauche* conformer. If we started on the other side of the 120° barrier, where the $C_{sp^3}-C_{sp^3}-C_{sp^3}-C_{sp^3}$ dihedral angle was 150° , the molecular structure would be energy minimized to the *anti* conformer. Second, some conformations are more important than others. Third, as noted above, many physical problems are a consequence of a statistical average of the conformers present. Fourth, having a conformational search algorithm is a check against having biased structural data. In the case of butane, if only *anti* butane were known, there would be a lot of information missing. The majority of drug-like molecules are structurally more complex than butane, but this hydrocarbon is a straightforward example.

The importance of knowing available conformations for property predictions can be illustrated by looking at substituted cyclohexane. For cyclohexanol, the axial:equatorial ratio is derived by using Boltzmann statistics to calculate the ratio. Equation 28-27 shows the Boltzmann equation, where P_i is the probability of finding one conformation, f_i is a frequency factor indicating the degeneracy of the energy, E_i is the relative energy (kcal/mol), R is the gas constant (0.0199 kcal/mol-K), and T is the temperature (K). For room temperature calculations, the product RT is 0.59 kcal/mol. If one took a single conformation of axial cyclohexanol and compared it with a single conformation of equatorial cyclo-

hexanol, an erroneous answer would result. The right way to do the calculations is to look at all possible axial and equatorial conformations. With cyclohexanol, this is not difficult and can be done by manually altering the orientation of the OH group. For more complex structures, conformational searching routines must be used.

$$P_i = \frac{n_i}{\sum n_i} = \frac{f_i e^{-E_i/RT}}{\sum f_i e^{-E_i/RT}} \quad (\text{Eq. 28-27})$$

Table 28-1 shows the three possible axial and equatorial conformations. Substitution in Equation 28-27 generates the calculated ratio of each conformer. Because MMFF94 was parameterized to reproduce the quantum mechanical calculations, it is illustrative to look at the ratio calculated with MMFF94. The Boltzmann-averaged distribution may then be compared with the experimental data as well as the other force field results.

Equation 28-28 outlines the procedures for calculating the denominator in Equation 28-27. Note that in Table 28-1, entries 1 and 2 (as well as 4 and 5) are equivalent in energy, with relative conformational energies of 0.000 kcal/mol and -0.323 kcal/mol, respectively. Consequently, the frequency factor is 2 for both cases. The summation of Equation 28-28 is shown in Equation 28-29 to be 4.057.

$$\sum f_i e^{-E_i/RT} = (2)e^{\frac{-0.00}{0.593}} + (1)e^{\frac{-0.199}{0.593}} + (2)e^{\frac{-0.323}{0.593}} + (1)e^{\frac{-1.011}{0.593}} \quad (\text{Eq. 28-28})$$

$$\sum f_i e^{-E_i/RT} = 2.00 + 0.715 + 1.160 + 0.182 = 4.057 \quad (\text{Eq. 28-29})$$

The ratio for each entry in Table 28-1 can be calculated by using Equation 28-27. It is more interesting to look at the summation of the total calculated equatorial versus total axial cyclohexanol conformations, which, on a percentage basis, is calculated by Equations 28-30 and 28-31. MMFF94 results give approximately 67% equatorial and 33% axial. This is in close agreement with the Hartree-Fock (HF) 6-31G(d) quantum mechanical calculations of 66% equatorial and 34% axial, which is in reasonable agreement with experimental data. The calculated percentages with MM3 are 82% equatorial and 18% axial, while the calculated percentages with the Tripos force field yield 46% equatorial and 54% axial. In general, the Tripos force field is qualitative (at best) and does not give particularly good energy values, so one must be cautious when trying to make accurate predictions using force field methods.

$$P_{\text{equatorial}} \times 100\% = \left[\frac{\sum_{\text{equatorial}} f_i e^{-E_i/RT}}{\sum_{\text{all conformers}} f_i e^{-E_i/RT}} \right] (100\%)$$

$$= \left[\frac{2.00 + 0.715}{4.057} \right] (100\%) = 66.9\% \quad (\text{Eq. 28-30})$$

$$P_{\text{axial}} \times 100\% = \left[\frac{\sum_{\text{axial}} f_i e^{-E_i/RT}}{\sum_{\text{all conformers}} f_i e^{-E_i/RT}} \right] (100\%)$$

$$= \left[\frac{1.160 + 0.182}{4.057} \right] (100\%) = 33.1\% \quad (\text{Eq. 28-31})$$

TABLE 28-1 Three Axial and Three Equatorial Conformations of Cyclohexanol With Their Relative Energies Calculated Using Force Field (MMFF94, MM3, Tripos) and Ab Initio Quantum Mechanics (6-31G(d,p) or 6-31G)**

No.	Conformer	MM3	Sybyl	MMFF	HF
1		0.000	0.129	0.000	0.000

-ΔG		0.88	-0.09	0.42	0.40

The goal of conformational searching is to find all possible values of the dihedral angles that could be assigned to each rotatable bond in a molecular structure. Conformational searching may be divided into two general categories: *systematic* and *nonsystematic* searching. As the name implies, systematic searching uses methods that are guaranteed to find all minima within the defined search parameters, while nonsystematic searching uses statistical approaches. Systematic searching includes grid searching, torsion driving, and constrained searching. Nonsystematic searching includes dynamics, stochastic (random), and distance geometry.

Systematic searching has been described as an exhaustive sampling of conformational space,^{68, 69} but the success is a function of the number of increments used to explore each rotatable dihedral angle. No conformation will be overlooked (unless the search parameters are not small enough). A simple analogy should make this clear. Imagine walking along a paved highway blindfolded (not recommended) with the goal of discovering all possible potholes. The number of potholes that may be located is a function of the step size and the distance traveled. The longer the gait, the faster one travels down the road, but with a reduced probability of finding all the potholes. Systematic searching generally cannot handle solvents, and the method is only amenable to searching fewer than 10 dihedral angles, because of the exponential explosion of possible conformations that results (see Equation 2-30 in Chapter 2). Large amounts of computer time are expended because small dihedral angle increments are required for each rotatable bond.

In grid searching (GS), each torsion angle is examined, but the structure is not subjected to geometry optimization.

According to Equation 2-30, the number of conformations generated rises exponentially with the number of bonds rotated. Torsion angle driving is GS, while the rest of the structure (with the exception of the torsion being systematically rotated) is energy minimized. Many programs have this feature, and accurate conformational energies are obtained with the minimization.

Nonsystematic searching typically is more suitable for larger molecules, and solvents may be included.^{70, 71} In general, more time is necessary to apply statistical analyses for the "completeness" of a search. Although stochastic searches are useful, there is an inherent incompleteness to them. Stochastic searching can use either internal or cartesian coordinates. From a starting low-energy conformation, the cartesian coordinates are randomized with a "kick." If the randomization is not large enough, the structure will return to its starting points. Too large a perturbation generates unrealistic high-energy conformations. The randomized geometry is energy minimized with a force field, and the newly generated structure is compared with the original structure according to the Metropolis algorithm (MA).⁷² The current conformation is compared with the newly generated one. If the energy of the newly generated conformation is lower than the energy of the original conformation, the new one is accepted. If the new conformation has a higher energy, there is a statistical chance it may also be retained. In this second case, a Boltzmann factor is calculated (Equation 28-27), which is then compared with a random number between 0 and 1. If the Boltzmann factor is less than the randomly generated number, the conformation is accepted; otherwise, it is rejected.

With all methods, there are strengths and limitations. Conformational searching is no exception. A comparison of the methods was carried out on cycloheptadecane in an effort to find out "what conformations are significantly populated at room temperature or within, say 3 kcal/mol of the global minimum?"⁷³ The authors reached the following conclusions: (a) the effectiveness of the search appears to depend highly on the method used, and (b) except for distance geometry, all methods could locate the global minimum; none of the methods found all 262 low-energy conformations in a single search. Because of the importance of conformational searching, newer algorithms have been developed since this benchmark study.

The Confort algorithm, developed in the laboratory of Robert Pearlman, performs a systematic search over all possible combinations of "worthy dihedral angle ranges" rather than searching over all possible combinations of dihedral angles per se. Very fast partial optimizations are carried out for each such combination of dihedral angle ranges. Each of the torsion ranges generated by Confort brackets a single local minimum and is followed by energy minimization. Although still of exponential order, the number of increments used per rotor is typically between 2 and 4, thereby making the Confort algorithm extremely fast and enabling its use for searching rings and ring systems in addition to acyclic substructures.⁷⁴

Methods have been devised that alter the potential energy hyperspace, which have been useful in locating the global minimum. Second-derivative information, discussed above, indicates the curvature of the energy surface, which may be flattened or inflated, depending on whether the surface has a positive curvature (negative second derivative) or negative curvature (positive second derivative), respectively.⁷⁵

Genetic algorithms (GAs) have become popular for many applications in science, including the determination of possible conformations.⁷⁶ The widespread use of GAs may be attributed to their robust nature, simplicity, and computational efficiency. One approach to the stochastic sampling of the conformational energy hypersurface uses a GA with a fitness function that attempts to select dihedral angle values leading to low-energy conformers and, possibly, simultaneously attempts to select dihedral angle values corresponding to "diverse" conformations. Although GA-based search results are incomplete, the energies used to "score" various conformations are calculated in an appropriate fashion.⁷⁴

Another stochastic approach involves the "poling" algorithm,⁷⁷ which locates minima and artificially increases the conformational energy hyperspace until there are no minima at that location. The name is derived from the analogy of literally placing a pole in the energy well and pulling up the surface around the pole, like raising a circus tent. All methods that involve reshaping the potential energy hypersurface suffer from alterations to the surface being explored. The artificial increase in the conformational energy hypersurface near each low-energy conformation ensures that nearby conformations will not be selected. Although this approach is much faster than GA-based approaches, poling algorithms are often less reliable. They fail to find low-energy conformations because the conformations selected are based on artificially perturbed values of the conformational energy.

MOLECULAR DYNAMICS SIMULATIONS

The molecular configuration is a function of time. Molecular systems are not stationary; molecules vibrate, rotate, and tumble. Force field calculations and the properties predicted by them are based on a stationary model. What is needed is some way to predict what motions the atoms within a molecule will undergo at various temperatures. Molecular dynamics (MD) simulations use classical mechanics—force field methods—to study the atomic and molecular motions to predict macroscopic properties.⁷⁸

MD simulations have the potential to reveal important insights into drug–receptor interactions, but some important assumptions should be reviewed:

1. Molecular systems obey classical mechanics.
2. The forces acting on each atom are equal to the negative gradient of the potential energy.
3. The potential energy may be calculated from force fields.
4. The temperature is proportional to the velocity.
5. The time average is equal to the ensemble average, which is known as the ergodic hypothesis.

In applying classical mechanics to simulate molecular motion, it is necessary to use Newton's laws of motion. The three laws are summarized below:

1. *Law of inertia:* A body stays in motion or at rest unless acted on by outside forces.
2. *Fundamental definition of force:* mass \times acceleration.

$$\vec{F} = m \frac{d^2 \vec{r}}{dt^2} = m \vec{a} \quad (\text{Eq. 28-32})$$

3. *Law of action–reaction:* For every action, there is an equal and opposite reaction.

$$\vec{F}_{i \rightarrow j} = \vec{F}_{j \rightarrow i} = -\vec{F}_{i \rightarrow j} \quad (\text{Eq. 28-33})$$

Using Equation 28-32 as the starting point, the mass m may be eliminated and integrated with respect to time t according to Equation 28-34 to give Equation 28-35, where \vec{v} is the velocity and C is the integration constant. It is a simple matter to determine the integration constant. At the initial time, $t_2 = t_1$, which means that $\vec{a} \Delta t = 0$. Therefore, the integration constant must equal the initial velocity ($C = \vec{v}_0$).

$$\int \frac{d^2 \vec{r}}{dt^2} dt = \int \vec{a} dt \quad (\text{Eq. 28-34})$$

$$\frac{d\vec{r}}{dt} = \vec{v} = \vec{a}(t_2 - t_1) + C = \vec{a} \Delta t + \vec{v}_0 \quad (\text{Eq. 28-35})$$

Integration of Equation 28-35 provides the distance a particle has traveled from its initial position \vec{r} at time t to its new position $\vec{r}(t + \Delta t)$ at $t + \Delta t$ (Eq. 28-36).

$$\vec{r}(t + \Delta t) = \frac{1}{2} \vec{a} \Delta t^2 + \vec{v}_0 \Delta t + \vec{r}(t) \quad (\text{Eq. 28-36})$$

Equations 28-35 and 28-36 are known as Newton's equations of motion. MD simulations apply these two equations to all the atoms in a molecular structure. According to the kinetic-molecular theorem, the kinetic energy is proportional to the temperature. This remarkable relationship is shown in Equation 28-37 without derivation, where N is the number of molecules, k is the Boltzmann constant, and T is the abso-

lute temperature. Equation 28-37 connects classical physics to statistical mechanics. The basic idea behind MD simulations is to introduce heat into the system and adjust the velocities to maintain the temperature. The forces on the atoms can be calculated with a force field. Once the forces are known, based on Newton's celebrated second law (Eq. 28-32), the accelerations can be calculated. Using the laws of motion (Eq. 28-35 and 28-36), the velocities and new positions can be calculated. This procedure is repeated for the duration of the simulation.

$$\sum_{i=1}^N \frac{1}{2} m_i \langle \dot{r}_i^2 \rangle = \frac{3}{2} NkT \quad (\text{Eq. 28-37})$$

The fundamental steps in a MD simulation may be summarized:

1. Energy minimization
2. Heating
3. Equilibration
4. Production runs
5. Analysis

It is informative to review some of the information regarding MD time steps. It has been learned that the best time step should be 1/10th of the largest frequency in the system. The largest frequency is associated with bond vibrations. The largest frequency ($\nu_{\text{max}} = 10^{14} \text{ sec}^{-1}$) involves C-H bonds. Because the largest frequency is inversely proportional to the period of oscillation, the time step Δt is usually 10^{-15} sec or 1 fs. Longer simulation times may be achieved by a factor of 2 or 3 if the C-H bond vibrations are constrained. The SHAKE algorithm was developed whereby constraints are placed on the vibrations of C-H bonds.⁷⁹

When calculating protein structures, one must have a good solvation model. Because water plays a critical role in enzyme reactions and stabilizing proteins, it is important to have effective ways to model water. In the structure-based design of human immunodeficiency virus (HIV) inhibitors, for example, the presence of a single water molecule in the binding cavity was effectively exploited in structure-based drug design. There are essentially two ways to include solvent in MD simulations: (a) continuum solvent models and (b) explicit solvation models. In principle, the latter should give more accurate protein simulations, but it depends highly on the water model used.

The simplest continuum solvent model simply adjusts the dielectric constant to equal the medium dielectric. An approximation widely used in MD simulations is known as the distance-dependent dielectric constant. In this approach, the dielectric constant is set equal to the distance r_{ij} , as shown in Equation 28-38. The electrostatic energy is now proportional to $1/r^2$ rather than $1/r$. When this was first proposed, the idea was to help reduce CPU time. The rationalization is that the charges on two nonbonded atoms in a macromolecule are separated by the protein, which should reduce the interaction terms. Thus, the interaction energy should fall off faster than $1/r$ because the charges are masked.

$$E_{\text{electrostatic}} = \sum_{i < j} \frac{q_i q_j}{4\pi\epsilon_0 \epsilon(r_{ij})} = \sum_{i < j} \frac{q_i q_j}{4\pi\epsilon_0 r_{ij}^2} \quad (\text{Eq. 28-38})$$

The other approach is to treat the solvent explicitly. There are a number of water models available.⁸⁰ Two of the most

widely used water solvent models are SPC⁸¹ and TIP3P.⁸² In the former, the oxygen atom has a charge of -0.82 , and the hydrogens have a charge of 0.41 . The H-O-H angle is 109.5° , and the O-H bond length is 1.0 \AA . In the latter, the oxygen atom has a charge of -0.834 , and the hydrogens have a charge of 0.417 . The H-O-H angle is 104.5° , and the O-H bond length is 0.957 \AA .

To avoid potential water-vacuum interface problems that might arise in a MD simulation, periodic boundary conditions are commonly used.⁸³ Basically, a protein is surrounded by a rectangular box of water with a defined number of water structures. This water box is then surrounded on each face by another water box. When the MD simulation is being carried out, water near the edges of the central box containing the protein may leave and be replaced with a water coming from the water box on the opposite side. This procedure ensures that the waters inside the central water box remain constant.

The long-range forces found in the nonbonded terms of Equation 28-19 present some unique difficulties for a MD simulation. Calculating these energy terms is CPU intensive. One early solution was to impose 8- to 10- \AA cutoffs. Although this saved dramatically on the simulation times, unrealistic protein structures resulted after long runs. There were several potential workarounds, including longer cutoffs and updating these interactions beyond the standard cutoff less frequently.⁸⁴ A very attractive approach to circumvent this problem altogether, proposed by Darden, York, and Pedersen, used the particle mesh Ewald (PME) method.⁸⁵

Free energy perturbation (FEP) calculations^{86, 87} allow direct $\Delta\Delta G'$ comparisons between a drug D that binds to a protein P to form the drug-protein complex D-P and a structural analogue D' and the same protein P (see Fig. 28-17, which depicts the free energy perturbation cycle). Determining the free energies of binding, ΔG_1 and ΔG_2 , experimentally can be difficult and time consuming. Converting D into D', ΔG_3 , and D-P into D'-P, ΔG_4 , is experimentally fictitious. Such conversions would amount to alchemy. The conversions can, however, be carried out in silico.

Figure 28-17 ■ Free energy perturbation (FEP) calculations take advantage of a thermodynamic cycle. Here, the *top* reaction shows a drug D combining with a protein P to form the drug-protein complex D-P with a free energy change ΔG_1 . The *bottom* reaction shows another drug D' combining with an identical protein P to form a second drug-protein complex D'-P with a free energy change ΔG_2 . Both of these physically observable reactions have a free energy change, ΔG , associated with them. The free energy difference between the two drug-protein reactions is $\Delta\Delta G = \Delta G_2 - \Delta G_1$. According to the first law of thermodynamics (conservation of energy law), the fictitious conversions, ΔG_3 and ΔG_4 , must be related to the experimental $\Delta\Delta G$.

In a thermodynamic cycle, Equation 28-39 must hold, as the energy differences depend only on the initial and final states. Subtracting ΔG_3 and ΔG_1 from both sides of Equation 28-39 provides the rearranged Equation 28-40. Recognizing that $\Delta\Delta G = \Delta G_2 - \Delta G_1$, Equation 28-40 can be simplified to give Equation 28-41. This remarkable relationship, taking advantage of the thermodynamic cycle, indicates that the free energy differences based on *in silico* alchemy must be equivalent to the experimental $\Delta\Delta G$. The method has been used to calculate and compare the binding energies for many different drug–protein complexes. Although the approach is intellectually stimulating, it requires significant computer resources.

$$\Delta G_1 + \Delta G_2 = \Delta G_1 + \Delta G_4 \quad (\text{Eq. 28-39})$$

$$\Delta G_2 - \Delta G_1 = \Delta G_4 - \Delta G_3 \quad (\text{Eq. 28-40})$$

$$\Delta\Delta G = \Delta G_4 - \Delta G_3 \quad (\text{Eq. 28-41})$$

Another application of interest to medicinal chemists involves the thermodynamic perturbation cycle applied to relative property calculations. For example, directly calculating the solvation of a small drug requires extensive simulation times. The drug has to transfer from *in vacuo* into an aqueous environment. This transfer from the gas phase to the aqueous phase is CPU intensive, given that the solvent has to be reorganized to accommodate the solute. Calculating a second drug analogue will involve a similar process. Making use of a thermodynamic cycle, however, can expedite the process (analogous to the above discussion for the drug–protein binding).

There are two types of motion (harmonic and stochastic) that may be studied by MD simulations. *Harmonic simulations* refer to oscillations near equilibrium (i.e., near the minimum of a potential energy well). *Stochastic* refers to simulations that lead from one local minimum to another local minimum.

From a harmonic oscillator, the frequencies may be calculated according to Equation 28-42, where k is the stretching constant and m is the mass. Extending the concept from a single mass held to a surface by a spring to N particles requires an extension of the Taylor series expansion (Eq. 28-13) to a matrix formulation of partial second derivatives. Each mode has associated its own force constant, frequency, and $3N$ relative displacements. The normal modes are assigned to the experimental IR or Raman spectrum.

$$\nu = \frac{1}{2\pi} \sqrt{\frac{k}{m}} \quad (\text{Eq. 28-42})$$

MD simulations have been applied to generate new conformations.^{73, 88} The basic idea is to add enough thermal energy (through high temperatures) and carry out the simulations long enough for the molecular systems to overcome conformational barriers. After the simulations are completed, the trajectory can be reviewed. The temperature of the system can be cooled down to sample potential new conformations. MD simulations are suitable for larger molecules, and solvent may be included. No statistical or geometrical means are used to determine their completeness. In general, MD simulations are not as efficient as stochastic or distance geometry methods.

QUANTUM MECHANICS

One of the great theoretical accomplishments of the 20th century was the development of quantum mechanics.¹⁵ The philosophical interpretations of quantum mechanics may be considered weird from the standpoint of our practical everyday experiences in the macroscopic world. Nevertheless, the applications of quantum mechanics to chemical bonding have changed the way chemists think about molecular structures and have made chemistry a subdiscipline of physics. Many unexplained chemical effects may be understood in the context of molecular orbital (MO) calculations. For example, the anomeric effect seen in carbohydrate chemistry can be rationalized as a combination of MO interactions and electrostatic effects. Although chemists like to follow the example of G. N. Lewis and write simplified molecular structures (Lewis structures), molecules are really nuclei embedded in a sea of electrons. It is remarkable that so many organic structures can be represented, as a first approximation, by localized chemical bonds and lone pairs of electrons. As any student going through a course in organic chemistry can attest, chemical reactivity and physical properties may be explained, in many situations, by extending our simplified bonding concepts to include resonance and electron delocalization. Because most drugs (or organic molecules) and their interactions with macromolecules are responsible for the observed biological effects called “drug action,” it is quite reasonable to use theoretical MO methods to understand electron distributions and predict physical properties of drug-like structures. The only way this can be achieved is through the use of quantum chemistry, since force field methods do not explicitly treat electrons.

The history of quantum mechanics, while fascinating, is too lengthy to discuss here, as is a full development of the theory. The goal of this chapter is to present the concepts succinctly for readers who have never taken courses in physical chemistry, where these topics are more fully developed. The emphasis is on following the logical order of concepts, not on the mathematical details, which means some relationships have been simplified. With the fundamentals presented below, it is possible to understand the impact quantum mechanics has, and will continue to have, on medicinal chemistry. The sections that follow contain references to quantum mechanical applications in CADD.

We start with the contributions of Max Planck. At the beginning of the 20th century, physics was in a theoretical crisis. It was believed that Newton's equations and Maxwell's electromagnetic theory could explain all natural phenomena, but the application of these classical mechanics methods to the emission of electromagnetic radiation from perfect “black bodies” did not correlate with experiment. In the theoretical treatments, the radiation was assumed to result from the microscopic oscillators, and the inescapable conclusion of classical mechanics was that a continuous range of energies was available to the oscillator. Planck suggested in 1900 that the energy associated with oscillators was a function of integral values of quanta (Eq. 28-43), where E is the energy of the oscillator, h is Planck's constant (6.626×10^{-34} J-sec), and ν is the frequency. The suggestion worked, but many scientists of that period thought this solution was simply a mathematical trick, because the logical

extension meant that energy was available only in discrete quantum values and was not continuous.

$$E = h\nu \quad (\text{Eq. 28-43})$$

The quantum idea was used by Einstein to explain the photoelectric effect. When metal surfaces are subjected in vacuo to electromagnetic radiation of specific frequencies, electrons are released. The phenomenon could not be explained by classical mechanics. Einstein used the quantum concept to suggest that electromagnetic radiation was simply a stream of photons where Equation 28-43 correctly defined the energy. Using this quantum idea, Einstein formulated a relationship (Eq. 28-44) between the incident electromagnetic radiation and the expelled electrons. Einstein's work supported the Planck quantum theory. In this equation, Φ is called the work function, which is the minimum energy necessary to eject electrons from the metal surface. Some simple deduction, knowing that the kinetic energy $mv^2/2$ cannot be zero, requires that $\Phi = h\nu_0$; therefore, ν_0 is the minimum frequency allowed. (Interestingly, Einstein won the Nobel Prize for his contributions to understanding the photoelectric effect and related matters rather than for his theory of relativity.)

$$h\nu - \Phi = \frac{1}{2}mv^2 \quad (\text{Eq. 28-44})$$

Because light has particle-like characteristics, de Broglie argued that electrons should therefore exhibit wave-like characteristics. This is odd because it defies our macroscopic experiences. The wave-like character exists for all objects, but only manifests itself—for all practical purposes—with microscopic particles (e.g., electrons). The de Broglie relationship (Eq. 28-45) quantifies the wave-like properties that matter exhibits, where λ is the wavelength, h is Planck's constant, and mv is the momentum (mass \times velocity). Clearly, the relationship shows that for tiny masses, the wave property of matter is significant, whereas for large objects, the wave-like character is vanishingly small.

$$\lambda = \frac{h}{mv} \quad (\text{Eq. 28-45})$$

At this point in 20th century science, it was becoming accepted that matter had both wave-like and particle-like characteristics. Depending on the experimental setup, these seemingly contradictory properties could be observed. If matter has wave-like properties, then there had to exist some generally descriptive wave equation. It was Erwin Schrödinger who recognized that standing waves with imposed boundary conditions yielded sets of integers, which would be consistent with spectroscopic observations.⁸⁹⁻⁹¹ He developed the now famous Schrödinger wave equation (Eq. 28-46) for a single particle such as an electron in a 3D box. This equation is a linear (meaning the wave function is raised to a power greater than 1), second-order differential equation (meaning second derivatives are involved), where E is the total energy of the system, U is the potential energy, and $\psi_{el}(x,y,z)$ is the electronic wave function. (Different symbols are used routinely in the literature when discussing wave functions. In this chapter, lower-case psi, ψ , and upper-case psi, Ψ , are used to denote the wave functions for a single particle or a multiparticle system, respectively. Also, lower-case phi, ϕ , is used to represent atomic orbitals,

and lower-case chi, χ , is used for a spin orbital, which is defined below.)

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \psi_{el}(x,y,z) + \frac{8\pi^2m}{h^2}(E - U)\psi_{el}(x,y,z) = 0 \quad (\text{Eq. 28-46})$$

Equation 28-46 can be arranged to give Equation 28-47.

$$\frac{-h^2}{8\pi^2m} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \psi_{el}(x,y,z) + U\psi_{el}(x,y,z) = E\psi_{el}(x,y,z) \quad (\text{Eq. 28-47})$$

A more compact (and perhaps less offensive) form of the Schrödinger equation is given by Equation 28-48, where

$\hat{H} = -\frac{h^2}{8\pi^2m} \nabla^2 + U(x,y,z)$, ψ_{el} is understood to be a function of the x,y,z coordinates, and ∇^2 was defined earlier in Equation 28-26. (It is not necessary to demand that ψ be a function of cartesian coordinates. The choice of the coordinate system may be dictated by the nature of the problem being solved. In other words, it may be easier to solve a problem within a different reference frame. ψ_{el} may be a function of spherical polar, plane polar, or cylindrical coordinates or of other coordinate systems. For example, solution to the hydrogen atom involves the use of spherical polar coordinates.) \hat{H} is the hamiltonian operator, which is the quantum mechanical equivalent of the classical mechanics formulation $H = T + U$, where T is the kinetic energy and U is the potential energy. Note the similarities between the classical and quantum mechanical formulations of the hamiltonian.

$$\hat{H}\psi_{el} = E\psi_{el} \quad (\text{Eq. 28-48})$$

Equation 28-48 is the Schrödinger equation for a single particle. For the application of quantum mechanics to medicinal chemistry, it is necessary to think in terms of electrons moving around nuclei. The Schrödinger equation can be converted into a multiatom problem, given by Equation 28-49. In Equation 28-49, the hamiltonian is

$$\hat{H} = -\frac{h^2}{8\pi^2} \sum_i \frac{1}{m_i} \nabla_i^2 + \sum_i \sum_{j \neq i} \frac{e_i e_j}{|r_{ij}|}$$

The first term (kinetic energy) is a summation over all the particles in the molecule. The second term (potential energy) uses Coulomb's law to calculate the interaction between every pair of particles in the molecule, where e_i and e_j are the charges on particles i and j . For electrons, the charge is $-e$, while the charge for a nucleus is Ze , where Z is the atomic number. The summation notation $i < j$ for the indices means that one does not doublecount pairwise interaction terms in the summation (e.g., $e_i e_j = e_j e_i$ and should only appear in the potential energy term once). The denominator $|r_{ij}|$ in the second term is the distance between particles i and j . Ψ_{el} is understood to be the electronic wave function for a many-atom system.

$$\hat{H}\Psi_{el} = E\Psi_{el} \quad (\text{Eq. 28-49})$$

Originally, Ψ was thought to be a physical wave that was propagated through space. Today, Ψ^2 is more properly interpreted, from the work of Born who first made the proposal, as being proportional to the probability of finding a particle in a small volume element $d\tau$, where $d\tau = dx dy dz$. In the more general case, the probability is represented by $\Psi_i^2 \Psi$.

where Ψ is multiplied by the complex conjugate Ψ^* . The complex conjugate is necessary, in that the wave function may contain imaginary numbers. Because $\Psi^*\Psi d\tau$ represents the probability for a small volume element, it is possible to define Ψ_{el} such that the integral over all space is unity ($\int \Psi_{el}^* \Psi_{el} d\tau = 1$) through the appropriate choice of coefficients. The integral symbol is more complicated than it may appear. It really spans all of coordinate space, so for cartesian coordinates, the range goes from negative to positive infinity for each of the three x , y , and z coordinates. This means that Equation 28-49 is deceptive, since it involves solving a triple integral, $\iiint \Psi_{el}^*(x,y,z) \Psi^*(x,y,z) dx dy dz$. To be an "acceptable" Ψ_{el} , there are certain conditions that are required:

1. The wave equation must be well-behaved mathematically.
2. The equation must be a continuous function, which becomes zero at infinity.
3. The wave equation must be single valued.

Equation 28-49 is a complex equation, even in the simplest of examples. It must be applied to every electron in a molecule or molecular system under examination. The Schrödinger equation has exact solutions for only a few simple cases (e.g., a particle in a box, a particle on a ring, the harmonic oscillator, the rigid rotor, the hydrogen atom, the hydrogen molecule ion). Each example listed builds on the previous ones but gets more mathematically challenging. Solution of the nonrelativistic Schrödinger equation for the hydrogen atom yields the set of quantum numbers n , l , and m familiar from general chemistry. The spin quantum number s is not one that comes from the Schrödinger treatment. It may be added in an ad hoc fashion, using the magnetic quantum number m as a guide. The fourth quantum number does, however, naturally arise from an alternative mathematical development of quantum mechanics that is formulated by using matrix methods.⁹² Later it was shown that both the wave and matrix approaches are equivalent.^{93,94} Exact solutions to drug-like molecules, whether by wave or matrix quantum mechanics, are impossible. Nevertheless, some simplifying assumptions have been developed over the years, beginning in the 1950s when computers made approximate solutions feasible, that result in good electron-based models.

Equation 28-49 may be arranged to give Equation 28-50 by multiplying both sides of the equation by $\int \Psi_{el}^*$ and then solving for the energy of the system E . If the Ψ_{el} function is normalized, meaning it has been scaled such that $\int \Psi_{el}^* \Psi_{el} d\tau = 1$, the denominator is unity.

$$E = \frac{\int \Psi_{el}^* \hat{H} \Psi_{el} d\tau}{\int \Psi_{el}^* \Psi_{el} d\tau} \quad (\text{Eq. 28-50})$$

For a many-electron system, the Hartree-Fock wave function Ψ_{HF} , defined as the product of spin orbitals χ_i as outlined in Equation 28-51, where $A(n)$ is an antisymmetrizer for the electrons, provides good answers.⁹⁴ This is the starting point for either semiempirical or ab initio theory. It is necessary to have $A(n)$ to make the wave function antisymmetric, thus obeying the Pauli exclusion principle, which asserts that two electrons cannot be in the same quantum state.

$$\Psi_{HF} = A(n) \chi_1(1) \chi_2(2) \chi_3(3) \cdots \chi_n(n) \quad (\text{Eq. 28-51})$$

Another consequence of the Pauli exclusion principle is that the spin orbital is a product of a spatial function ψ and a spin function α or β (Equation 28-52).

$$\chi_i = \begin{cases} \psi_i(x,y,z)\alpha \\ \psi_i(x,y,z)\beta \end{cases} \quad (\text{Eq. 28-52})$$

The antisymmetric wave function, shown in Equation 28-51, is a more compact way of writing a Slater determinant (Eq. 28-53). In a Slater determinant, an exchange of any two rows or columns results in the same wave function multiplied by -1 . This is another statement of the Pauli exclusion principle. The columns in Equation 28-53 are the single electron wave functions. Equation 28-53, however, is only an approximation, since the electrons are independent of one another and therefore not correlated. This correlation problem reveals itself when calculating the energies and is discussed below.

$$\Psi_M = \frac{1}{\sqrt{N!}} \begin{vmatrix} \chi_1(1) & \chi_2(1) & \cdots & \chi_N(1) \\ \chi_1(2) & \chi_2(2) & \cdots & \chi_N(2) \\ \vdots & \vdots & \ddots & \vdots \\ \chi_1(N) & \chi_2(N) & \cdots & \chi_N(N) \end{vmatrix} \quad (\text{Eq. 28-53})$$

Usually, the spatial function ψ is constructed from the summation of one-electron spatial orbitals (atomic orbitals) ϕ , known as the basis set, used to construct a MO. This approach is known as the LCAO method (linear combination of atomic orbitals).^{17,18} It is an approximation of the accurate many-electron wave function (Eq. 28-54). The atomic orbital contributions are weighted by coefficients c_i . The summation is truncated, so the ψ function is not complete, which has consequences when solving for E .

$$\psi_{MO} = \sum_{i=1}^n c_i \phi_i \quad (\text{Eq. 28-54})$$

The energy of the system E is a function of ψ . The variational theorem⁹⁵ is an important starting point in computational quantum chemistry. It states that the calculated energy of the system is always going to be greater than or equal to the true experimental energy (Eq. 28-55). For the calculated and true energies to be equal, the Ψ function must be exact. Exact wave functions are not possible for molecular structures, since there are an infinite series of atomic orbitals, described above. Therefore, every selection for Ψ will generate a trial wave function, Ψ_{trial} , and the variational theorem demands that the energy will always be higher than the true energy. As Ψ_{trial} approaches the true wave function Ψ , the energy becomes lower and lower, approaching the true experimental energy E .

$$\frac{\int \Psi_{\text{trial}}^* \hat{H} \Psi_{\text{trial}} d\tau}{\int \Psi_{\text{trial}}^* \Psi_{\text{trial}} d\tau} \geq E_{\text{true}} \quad (\text{Eq. 28-55})$$

Solutions to the Schrödinger equation for drug-like molecules may be obtained by making approximations and simplifying assumptions. There are three basic divisions of computational quantum chemistry calculations: (a) semiempirical, (b) ab initio, and (c) density functional theory (DFT).

Early efforts by Pople and coworkers produced a method called CNDO (complete neglect of differential overlap).⁹⁶⁻¹⁰² In general, the semiempirical approach eliminates integrals that are too complicated to solve analytically. (This

is an interesting concept in higher math: if the term is too hard to solve, discard it.) In their place, appropriate factors (constants and equations) are introduced to compensate. Fortunately, the integrals eliminated in the semiempirical approach give relatively small values if solved. Equation 28-56 shows the most complicated type of integrals that are removed in the semiempirical model. They are known as two-electron integrals, where l and 2 represent the two electrons, spanning four atomic centers i, j, k, l .

$$\phi_i^*(1)\phi_j(1)\frac{1}{r_{12}}\phi_k^*(2)\phi_l(2) \quad (\text{Eq. 28-56})$$

The extensive efforts of Dewar resulted in a series of reasonably accurate semiempirical models: MINDO (*modified intermediate neglect of differential overlap*).^{103, 104} The third version in this series, MINDO/3,¹⁰⁵⁻¹⁰⁹ gave much improved results. The program allowed organic and medicinal chemists to apply electron-based calculations to diverse compounds. The availability of MINDO/3 helped make computational chemistry accessible to experimentalists. The MNDO (*moderate neglect of differential overlap*) model,¹¹⁰⁻¹¹⁵ after some modifications of the observed systematic errors, served as the basis for the AM1 (Austin method 1).¹¹⁶ Stewart took the AM1 model and introduced automated parameterization techniques with a different parameterization philosophy than Dewar. The result was PM3 (parameter method 3).¹¹⁷

There are known strengths and weaknesses of each semiempirical method. The AM1 and PM3 models only include s - and p -functions, which limits their usefulness for most elements of the periodic table that require d -orbitals. Many of these elements, however, are not typically found in most drug-like molecules. More recent advances with MNDO/d include the incorporation of d -functions in the NDDO (*neglect of diatomic differential overlap*) model.^{118, 119}

Extensive use has been made of semiempirical methods in drug design.^{120, 121} Calculations of the highest occupied MO and lowest unoccupied MO (HOMO/LUMO) energies for a series of active and inactive compounds have been used as descriptors for QSAR. AM1, for example, has recently been used to develop a predictive ADME model for P-450 oxidation of drugs, which is discussed below.

The more mathematically rigorous *ab initio* calculations, as the name implies ("from first principles"), do not use parameters in the same way as the semiempirical models.⁹⁵ Unlike semiempirical calculations, no classes of integrals are eliminated. *Ab initio* methods have, however, a number of approximations. Aside from truncated basis sets, in which the constants have been adjusted to give the optimal basis set, one of the most noteworthy approximations involves the functional form of the wave function ψ . Solving the Schrödinger equation for the hydrogen atom produces the familiar hydrogenic orbitals, which can be approximated by Slater type (ST) functions. Both are exponential functions having the form $e^{-\zeta r}$, where ζ is the exponential coefficient and r is a function of the electronic and nuclear positions \vec{r} . Solving integrals, which are products of exponential functions, can be CPU intensive. Boys proposed that gaussian type (GT) functions of the form $e^{-a(r)^2}$ could be substituted for ST functions.¹²² The theoretical community did not immediately embrace the idea until Pople demonstrated convincingly that a linear combination of GT functions could

mimic ST functions reasonably well. Using three GT functions for every ST function gave rise to a popular basis set known as STO-3G, and many calculations were carried out by using this minimal basis set. STO-3G means three GT functions are used to reproduce every ST function.¹²³⁻¹²⁶

Pople and coworkers discovered that more extensive combinations of GT functions improved the accuracy of *ab initio* calculations. The next advance was an attempt to give greater flexibility to the *ab initio* models. By splitting the GT functions used to describe the valence shell electrons into two separate functions, better agreement between experiment and calculations was achieved. This method is known as split-level basis sets and is more time consuming. For example, 3-21G basis sets quickly replaced STO-3G.¹²⁷⁻¹²⁹ The symbolism 3-21G means that the inner core or nonvalence electrons are described by three GT functions, and the outer shell or valence electrons are broken into an inner and outer set. The inner set is simulated by two GT functions, while the outer set is simulated by one GT function. Equation 28-57 shows the expansion of the atomic orbitals into GT functions g_i , where a_j represent fixed coefficients.

$$\phi_{iAO}(r) = \sum_{j=1}^n a_j g_j \quad (\text{Eq. 28-57})$$

Additional basis sets may be added to the split-level formulations to achieve greater accuracy. These additional functions are known as polarization functions. For example, 6-31G(d), formerly represented as 6-31G*, has a set of diffuse d -orbitals added to the heavy atoms (nonhydrogen atoms).¹³⁰⁻¹³² In another example, 6-31G(d,p), formerly known as 6-31G**, has a set of d -orbitals added to each heavy atom, as in 6-31G(d), in addition to a set of three p -orbitals for all the hydrogens.¹³³ The next level of approximation divides the valence electrons into three sets of GT functions (e.g., 6-311G).¹³⁴ An additional set of very diffuse functions can be added to the model to help calculate negatively charged species or hydrogen bonding, denoted by the plus sign in the examples 6-31+G(d,p) and 6-311+G(d,p).^{135, 136}

An iterative solution of the Hartree-Fock-Roothaan equations is required for semiempirical and *ab initio* quantum chemical calculations.¹³⁷⁻¹³⁹ The approach is also called the self-consistent field (SCF) approach. In SCF calculations, each single electron's position in space is optimized in the electric field of all the other electrons. This procedure is repeated until all the electron positions have been optimized, and there is no further significant drop in energy through the adjustment of the electron positions. Hartree-Fock (HF) calculations give good results. The better the basis set, the lower the energy according to the variational theorem. There comes a point of diminishing returns, however, in that the energy approaches a limit known as the Hartree-Fock limit. No further adjustment in the basis set breaks this barrier. The Hartree-Fock limit occurs because the electron motion is correlated, and this is not accounted for in a single Slater determinant. That is, the adjustment of one electron affects the position of the other electrons, and this is not fully taken into account by the SCF approach. To circumvent not taking electron correlation into account, post-SCF calculations must be used in the form of configuration interaction or perturbation methods.

T'wso commonly used post-SCF (or post-Hartree-Fock) methods are used: configuration interaction and perturbation methods.^{140–144} In the former, the wave function is a summation of other Hartree-Fock determinants. This is analogous to exciting electrons to higher energy orbitals. In the latter, as the name implies, a perturbation is added to the Hartree-Fock hamiltonian. Møller-Plesset perturbation theory (MP2, MP3) is not a variational approach, so it is possible to calculate an energy lower than the true value.

There are no quantum mechanical charge operators. Thus, charges are determined on the basis of a population analysis. The electron density $\rho(r)$ is calculated and divided between the atoms of a molecule. The difficulty, however, is in determining how to assign shared electron density between two atoms i and j of different electronegativity. In the Mulliken population analysis,¹⁴⁵ the shared electron density is divided evenly between atoms i and j , regardless of the electronegativity. This, of course, is unrealistic but remains a useful technique. Other electron population analyses have become increasingly popular over the years. As discussed above, fitting charges to electron densities is a way to get more realistic atomic charges. With the electron density distributed throughout a molecular structure, according to an ad hoc population analysis, it is possible to generate dipole moments and color-code the electrostatic potential on molecular surfaces. The electrostatic potential may be useful in developing a pharmacophore and deciding what properties a receptor must have.

Density functional theory (DFT) has been used increasingly over the years.¹⁴⁶ DFT has a radically different approach than that in the preceding discussion on semiempirical and ab initio methods and may be more easily understood. In the DFT formulation, Kohn-Sham equations, electron correlation is built-in.¹⁴⁷ This means that DFT rivals post-SCF calculations for accuracy. Rather than dealing with the multielectron wave function, the electron density is used directly. According to the Kohn-Hohenberg theorem,¹⁴⁸ the energy is minimized when the calculated and true electron densities are equal. DFT calculations rival the accuracy of standard post-Hartree-Fock methods. Of practical importance to medicinal chemists interested in studying drug-like molecular structures with quantum-based energy calculations, there is a significant reduction in the CPU time. Thus, DFT is an attractive alternative. For example, the CPU time required to complete Hartree-Fock calculations, which of course is a function of the number of electrons in the system being examined, is proportional to the number of electrons raised to the fourth power. DFT calculations, however, also a function of the number of electrons in the system, are proportional to the number of electrons raised to the third power.

STRUCTURE-BASED DRUG DESIGN AND PHARMACOPHORE PERCEPTION

The choice of CADD methods that may be applied to drug design depends highly on the availability of the receptor information. If the receptor structure has been characterized by either high-resolution x-ray crystallography or NMR

spectroscopy techniques, structure-based drug design methods may be appropriate. (The term *structure-based drug design* refers to the fact that experimental structural data of the macromolecule of the drug-receptor complex is involved in the modeling process explicitly.) The x-ray structures of a receptor and ligand-receptor complex provide information about the binding mode of the ligand. If available, multiple x-ray structures with different ligands provide greater insight into the steric and electrostatic tolerances of the binding cavity. Using sophisticated molecular modeling software, the ligand is modified structurally in silico to achieve a better fit between the complementary binding sites and molecular volumes. The small molecule typically is clipped out of the ligand-receptor complex altogether, and new molecular structures are *docked* into the binding site. It is no coincidence that structure-based modeling began to be applied more frequently in the mid-1980s. The exponential explosion of protein 3D structural information¹⁴⁹ (Fig. 28-18), which was made possible by cloning techniques, made it possible to have macromolecular structural data. The advances in a seemingly unrelated field have helped to usher in the age of structure-based drug design by making proteins available in larger quantities for x-ray studies.

If scant structural information about the receptor is known, which is most commonly the situation confronting medicinal chemists, a more indirect approach is required. This second approach has been characterized as pharmacophore mapping or pharmacophore perception.¹⁵⁰ The critical functional groups and their 3D spatial orientations may be perceived by examining all molecular structures that induce biological activities. A comparison of active versus inactive compounds helps to understand the structural and conformational requirements of a drug candidate. Once a model has been developed, a 3D search query can be submitted to 3D databases. The goal of using a 3D database is to find existing structures that meet the constraints of the query for immediate biological evaluations, thus avoiding synthesis. If the retrieved compounds show activity, they can serve as lead structures for further structural refinements.

Figure 28-18 ■ The growth of a 3D structural protein database is exponential. The availability of structural information in the Protein Data Bank has helped fuel the growth and success of structure-based drug design. Values are as of May 9, 2003.

Figure 28-19 ■ Three compounds designed by Beddell and coworkers to mimic the binding of 2,3-diphosphoglycerate (DPG) (**2**) to hemoglobin.

The concepts of structure-based or receptor-based drug design predate the use of computers. Beddell and coworkers are credited in 1976 with successfully predicting compounds that bind to human hemoglobin.¹⁵¹ Although not strictly a drug-receptor interaction, the approach demonstrated the feasibility of molecular modeling applied to drug design. The goal of their study was to exploit the known binding site of the human deoxyhemoglobin tetramer. The tetramer consists of four single polypeptide chains: two α and two β subunits. The small molecule 2,3-diphosphoglycerate (DPG), **2**, binds with subsequent stabilization of the deoxy conformation (Fig. 28-19). The binding results in the liberation of oxygen, which is readily measured. Wire molecular models of the protein were used to measure bond distances and interacting atoms between the protein and the proposed small molecules. Based on the best fit, predictions were made as to which compounds would bind the best. These early modeling studies suggested that compounds **3–5** would have an affinity for the 2,3-binding site of human hemoglobin. Based on the liberation of oxygen, it was determined that the binding affinities corresponded to **2** \approx **5** > **4** > **3**.

The often-cited design of the first angiotensin-converting enzyme (ACE) inhibitors by Ondetti and Cushman during this time effectively demonstrated the concept of mechanism-based and structure-based drug design.^{152, 153} The Ondetti and Cushman approach resulted in the first marketed ACE inhibitor, captopril, **6** (Fig. 28-20). Many other ACE inhibitors have been designed using computer-based models,

Figure 28-20 ■ Captopril was the successful outcome of a rational design approach in which the mechanism of the conversion of angiotensin I to angiotensin II was known. The angiotensin-converting enzyme (ACE) was assumed to have binding cavities similar to the known x-ray structure of carboxypeptidase.

although not by direct structure-based modeling, since to date the structural determination of ACE has not been accomplished. Ondetti and Cushman conceived of captopril based on a related enzyme, carboxypeptidase A, and the earlier reports of succinic acid inhibitors by Wolfenden.¹⁵⁴ Other computer-based methods have been used successfully in ACE inhibitor design. Force field calculations, conformational searching, and analogue design strategies were used by Merck scientists to develop inhibitors. Scientists at Merck have used small molecule structural data (x-ray crystallographic data and NMR solution studies) coupled with conformational methods to design conformationally restricted ACE inhibitors.¹⁵⁵

Since the 1980s, there have been many success stories using structure-based drug design. One of the first convincing examples of the combined use of an x-ray crystal structure and molecular modeling software was reported in 1982.¹⁵⁶ Again, although this was not a true drug-receptor interaction, the work demonstrated fundamental principles that would be applied later. The x-ray crystallographic coordinates of the L-thyroxine-prealbumin compound have three pairs of symmetry-related cavities (Fig. 28-21). It was noticed that one binding pocket of the symmetric prealbumin

Figure 28-21 ■ The molecule L-thyroxine, **7**, binds to prealbumin, a protein found in blood. Based on x-ray data of the L-thyroxine-prealbumin complex, the binding affinity of novel analogues was predicted by using a molecular modeling approach.

dimer was unoccupied by L-thyroxine, **7** (Fig. 28-22). This unoccupied binding pocket had the potential to accommodate a portion of new compound, which presumably would result in greater binding affinity by increasing the contact between the van der Waals surfaces in this hormone-protein complex.

The scientists used a guiding hypothesis that the "tightness of fit" between the computer-generated complementary molecular surfaces of the ligand and prealbumin would correlate to enhanced binding affinities. They modeled the molecular surface interactions with the MS program on an Evans and Sutherland PS2 graphics station. With available modeling software, the UCSF (University of California at San Francisco) scientists stripped L-thyroxine from the binding site and docked various naphthalene-based structures with different substitution patterns, shown in Figure 28-23. The modeling studies were carried out without the aid of force field refinement. After modeling a diverse set of analogues, the scientists concluded that at least three of the four outer binding pockets needed to be filled. Four thyroid hormone analogues (structures **8**–**11**) were ranked based on visual inspection using their complementarity of fit hypothesis. Structure **8** did not present any bad contacts, while **11** had some obviously bad surface contacts. Structures **9** and **10** appeared to have equally good molecular surface interactions. Once the compounds were ranked ($8 > 9 \approx 10 > 11$), their binding affinities were determined. The binding data were consistent with the predictions, except structures **9** and **10** were not equivalent. Closer inspection revealed that the phenolic hydroxyl group of **10** had a better surface fit and is in close proximity to Ser-117C and Thr-119C, thus providing additional binding interactions not available to **9**.

Figure 28-23 ■ Using molecular modeling methods, four L-thyroxine analogues were predicted to have good binding affinity ($8 > 9 \approx 10 > 11$) to prealbumin.

Figure 28-22 ■ The experimental x-ray crystal structure of prealbumin with bound L-thyroxine. Prealbumin is a tetramer with four identical subunits, A, B, C, and D. The four identical subunits form a channel with two bound L-thyroxine molecules. The binding sites have a C_2 axis of symmetry.

Presumably, the additional interactions would have been detected with force field calculations.

In 1985, scientists at Burroughs Wellcome (United States) and the Wellcome Research Laboratories (England) reported some of their CADD efforts for the prediction of dihydrofolate reductase (DHFR) inhibitors.¹⁵⁷ DHFR is an excellent target, since this enzyme pathway is the only known *de novo* synthetic route to prepare thymine *in vivo*. Thymine, of course, is one of the four nucleic acids of DNA. For many years DHFR had been a popular drug target for medicinal chemists. Significant drug design activity using the prevailing principles of medicinal chemistry was associated with the development of DHFR inhibitors for antibacterial and antitumor agents. Methotrexate (MTX), **12**, and trimethoprim (TMP), **13**, are good inhibitors of DHFR. Figure 28-24 shows the obvious structural similarities of MTX and folic acid, **14**.

Over the years, literally thousands of inhibitors of DHFR were prepared on the basis of medicinal chemistry intuition preceding the structure-based efforts. A series of 3'-carboxyalkoxy analogues of TMP were designed based on molecular models of the *Escherichia coli* DHFR–MTX complex. The designed TMP analogues had up to a 55-fold higher enzyme affinity than TMP itself. Kuyper and coworkers noticed that in the *E. coli* DHFR–MTX complex, the α - and γ -carboxyl groups formed ionic interactions with the guanidinium group of Arg-57 and the aminoalkyl side chain of Lys-32, respectively. The observation that there was a possible third ionic interaction with Arg-52 suggested that TMP analogues, with judiciously selected carboxylate groups, could interact with one or more of these complementary residues. The analogue with the carboxylate extended by five methylene units,

shown in Figure 28-25, was found to have the optimal binding. Much of the experimental binding data were consistent with the molecular modeling studies and the subsequent structural data. Although all the observations could not be explained, this work represents one of the first successful structure-based drug design approaches.

There is a growing body of successful examples using structure-based drug design approaches. Today, many of these have resulted in approved drugs. These methods are applied widely when appropriate experimental data are available. Structure-based drug design is now considered a standard approach to drug design, and the question posed early can be answered with specific examples.

In the 1980s, the target enzyme for inhibitor design was DHFR, as discussed above. In the 1990s, the target enzyme

13

Figure 28-25 ■ With the aid of x-ray data and molecular modeling, scientists designed trimethoprim (TMP), **13**, analogues that had up to 55-fold higher enzyme affinity than the parent inhibitor.

Figure 28-26 ■ Saquinavir (Fortovase, Invirase), **15**, was the first HIV-1 protease inhibitor designed with structure-based CADD methods to receive FDA approval. Here saquinavir is shown inside the binding cavity of HIV-1.

was the HIV protease. The enzyme is one of the proteins coded by the HIV genome, and it is expressed as part of the reproductive cycle of the virus. The x-ray crystal structure for HIV protease has been available for well over a decade now, and it is classified as an aspartyl protease, since there are active aspartate residues present. HIV protease is a symmetric dimer. There are 99 amino acid residues in each monomer. The binding cavity can be seen clearly in Figure 28-26.

In the late 1990s, several HIV-1 protease inhibitors were introduced into the market that were designed using structure-based methods (Fig. 28-27).^{158, 159} Hoffmann-La Roche scientists used modeling methods to design saquinavir¹⁶⁰ (Fortovase, Invirase) **15**, which was the first protease inhibitor to be approved. The drug was made available in June 1995 through a compassionate treatment program. Invirase was given Food and Drug Administration (FDA) approval in December 1995, and Fortovase was approved in November 1997. Indinavir¹⁶¹ (Crixivan), **16**, was developed by Merck scientists and given quick approval in only 42 days in March 1996. In March 1996, Abbott received approval for Ritonavir¹⁶² (Norvir), **17**. The following year, March 1997, Agouron received final approval for Nelfinavir¹⁶³ (Viracept), **18**. Each of these drugs, designed using structure-based methods, represents major triumphs of CADD. Agouron originally was a company founded, like Vertex, on the premise that structure-based drug design is an effective approach for drug discovery. Amprenavir (Agenerase), **19**, developed at Vertex, was given FDA approval in April 1999. The ability to collect rapid x-ray crystallographic data allowed scientists at Pharmacia & Upjohn to use structure-

Figure 28-27 ■ The six HIV-1 protease inhibitors given FDA approval between 1994 and 1999 were designed by using structure-based drug design methods.

based methods. The resulting compound tipranavir, **20**, is a small nonpeptidic inhibitor that may soon be available.¹⁶⁴

The first drug designed with structure-based methods to reach the market was dorzolamide^{9, 165} (Trusopt), **1**. Ab initio calculations and modeling methods were used to predict substitution patterns. After a decade of research and development at Merck, dorzolamide was given FDA approval in December 1994 and introduced into the market in the sum-

mer of 1995. Dorzolamide is an effective carbonic anhydrase inhibitor used to reduce intraocular pressures that occur in glaucoma patients. It is extremely effective. Inhibition of carbonic anhydrase results in reduced bicarbonate formation in the eye, which has the beneficial effect of lowering sodium ions with the subsequent reduction of fluid secretions. Merck had been working on various lead thienothiopyran-2-sulfonamides by developing models and fitting them into electron density difference maps of carbonic anhydrase. The first carbonic anhydrase inhibitor to lower intraocular pressure in glaucoma patients was MK-927, **21**,¹⁶⁴ which is a close structural analogue of the compound finally approved (Fig. 28-28).

Another successful advance in therapeutics involved a combination of x-ray crystallographic studies and molecular shape analysis (MSA) to produce donepezil¹⁶⁶ (Aricept), **22** (Fig. 28-29). Donepezil is a potent acetylcholinesterase (AChE) inhibitor used in patients with Alzheimer's disease to help stave off the loss of cognitive abilities. Docking simulations of donepezil suggested that the drug does not actually bind to the AChE active site but rather inside the long channel leading to the active site in a tight, narrow region. In addition to the structure-based modeling studies, 3D-QSAR studies were carried out using semiempirical descriptors.

Figure 28-28 ■ Dorzolamide (Trusopt), **1**, also a constituent of Cosopt, was the first drug designed with structure-based CADD methods to become commercially available. MK-927, **21**, is a close structural analogue and was the first carbonic anhydrase inhibitor to lower intraocular pressure in glaucoma patients

22

The pharmacophore concept plays a central role in drug design. The pharmacophore, first proposed in the early 1900s by Paul Ehrlich, may be defined as the 3D arrangement of the essential functional groups necessary to cause the biological response. The definition only assumes that it is necessary for a drug to present its properly oriented functional groups to the receptor's complementary amino acid residues. Although the idea may be somewhat simplistic, since it ignores explicit consideration of the molecular structure that correctly orients the functional groups, the idea has withstood the test of time as a first approximation for a model of drug–receptor interactions.

Prior to the explosion of structural data now available to medicinal chemists who may use 3D structures of proteins, typically only indirect information about the nature of the receptor was available. The most common situation faced by medicinal chemists was a series of active and inactive compounds. The fact that there was no structure of the drug bound to its receptor meant that drug design had to follow a procedure of comparing the efficacy of compounds and determining which functional groups were important and which functional groups were not.

The active analogue approach, developed by Garland Marshall, was one of the earliest CADD pharmacophore procedures.^{167–169} The approach avoids having to worry excessively about the subtle energy differences between conformations. Systematic conformational searching is applied to a series of biologically active and inactive compounds. The central idea is that there is a limited set of conformations that an active compound (with appropriate functional groups) may adopt. Biological inactivity is assumed, as a first approximation, to result from the competition between small molecules and the receptor for occupation of the same physical space. Usually, the most rigid structure is considered first. Subsequent systematic searches are carried out on the remaining “active” molecular structures. It is possible to add screening filters to eliminate unacceptable conformations; for example, computer-generated structures must be able to adopt conformations similar to those available to the previous molecular structures and not be outside a specified relative energy range. At the conclusion of the process, a volume may be generated representing the union of all available conformations for the biologically active compounds. This “active” volume may be used to glean information about the receptor site. It is possible to generate an “inactive” volume as well, which is the region in 3D space that should not be used to make molecular modifications.

Examination of a series of active and inactive compounds provides important structural information that is used to de-

velop a pharmacophore hypothesis. Once a pharmacophore is developed, it is possible to search 3D structural databases. The first 3D searching software was developed in-house by pharmaceutical firms to mine the corporate 3D databases (ALADDIN,¹⁷⁰ developed at Abbott, and 3DSEARCH,¹⁷¹ developed at Lederle). The construction of 3D databases was made possible by software such as CONCORD¹⁷² and CORINA¹⁷³ that allowed rapid generation of 3D structures from 2D structures. CONCORD has become the standard program used for the creation of 3D structures from 2D input. It is important in 3D searches to account for structural flexibility. There are essentially three ways this may be achieved: (a) storing multiple conformations in the database itself; (b) developing specialized queries; and (c) generating conformations during the search query. The first idea requires that all conformations for every molecular structure be stored in a 3D database. This approach is not practical. Although the second approach is appealing, it requires the scientist to design the query appropriately. The third approach seems to solve the problem, inasmuch as only one (or a few) conformation needs to be stored and adjusted to match the pharmacophore search query. Today, there are several commercial programs available for 3D database and pharmacophore searching.

Goodford proposed that a grid of test points enveloping a molecular structure could be used to calculate favorable interactions (initially with 6–12 nonbonded, electrostatic, and hydrogen-bonding potential energy functions) between it and a target receptor. The program GRID¹⁷⁴ was an interesting innovation. The DOCK^{175, 176} program can be considered the first *virtual* high-throughput screening software. The goal was to allow prescreening of compounds that could bind to an active site. A series of molecular structures can be evaluated for their fit into a receptor by use of scoring functions. An early study using α -chymotrypsin ranked several known inhibitors in the top 10 structures, based on the scoring functions used to evaluate the binding potential.¹⁷⁷ Another early academic 3D searching program was CAVEAT.¹⁷⁸

Predictive pharmacophore models can be generated based on 3D-QSAR analyses. Hansch demonstrated the usefulness of QSAR.¹⁷⁹ In the 1970s, many studies were undertaken to infer biological activity on the basis of physical properties of a molecule. The method remains useful and provides valuable information.¹⁸⁰ Richard Cramer developed a popular program involving a comparative molecular field analysis (CoMFA).¹⁸¹ The basic idea is to probe a molecular structure for steric and electrostatic interactions directly, and then generate a QSAR equation based on these molecular descriptors, using partial least squares (PLS). The validity of the model can be predicted.

PREDICTIVE ADME

The ultimate goal of CADD is to understand at the molecular level the complex relationships between a disease-causing target (macromolecule) and a drug-like molecule so that reliable predictions can be made to enhance molecular interactions. Other important pharmacokinetic factors are critical, however, for an effective therapeutic medicine. Essentially,

potency, solubility, and permeability are the only three physical variables that can be adjusted to enhance the activity of potential oral medications.¹⁸² Lipinski has suggested "poor absorption or permeation is likely when the molecule has more than one of the following properties."

1. More than 5 hydrogen bond donors
2. More than 10 hydrogen bond acceptors
3. Greater than 500 molecular weight
4. Greater than 5 computed log P

Medical professionals must be aware of drug–drug interactions. Because a significant number of drugs are metabolized by the cytochrome P-450 (CYP), it behooves medicinal chemists to consider this oxidative pathway in the design process. Tragic consequences of drug–drug and food–drug interactions have resulted in two FDA-approved drugs, mibefradil (Posicor), **23**, and terfenadine (Seldane), **24**, being removed from the market in recent years. Mibefradil and terfenadine are shown in Figure 28-30. Each drug required P-450 for phase I metabolism.

A more recent predictive model for CYP 3A4 metabolism has been reported.¹⁸³ The method relies on PLS, but one of the descriptors is based on AM1-calculated hydrogen abstraction. There are several assumptions: (a) CYP 3A4 susceptibility is a function of the electronic environment around the hydrogen that is abstracted. (b) Abstraction of the hydrogen atom is the rate-determining step. (c) The drug being metabolized tumbles freely in the active site of the enzyme until the most active hydrogen is available. AM1 calculations (using a procedure to account for the fact that unpaired

electrons are involved) were carried out on a series of known drugs. The activity, defined as the AM1 H-atom abstraction, is modeled on the presence or absence of chemical descriptors.

Over the next decade, in silico property and toxicity predictions will increase. As the predictive methods become more reliable and robust, they will be included increasingly in the initial drug design process rather than being an afterthought. There are many other CADD success stories. Although drug discovery is a complex process, in the future, as our understanding of drug action increases, a growing number of therapeutically effective drugs will be designed using computer-based methods.

Acknowledgment

The author acknowledges Tedman Ehlers, who prepared many of the figures for this chapter, and Mark Volmer, who provided valuable manuscript assistance.

Figure 28-30 ■ Predictive ADME is becoming more important in the early stages of drug design. Drug–drug and food–drug interactions have resulted in two FDA-approved drugs, mibefradil (Posicor), **23**, and terfenadine (Seldane), **24**, being removed from the market in recent years.

Calculated Log P, Log D, and pK_a

The log P, log D at pH 7, and pK_a values are from Chemical Abstracts Service, American Chemical Society, Columbus, OH, 2003, and were calculated by using Advanced Chemistry Development (ACD) Software Solaris V4.67. The pK_a values are for the most acidic HA acid and most weakly acidic BH⁺ groups. The latter represent the most basic nitrogen. Keep in mind that pK_a values for HA acids that exceed 10 to 11 mean that there will be little, if any, anionic contri-

bution in the pH ranges used in pharmaceutical formulations and in physiological pH ranges. Similarly, for BH⁺ acids, there will be little, if any, cationic contribution for pK_a values below 2 to 3. Because Chemical Abstracts does not report calculated physicochemical values for ionized compounds including salts and quaternary ammonium compounds, the log P values in this appendix are for the unionized form.

Compound	Log P	Log D at pH 7	pK _a		Compound	Log P	Log D at pH 7	pK _a

 antibiotic, 235–238
 azole, 240–245, 241f
 historical perspective on, 230
 nucleoside, 235
 topical, 233–235, 239
Antigen(s)
 cellular, in vaccine production, 207
 major histocompatibility, 197
 Antigen-antibody reactions, 205–206, 205f
Antigen-presenting cells, 199, 199f
Antihemophilic factor, 664f, 665, 863
 recombinant, 167–168, 184–185, 665, 859f, 863
Antihistamines, 700–715
 dibenzocycloheptenes, 711–712, 712f
 dibenzocycloheptenes, 711–712, 712f
 discovery and development of, 700, 701–702
 drug interactions with, 702
 dual-acting, 717–718
 ethanolamine, 702–704, 702f
 ethylenediamine, 704–706, 704f

- Antihistamines (*continued*)
 first-generation (classical), 700–712
 index *PA₂* for, 700
 indications for, 701
 mast cell stabilizers, 715–717
 mechanism of action of, 700
 metabolism of, 87
 non-target-receptor interactions of, 701
 pharmacokinetics of, 701–702
 pheniramine, 707–710
 phenothiazine, 710–711
 piperazine (cyclizine), 706–707, 706f
 propylamine, 707–710, 707f
 second-generation (nonsedating), 701–702, 712–715
 structure-activity relationships for, 700–701
 Antihyperlipidemic agents, 659–663
 HMG-CoA reductase inhibitors, 662–663
 Antihypertensive agents, 642–657
 ACE inhibitor prodrugs, 646–648, 647f, 647i
 adrenergic system inhibitors, 649–650
 angiotensin antagonists, 648–649
 centrally acting adrenergic drugs, 652–653
 neurotransmitter-depleting, 650–651
 positive inotropic agents, 655–657
 potassium channel openers, 654–655
 renin-angiotensin system inhibitors, 645–646
 selective α -adrenergic antagonists, 651–652
 vasodilators, 653–654
 Anti-infective agents, 217–280
 classification of, 217–218
 germicidal, 217–218, 218t
 historical perspective on, 217
 selective toxicity of, 217
 Anti-inflammatory analgesics, 753–763
p-aminophenol, 760–762, 761t
 aniline, 760–762, 761t
 arachidonic acid metabolism and, 822
 arylacetic acid derivatives, 758–760
N-arylanthranic acids, 754–758
 mechanism of action of, 818, 822
 pyrazolidinedione derivatives, 762–763, 763t
 pyrazolone derivatives, 762–763
 salicylates, 754–757
 Antileptotic agents, 279–280
 Antimalarials, 282–298
 4-aminoquinolones, 287–288, 287f, 295t
 8-aminoquinolones, 288–289, 289f, 295t
 cinchona alkaloids, 286–287, 286f, 295t
 development of, 283
 dosage of, 295t–296t
 fixed-combination, 289–292, 289f–292f, 296t
 formulations of, 285–298
 in glucose-6-phosphatase dehydrogenase deficiency, 283
 indications for, 295t–296t
 mechanism of action of, 284–285
 new, 294–298, 296t
 polycyclic, 293–294, 293f, 296t
 for prophylaxis, 295t–296t
 selective toxicity of, 285
 for treatment, 295t–296t
 Antimanic agents, 503
 Antimetabolites, 402–414
 activation of, 402–411
 definition of, 402
 de novo synthesis of, 402–404, 403f–404f
 development of, 404
 drug products, 411–414
 mechanism of action of, 402–404
 Antimimic. *See* Pyrantel pamoate
 Antimuscarinic agents. *See* Cholinergic blocking agents
 Antineoplastic agents, 390–449
 alkylating agents, 394–402. *See also*
 Alkylating agents
 angiogenesis inhibitors, 447
 antibiotics, 414–424
 actinomycins, 414–415
 anthracyclines, 415–417
 discovery and development of, 414, 415
 mechanism of action of, 415
 structure of, 414–415
 antimetabolites, 402–414. *See also*
 Antimetabolites
 antisense oligomers, 447–448
 aureolic acids, 417
 biotechnology and, 448–449
 cancer curability and, 390
 candidates for, 446–449
 cell-cycle specificity of, 391, 391f
 clinical trials of, 394
 in combination therapy, 390
 cytoprotective, 445–446
 cytotoxicity of, 390, 391
 discovery and development of, 392–394
 first-order log-kill hypothesis for, 391
 hormones, 433–438
 immunotherapeutic, 440–442
 labeling index for, 391
 mechanism of action of, 390
 monoclonal antibodies, 442–444
 overview of, 390
 plant products, 424–428, 915
 platinum complexes, 428
 prodrug, 156–159
 radiotherapeutic, 444–445
 receptor tyrosine kinase inhibitors, 438–440
 research directions for, 446–449
 resistance to, 392
 screening of, 392–394, 393f
 signal transduction inhibitors as, 438–440
 site-specific delivery of, 158–159
 telomerase inhibitors, 448, 448f
 toxicity of, 392
 tumor cell properties and, 390–394
 Antinuclear antibodies, acetylation
 polymorphism and, 124
 Antipedicular agents, 268
 Antiplatelet agents, 632–634
 Antiprotozoal agents, 259–264
 Antipsychotics, 496–503
 β -aminoketones, 501–502
 antimanic agents, 503
 atypical, 485, 498
 benzamides, 502–503
 fluorobutylphenones, 500–501
 mechanism of action of, 497
 phenothiazines, 498–500, 499t
 typical, 485, 497
 Antipyretics, analgesic properties of, 753. *See also* Anti-inflammatory analgesics
 Antipyrene, 762, 763, 763t
 Antiscabious agents, 268
 Antisecretory agents, 573–574
 Antiseizure agents. *See* Anticonvulsants
 Antisense oligomers, 447–448
 Antisense RNA, 193–194
 Antisense technology, 193–194
 Antisepsis, 217–218, 218–223, 218t
 classification of, 218, 218t
 effectiveness of, evaluation of, 219
 improper use of, 219
 phenol coefficient for, 221
 Antispasmodics, 573–574
 Antithrombin III, 665
 Antithrombotic agents, 632–634
 Antithyroid agents, 673–674
 Antitoxin, 207
 Antitubercular agents, 254–259
 antibiotic, 257–259, 338, 339
 Antitussives, 752–753
 Antulcer agents
 chemical complexation of, 726
 histamine H₂ inhibitors, 710, 718–722
 prostaglandins, 726
 proton pump inhibitors, 722–726, 723f–725t, 723t
 Antivert. *See* Meclizine hydrochloride
 Antiviral agents, 375–388
 analogue inhibitors, 384
 bioactivation of, 135, 135t
 biochemical targets for, 370–372
 chemokine receptor binders, 387
 development of, 370
 DNA polymerase inhibitors, 372, 375–379
 gp41 fusion activity inhibitors, 387–388
 HIV entry inhibitors, 387
 HIV protease inhibitors, 384–387
 development of, 942, 943f
 integrase inhibitors, 388
 nomenclature of, 372
 nonnucleoside reverse transcriptase inhibitors, 383–384
 nucleoside antimetabolites, 372, 375–382
 as prodrugs
 activation of, 153–154, 155f
 in chemical delivery, 157
 resistance to, 382
 reverse transcriptase inhibitors, 372, 379–381, 382
 types of, 375–388
 Anxiolytics, hypnotics, and sedatives, 485–496
 alcohols, 495–496
 barbiturates, 493–495
 benzodiazepines, 488–493
 miscellaneous, 495
 overview of, 485
 structure-activity relationships for, 489–490
 Apolipoproteins, 657

Wilson and Gisvold's Textbook of **ORGANIC MEDICINAL and PHARMACEUTICAL CHEMISTRY**

Eleventh Edition

John H. Block, Ph.D., R.Ph. • John M. Beale, Jr., Ph.D.

Now in its Eleventh Edition, **Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry** continues its tradition as the essential resource for undergraduate and graduate students enrolled in medicinal chemistry courses.

Completely modern and highly readable, the text blends the chemical and pharmaceutical principles necessary for understanding structure–activity relationships and molecular mechanisms of drug action, making it highly effective as the core text in medicinal chemistry and a complementary text in pharmacology courses.

Features and highlights at a glance:

- New and revised content reflecting emerging trends and advances in the field plus challenges posed by new diseases
- New chapter on combinatorial chemistry that includes a discussion of how the process is automated, recognizing that the search for new drugs often involves both synthesis and screening of large numbers of compounds
- New chapter on computational chemistry and computer-assisted drug design, exploring techniques of molecular modeling and computational chemistry in response to the growth of powerful personal computers on the desks of today's medicinal chemists
- New chapter on herbal medicines, describing the chemical content of many of these products
- Expanded antiviral chapter containing the newest drugs that are changing how HIV is treated
- Expanded biotechnology chapter
- Logically organized by pharmacological and therapeutic class for quick, easy reference
- Brief introductions to disease states featured in appropriate chapters

Don't begin any medicinal chemistry course without it!
